The Edison machines are of the familiar bipolar type, and need no special description. They are of 25 k.w capacity, and adapted to be switched on to either leg of the three-wire system by the customary double throw head board switch. Their foundations are bolted to the floor timbers and, although the latter are not reinforced, the vibration is not noticeable. These machines deliver their output at 125 volts to a main distributing board supplied with Edison fixtures, protected by T. H. lightning arresters.

The boosters are of the Manchester type, and were made by the Electric Storage Battery Company, of Philadelphia, Pa. They are rated at 50 amperes at 70 volts, and operate at 900 r.p.m, being driven from a small counter shaft on the ceiling.

From Fig. 2, a general view of the plant, the arrangement of the machinery will be readily understood. From the main board three feeders run to the storage battery switchboard. A double-throw switch on the latter is provided, by which the batteries can be switched to discharge into the lighting system, or connected to the dynamos in series with the boosters. Fig. 5 will assist in making this arrangement plain.

During the seasons of heavy load the batteries and dynamos are connected directly in multiple, and all contribute to the station output. After the peak of the load has passed, the voltage applied to the batteries is increased by the boosters and the former charge. During the day the batteries carry the entire load. In this way constant service is attained by running the plant about six hours daily.

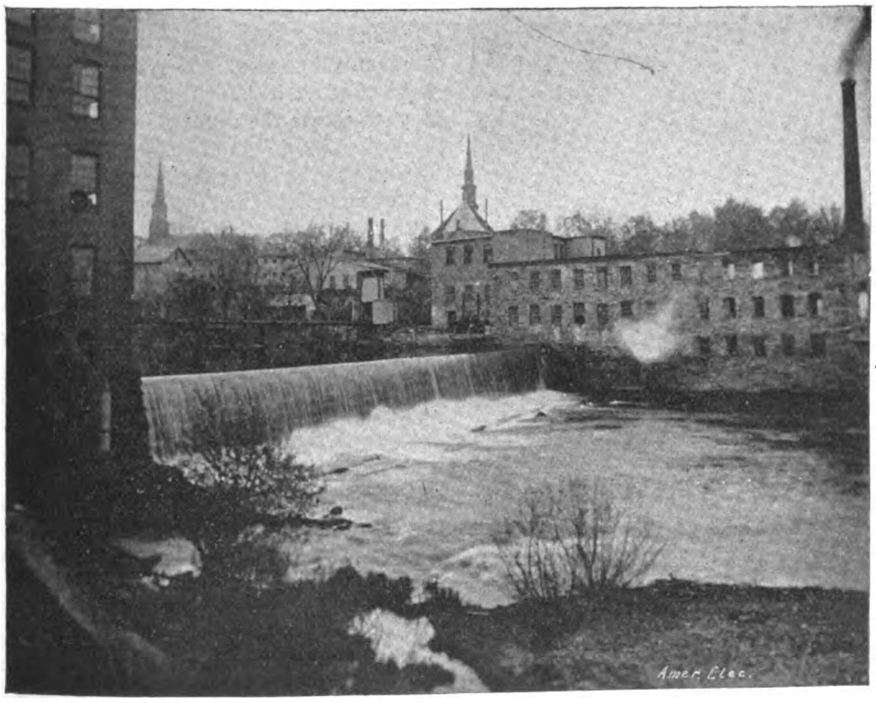

FIG. 2.—VIEW OF DAM.

The battery switchboard, shown in Fig. 4, comprises a differential ammeter and a voltmeter, both of the Weston round type; a ten-point battery switch, a booster rheostat and an underload switch, which breaks current should the batteries tend to motor the dynamos. These instruments are duplicated on each leg of the system. There is, further, a double-pole, double-throw switch already referred to, which cuts out the boosters. Fig. 5, showing the switchboard connections, will render the arrangement readily understood.

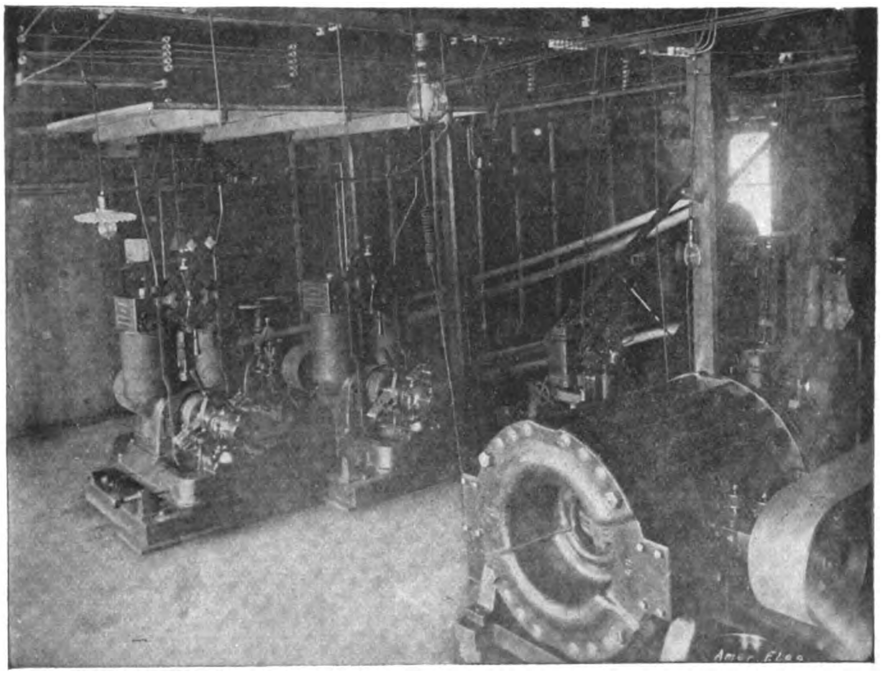

FIG. 3.—DYNAMO ROOM.

The underload switch is worth a few words, as it is quite ingenious. It consists of an iron core pivoted at each end to a horizontal brass support, which is fastened to a vertical piece of slate. At the ends of the core and at right angles thereto are secured heavy iron pole pieces. The supports extend beyond the core and carry an iron armature, which, when the switch is closed, completes the magnetic circuit. Around the core are wound a few turns of heavy wire with the ends bent in such a way that when the switch is closed they dip into mercury cups, completing the circuit from one main through the booster and battery back to the neutral. Should the booster voltage fail from a broken belt or other cause, the voltage of the charging circuit would drop to that of the dynamo, and the consequent reduction in current would allow gravity to act on the heavy pole pieces of the switch, causing the latter to fall and open circuit.

The battery plant was furnished by the Electric Storage Battery Company, which also supplied the switchboard. It consists of one hundred and thirty-four cells, sixty-seven on each leg, and by means of the regulating switch this number can be reduced to fifty-eight on a side. The cells are chloride accumulators, with Manchester positives. They are arranged on racks in three banks, as shown in Fig. 5. Each cell rests in a shallow wooden trough, which is supported upon four grooved glass insulators. The grooves in the insulators surround the supporting part and are flooded with oil. This effectually cuts off creeping currents. In order to absorb acid, the troughs are filled with sawdust. The insulators are so placed on the racks that the wooden troughs are separated by a distance not exceeding one inch. The jars are of glass, 10⅜x12½ in lateral dimensions and 15 ins. high.

Each cell has five positive and six negative plates. These are supported by lugs, which rest on the edge of the jar and are kept apart by hard rubber U-shaped separators. The grids clear the bottom of the jar by ¾ of an inch, which effectually prevents accumulated sediment from short circuiting them. Plates of like polarity are burned on to a massive lead bus-bar, and the unlike poles of the separate cells are connected together by brass bolts. The exposed portions of these bolts are coated with lead, which effectually protects them from fumes, and by this means a readily detachable non-corrosive joint is secured.

The complete cell weighs 250 lbs., and can be seen in detail in Fig. 6. Acid of a specific gravity of 1200 Baume is used, and is kept at that density by a weekly increment of about one pint of water. This constitutes the attention that the cells receive, and though they have been in constant service over two years, it would take a keen eye to detect any deterioration of the plates. They are free from fuzzy deposits, and have the same clean, firm appearance that newly installed plates possess. The cells have been cleaned once a year. The charging rate is 50 amps. and the discharging rate is the same, though at times 100 amps. have been drawn from the cells. The rated capacity of each cell at 50 amps. is 400 amp. hours.

The room is well protected from the action of fumes by thorough ventilation, and as an additional precaution it i lined with tar paper.

The distributing system has its centers in two poles, which are each supplied by a pair of feeders from the lighting station. From these points pressure wires are brought back to the switchboard voltmeters and the pressure is adjusted with reference to indication of these instruments.

The incandescent lamps used are of 16 c.p. The rates are low, being 15 cents per k.w.-hour, and correspondingly reasonable flat rates are made on special contract. The arc system is in two circuits, and 45 lamps are located throughout the town. The rate on the arc lamps is $65 per year.

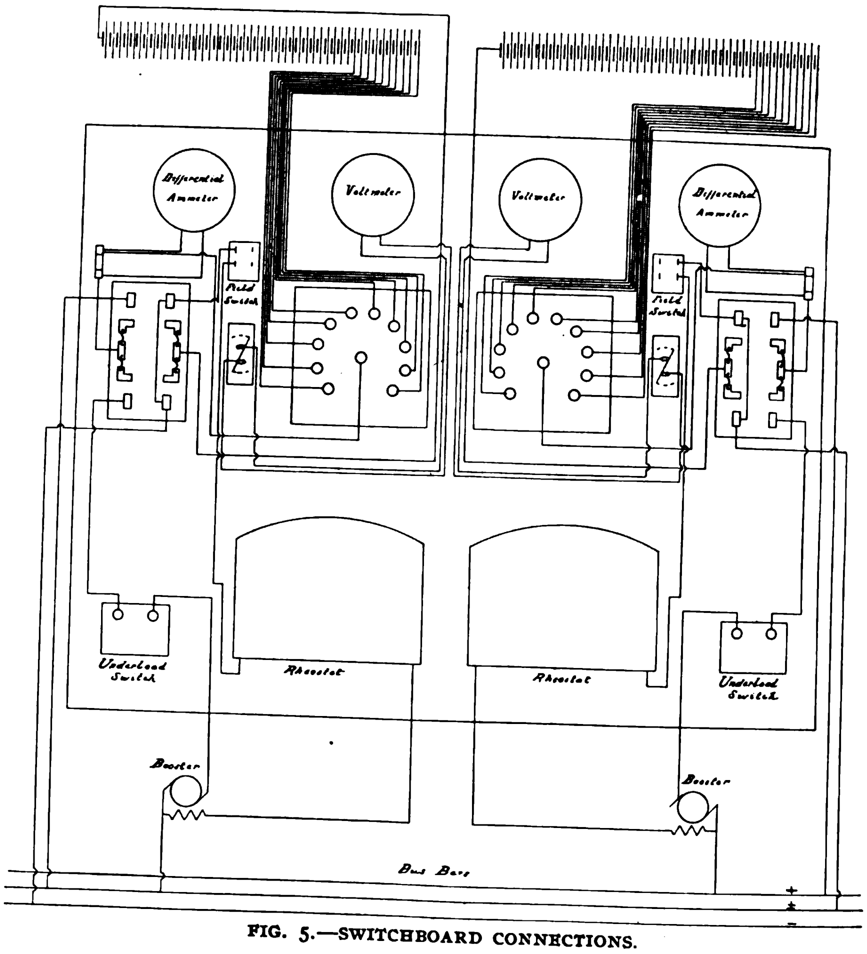

FIG. 5.—SWITCHBOARD CONNECTIONS.

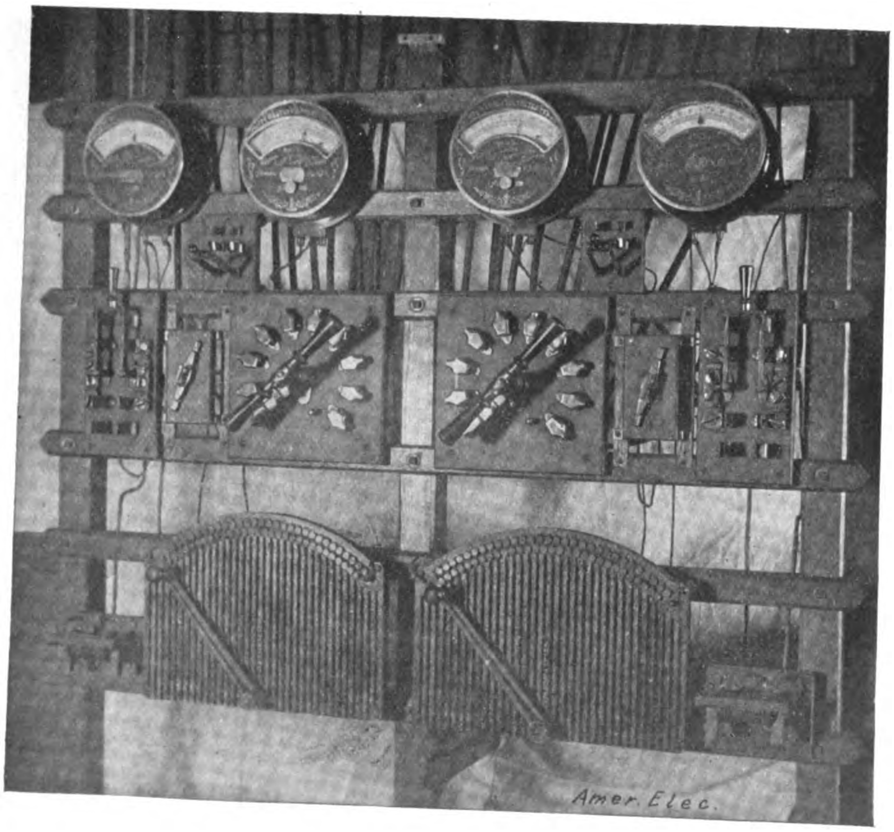

FIG. 4.—SWITCHBOARD.

The water wheel requires exact regulation only when the dynamos are running, for the large Corliss engine keeps the speed steady enough for the stamping machines of the rubber mill. At night the electric plant starts and monopolizes the water power. It is obvious that if the dynamo load is constant the speed will be so also, and so perfectly do the storage batteries accomplish the condition of constant load that the speed is sufficiently constant for incandescent lighting, the requirements for which are most exacting. In fact, a very efficient water wheel regulator has been abandoned and now stands idle in the plant. Of course, this arrangement will not be effective if the hydraulic head varies. In such a case the regulation must be accomplished by the gate, but this variation is so slow that hand regulation is convenient and satisfactory. That the batteries have been the source of considerable money saving is unquestioned, and the following statement given out by the company illustrates how the economy is apparent:

"In the month of January, 1896, before the batteries were installed, it was found necessary to run the auxiliary engine some 180 hours to supplement the water wheel. During January, 1898, after the batteries were installed, the same conditions as regards available water load prevailed. The station load was 33 per cent heavier, and yet it was only necessary to run the auxiliary engine 13 hours during the month. As the company was at the expense of coal, firing and boiler rent, this constitutes a considerable saving, and it is safe to say that the storage batteries have paid for themselves by this time. The service also has much improved, for current in the lines at all times enabled the company to secure more subscribers. This condition can be obtained in no other way excepting at a large expense."

From the foregoing description it will be seen that the plant is the result of a very moderate outlay in inexpensive machinery, but the storage battery has enabled it to supply a service that cannot be improved upon. It is practically impossible for the service to be interrupted. There are three prime movers, namely, the turbine, the auxiliary and the rubber mill engines, and any or all of them could be used. There are also the dynamos and the storage battery, either of which could temporarily handle the load when the batteries were just put in. However, the station load has grown since the instalment of the batteries, and the maximum is now nearly equal to the combined dynamo and the battery capacity of the station.

The entire force employed in this plant consists of a superintendent, a dynamo tender and a lineman, who also does the trimming. Before the battery was installed there was, in addition, a licensed engineer, and at that time the average load was considerably less than at present.

Although this plant contains nothing radically new, either in apparatus or arrangement, it is believed that it is a significant illustration of the value of storage batteries in small electric plants. It produces practically constant and full load on the dynamos during their operating hours. It keeps the speed constant on the one hand and the voltage on the other. In the case of steam plants, full continuous load enables the machiney to always operate at its highest efficiency, and effects a substantial saving at the coal pile. The feature of continuous service, however, has the greatest money value. Continuous service will always result in increased custom, particularly if there is a local gas company and competition is keen. There are thousands of plants in the United States to-day, both central station and isolated, that could materially benefit themselves by securing this most valuable feature and the incidental economy, and there are many that are contemplating increased capacity that can ill afford to overlook this most obvious method of supplying their needs.

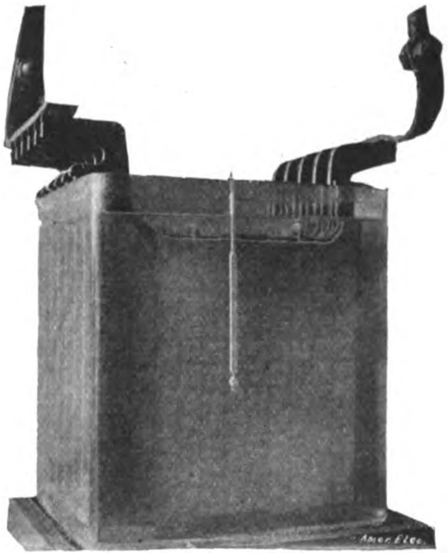

FIG. 6.—ONE OF THE STORAGE CELLS.

The discouraging early history of the storage battery has been largely responsible for the lack of general appreciation of its value in such cases as have just been recited. It has, however, fought its way through the almost insurmountable commercial obstacles that its premature exploitation cast in its way. It may now be confidently stated that the modern storage cell is an assured success for all stationary work, and since engineers have succeeded inventors the doubts that have impeded its progress have been dissipated.

A MODERN ARC LIGHTING PLANT.

A TRANSFORMED ARC LIGHT STATION.

An interesting transformation from a generating station, dependent upon boilers and steam engines for its motive power into one directly driven by high tension three phase current, is now being carried out without interruption to the lighting service by the Edison Electric Illuminating Company of Brooklyn, in what was the central station of the Citizens' Electric Illuminating Company. Last year the Brooklyn Edison Company absorbed the Citizens' Company, which owned an important and necessary overhead franchise, and up to a recent date continued the operation of its high tension series arc system from the existing steam station. As soon, however, as the great Union station at Bay Ridge was in condition to furnish current in sufficient quantities plans were perfected for the conversion of the central station into one of the substations of the great Brooklyn system, dispensing entirely with the steam plant.

The station is situated at the lower corner of Navy Street and De Kalb Avenue, and consists of two separate buildings, a two-story structure, in which the original Thomson-Houston generators were located, and a newer three-story building, formerly occupied by the Brush arc light machines. A part of the newer building only will be occupied by the remodelled plant.

The equipment of the old steam plant consisted of three 400 h.p. Wright-Corliss engines, two 400 h.p. vertical triple expansion McIntosh and Seymour engines, and one 1200 h.p. Hamilton-Corliss twin compound engine. These drove through counter-shafting twenty 120-light 1200-c.p. Brush generators, which replaced the smaller capacity T-H machines. In addition, two 150-h.p. Edison bipolar motors,

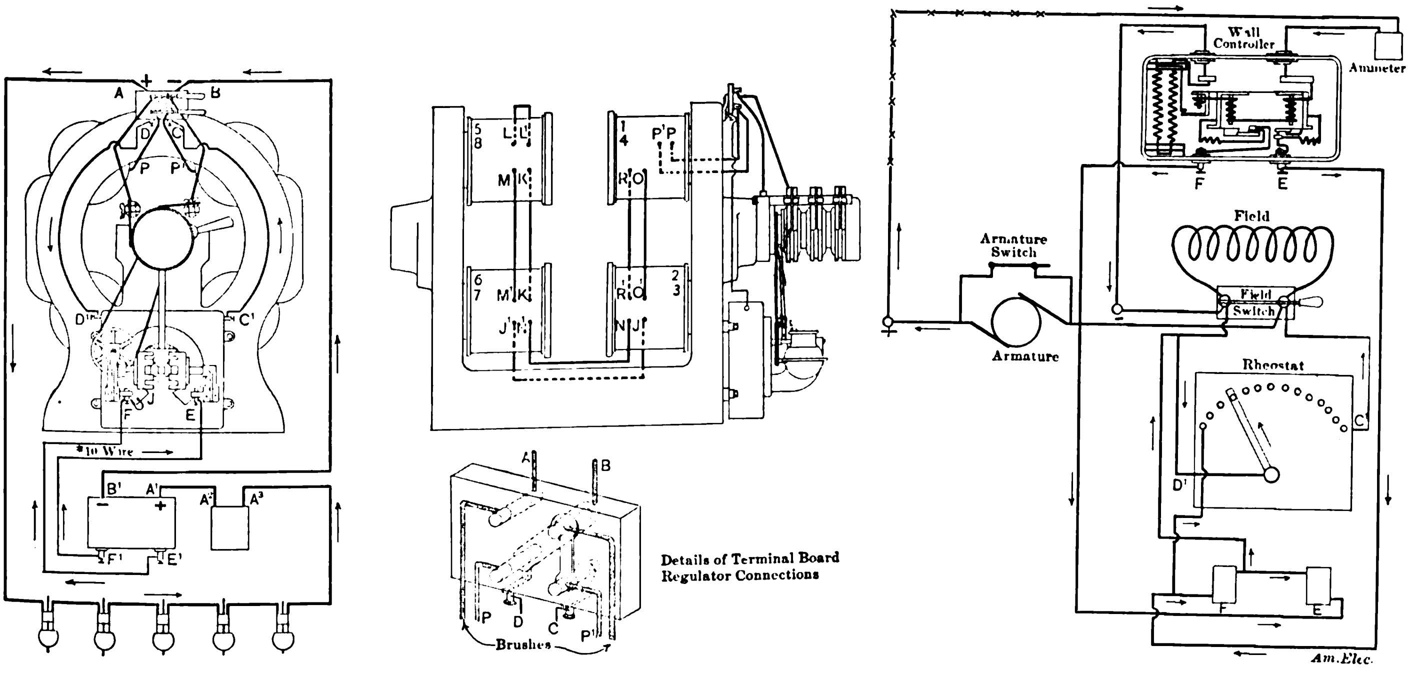

FIG. 1.—ARC MACHINE CONNECTIONS AND ELECTRICAL CIRCUIT.

operated by current from the low tension mains, furnished additional power after 7 at night, when the high tension arc load was thrown on. During the day the motors were driven as generators by the engines feeding low tension current into the Edison network. All the engines have been removed but the three first named, and these are only retained to drive the machines not yet moved.

The new fireproof building occupied by the substation apparatus has a frontage of 75 ft. on Navy Street and a depth of 100 ft. The lower floor, formerly occupied by the vertical and Hamilton engines and boilers, is below the street level, and is divided into two rooms, the larger 45 ft. by 90 ft., occupie by the synchronous motors, arc machines, booster and switchboards; the smaller, 24 ft. by 90 ft., containing an extensive storage battery plant. The upper floors will be occupied as storerooms, repair shops and the inspection department. Fig. 2 shows the lay-out of the second floor of the new building when the Brush machines were driven through counter shafting from the engines on the first floor. Fig. 3 shows the lay-out of the first floor. The comparison is most striking. The entire new plant occupies only the space formerly occupied by the steam portion alone of the old arc-lighting plant.

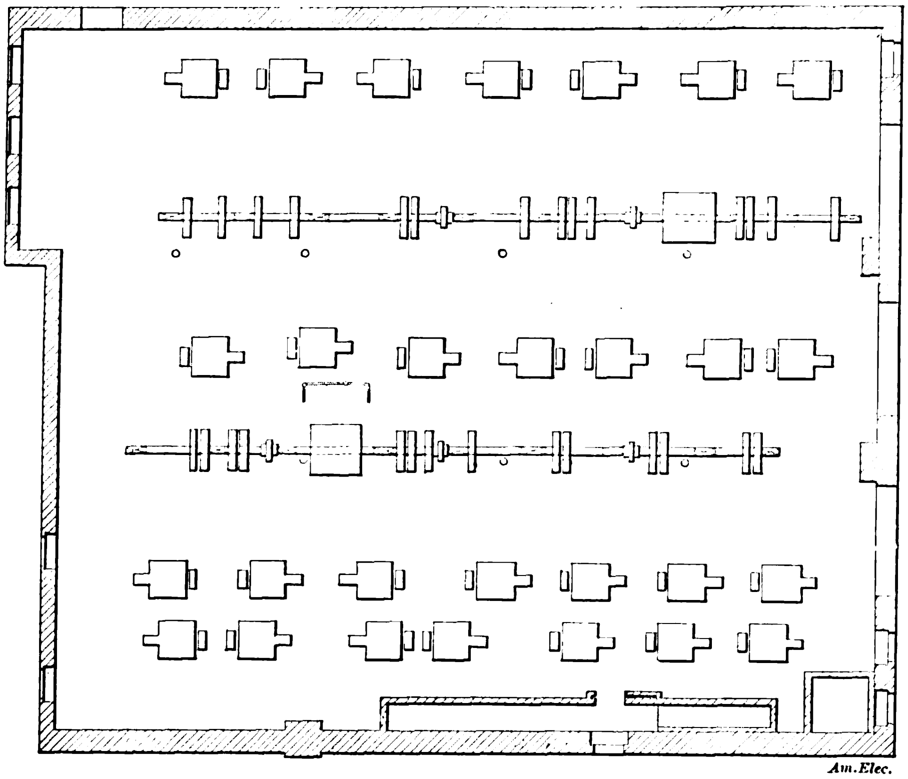

FIG. 2.—PLAN OF ABANDONED SECOND FLOOR WITH MACHINES BELT DRIVEN FROM COUNTERSHAFTING.

The method of driving the arc generators is similar to that to be followed at Buffalo and at Boston. Each unit consists of one General Electric 100-k.w. synchronous motor, directly connected to two 120-light Brush arc machines—one at each end of the shaft—the three machines being set on a heavy pine timber sub-base. The shaft of the motor is extended at each end, and is coupled to the shafts of the two arc generators by flexible couplings, consisting of two four-armed stars interlocking over rubber cushions. The commutators of the Brush generators are at either end of the set, facilitating inspection and attention.

The motors are classed as four-pole 100-k.w. revolving field machines, running at 750 revolutions. The stationary armature is similar in construction to that of the standard General Electric revolving field generators or to the field of an induction motor. Each pole has, wound close to the iron, a heavy copper strip short-circuited upon itself, the ordinary field winding being outside of this copper strip or shield. The ends of the ordinary winding are carried to two collector rings, furnished with carbon brushes. These motors are designed for a field excitation of 125 volts. The stationary armature is provided with a substantial connection board placed at one side near the base, and the leads brought out from this are furnished with couplings completely encased in hard rubber.

Each motor has a three-phase reactance coil, placed in circuit with the armature when starting and cut out by a switch when the machine has reached synchronism. By means of this reactance a limit is set to the current taken from the line when starting, and the potential of the transmission lines thus remains unaffected. A field rheostat is also provided with each motor to allow of the adjustment of the field excitation, so that the minimum current input will be taken for any given load. These motors take the full voltage current from the transmission lines from the Union station—6000 volts—without the intermediary of reducing transformers.

The dimensions of the motors are: From bottom of iron base to top of armature frame, 52½ ins.; length over ends of shaft, 86 ins.; width over base, 57½ ins.; approximate weight, 11,000 lbs.

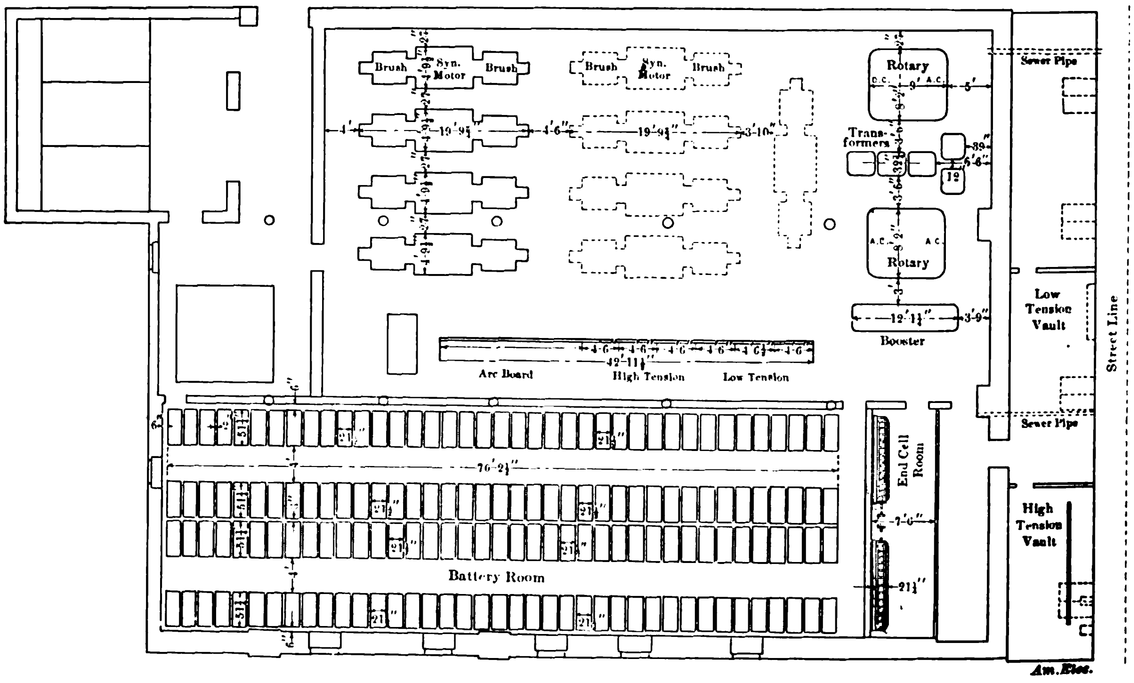

FIG. 3.—PLAN OF NEW STATION.

The arc light generators are four pole open coil Brush machines, with the rating of 6,000 volts and 6.6 amps., at a speed of

700 r.p.m. The design and construction have been carried out on very liberal lines, with ample strength of cast iron in both frame and bed plate. The ball bearings are self-aligning and self-oiling, are of ample size and run very cool—about 20°F. above the surrounding air after 10 hours' run. The pulley bearing is a plain straight bearing, while the commutator bearing has six thrust collars to provide for the magnetic pull in this type of machine.

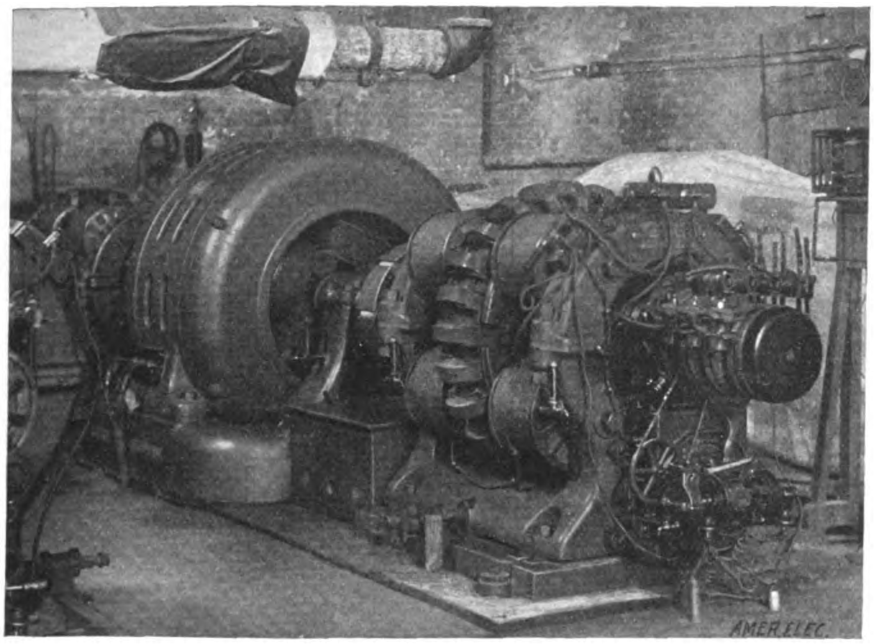

FIG. 4.—A 240-LIGHT UNIT.

The armature is built up on a gun metal spider clamped in a winding form. The end of a thin steel ribbon is screwed to it, and the ribbon is wound upon it, paper insulation being placed between each layer. Cross pieces are placed between the ribbon to form teeth to wind the bobbins between, and filling-in pieces are placed between the different armature teeth. The band is wound under heavy tension, and clamps are placed upon the spider over the iron, clamping it down and making the whole a solid mass. The core is attached to the spider by rivets, insulated from the core and riveted to the spider.

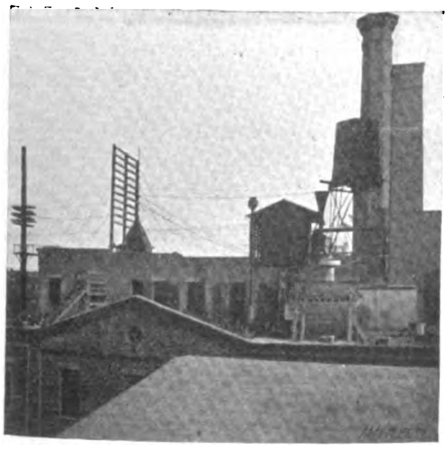

FIG. 5.—ROOF, SHOWING OLD LINES

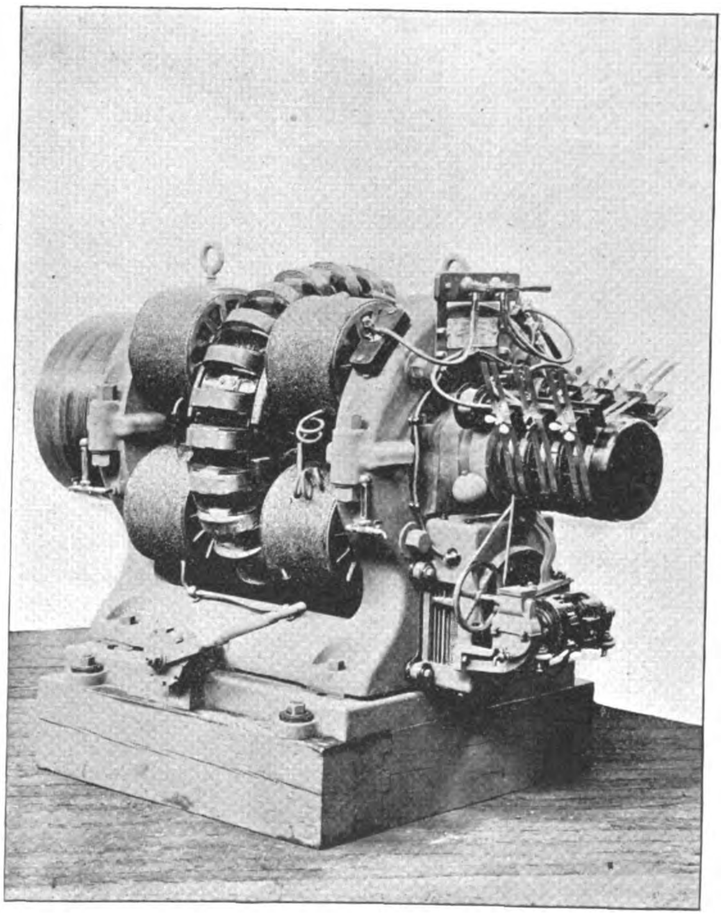

FIG. 6.—125-LIGHT ARC MACHINE.

The boxes in which the armature bobbins are wound are made of red rope paper, mica and shellac, built up on forms in two halves, with dove-tailed joints. The box is driven tightly on the armature core and the winding applied, interposing a layer of muslin between each layer of wire. The bobbin is constructed of rectangular cross sections to avoid crossing wires at sharp angles and lessening their life. The core is balanced, and the completed armature again balanced after winding. This is, however, not of frequent necessity, the armature usually being in perfect balance when it leaves the winder's hands. The wires connecting the armature bobbins to the commutator are of flexible rubber-covered cable run through a mica tube in the shaft.

The construction of the commutator has been the object of the greatest care. It is built upon an iron shell fitted upon the shaft. The commutator rings are built up of wood in small pieces glued together and fastened with screw dowels, then thoroughly dried and afterward soaked in oil. The rings are then turned to fit upon the iron shell, and the outside periphery turned to allow mica rings to be fitted upon and cover it. The ends are then turned off securely and fitted with mica end plates. The brass segments which hold the copper segments are then secured down upon the mica covered wooden rings. The cross connecting wires are put in grooves, covered with burned shellac and protected by mica end plates. The copper segments are then mounted upon the brass segments, the wooden blocks are fitted into their places and the whole is turned off.

The field magnet spools are wound upon brass shells, the insulation used being red rope paper, mica, rubber cloth and shellac. The winding is protected by a rope cover. There is ample insulation at all points, and especially long surface insulation.

The regulation is secured by automatic shifting of brushes and variation of current in the fields by means of a rheostat attached to the machine beneath the commutator. The diagrams show the connections of the machine with wall controller, regulator, etc.

The total floor space taken up by one set of two arc machines and one synchronous motor is, length over commutators, 19 ft. 9¾ ins.; width, 57½ ins.

Four 240 light units are now installed and the remainder are fast being placed in position. The ultimate capacity of the station as at present laid out will be eighteen 120-light arc machines and nine synchronous motors.

At the east side of the room will be set up two General Electric rotary converters, three static transformers cooled by air blast, and two induction regulators; current at 6000 volts and 25 cycles will be fed from the transmission lines into the static transformers, in which the pressure will be reduced to 83 volts. At this pressure it will pass to the rotary converters and will be delivered as 125-volt current to the storage battery, and the low-tension Edison network. Each rotary is of 200 k.w. capacity, and runs at 375 revolutions per minute; each static transformer is of 150 k.w. capacity. The air for cooling purposes will be furnished by a 1 h.p. bipolar ironclad motor. By means of the induction regulators the voltage of the direct current from the rotary converter is regulated by variation in the 83-volt secondary from the static transformers.

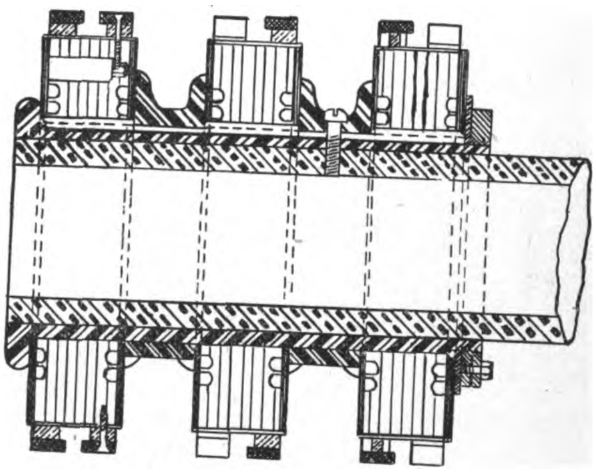

FIG. 7.—SECTIONAL VIEW OF COMMUTATOR.

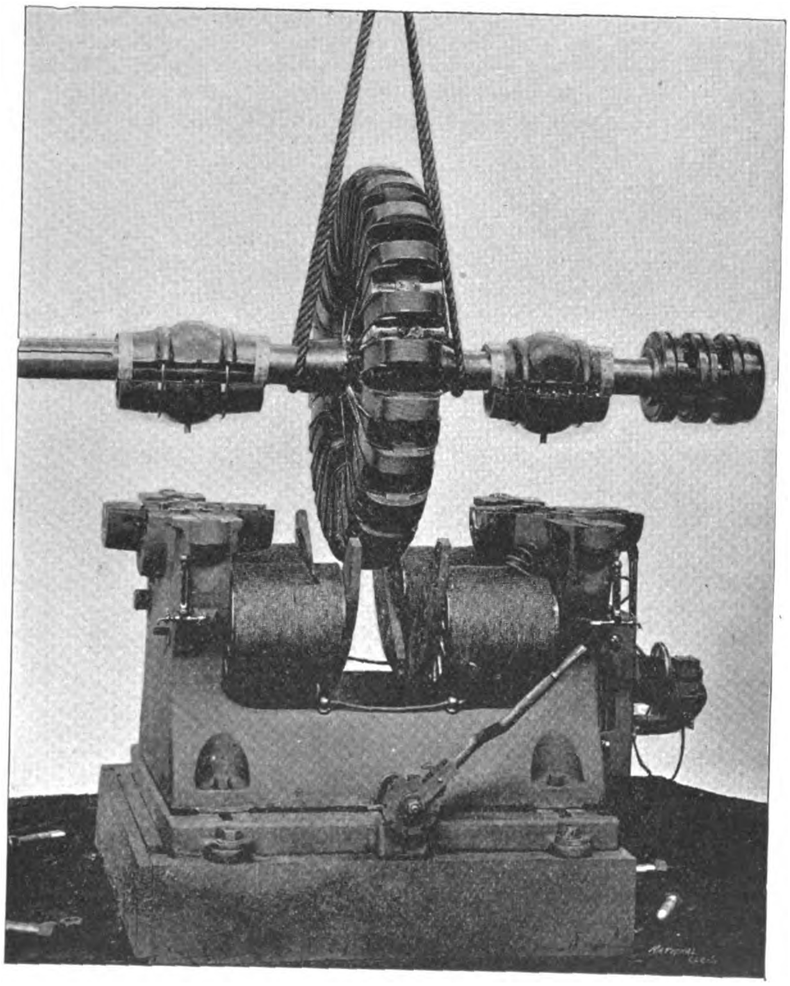

FIG. 8.—120-LIGHT ARC MACHINE, SHOWING ARMATURE.

The storage battery occupies a spacious room, formerly occupied by the boilers, to the south of the main dynamo room, and the cell regulating switches a small room on the Navy Street side, in as close proximity as possible to the end cells of the battery. The cells number 156 and have a total capacity of 1200 amps. for ten hours, 3000 amps. for three hours and 6000 amps. for one hour. The positive half of the battery is on the right side of the room, the negative on the left of the room. This battery was installed by the Electric Storage Battery Company, and acts as a reserve in the event of accident to the main station. It is designed to cope in case of accident with the entire demand of the district, including the high-tension series system, for a period of two hours, in which time the reserve stations may be started and thrown on. The battery is charged from the Pearl Street station through a Churchward booster. It discharges simultaneously and is connected at all hours to the low-tension mains for purposes of regulation.

The method of operation of the high-tension arc plant in case of break-down to the 6000-volt transmission lines is simple. It consists merely in reversing the normal operation of the battery, rotaries and transformers—the battery discharging to the rotaries, which deliver low-tension, three-phase current to the transformers, which, in turn, deliver to the synchronous motors the 6000-volt current necessary to their operation. That this may be readily and successfully effected is proved by the fact that when the Union Station is under heavy overload it is helped out by driving the synchronous motors from the battery in the manner stated.

The cell-regulating switches are now operated by hand wheels, but ½-h p. Lundell motors will shortly be installed to drive the worm gearing connected to the screws on which the contact brushes travel. The motors will be controlled from the main switchboard and may be run in either direction, throwing in or cutting out cells as the conditions require. By a novel arrangement the switchboard operator will be able to see when the travelling contact brushes are in normal position on the contacts. This will consist of two 16-c.p. incandescent lamps placed over each of the motor-control switches, and so connected that while the brush travels from one contact to another they will be in series across the 110-volt circuit, and will, therefore, burn dimly. When the brush is exactly over a contact one lamp is extinguished, the other burning to full candle-power. The operator is thus made aware that the motor must be stopped. An indicator, with scale and needle, shows the number of cells in circuit. This is operated on the same principle as a Wheatstone bridge. A resistance wire, stretching the full length of the cell-regulating switch, is in constant

LIBRARY

contact with the travelling brush. The position of the latter is shown on the indicator according to the relative proportion of the resistance wire on each side of the brush, the scale being calculated in divisions corresponding to the contacts on the switch.

The booster, which occupies a space on the south side of the room, is of the Churchward multipolar three-machine type, built by the Excelsior Company. The two end machines are dynamos, each of 1000 amps. and 50 volts capacity, while the center machine is a motor connected to run either on 125 or 240 volts, the former when the dynamos give their current output at a low e.m.f., the latter when they are required to give their current output at a high pressure; thus the dynamos always have a comparatively strong field.

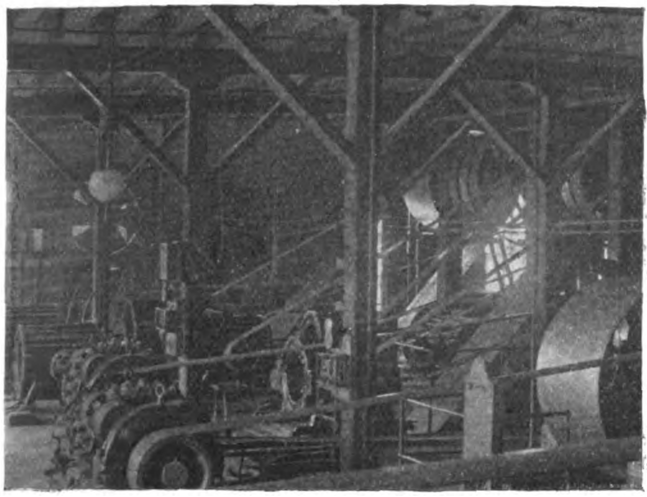

FIG. 8.—PART OF OLD STATION, SHOWING MACHINES BELT DRIVEN.

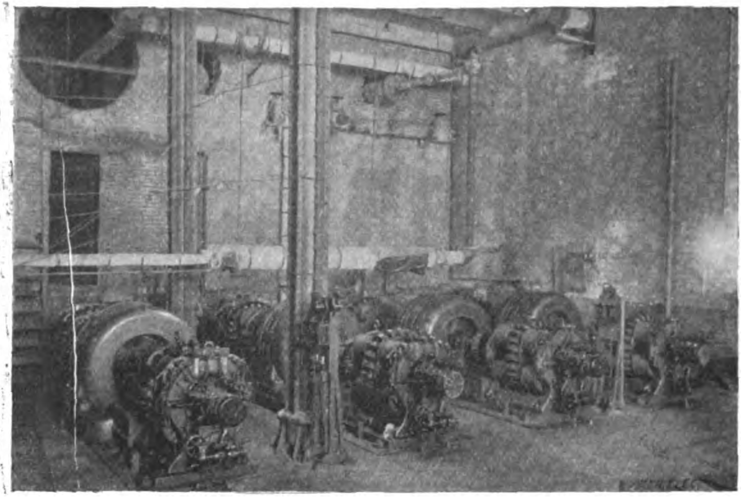

FIG. 9.—FOUR MOTOR AND ARC UNITS, SHOWING SIMPLICITY OF DRIVE.

The brushes are of carbon, and the drop forged commutation bars have sufficient surface to give the brushes bearing enough to carry the current at the low density of 20 amps. per square inch. The fields are separately excited from the station busbars, and the rheostats used have a large number of contact points, permitting of a variation in voltage from 1 volt on open circuit up to 50 volts and 1000 amps. The floor space occuped is 12 ft. 2 ins. by 34 ins. wide and 37½ ins. high.

The switchboard will be over 45 ft. long, and with the exception of the high-tension arc circuit board will be made up of panels of blue Vermont marble. The arc-circuit board will be placed at the end near the west wall of the room. Next to this will be placed the panels, through which the three-phase 6000 current will be supplied to the synchronous motors. Then will come the high-tension board, taking from the distribution switchboard in the vault 6,000-volt three-phase current, and distributing it to the synchronous motor board just mentioned and the next board, upon which are mounted the instruments necessary to the control and regulation of the transformers and converters. The fifth and last board near the east wall is the storage battery switchboard. All the high-tension switches are mounted on corrugated rubber stands and are separated by heavy wooden barriers.

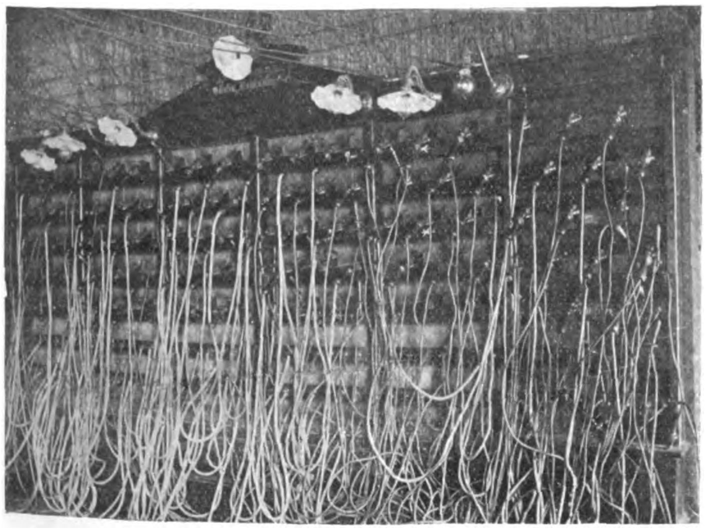

FIG. 10.—OLD ARC SWITCHBOARD ON A BUSY NIGHT.

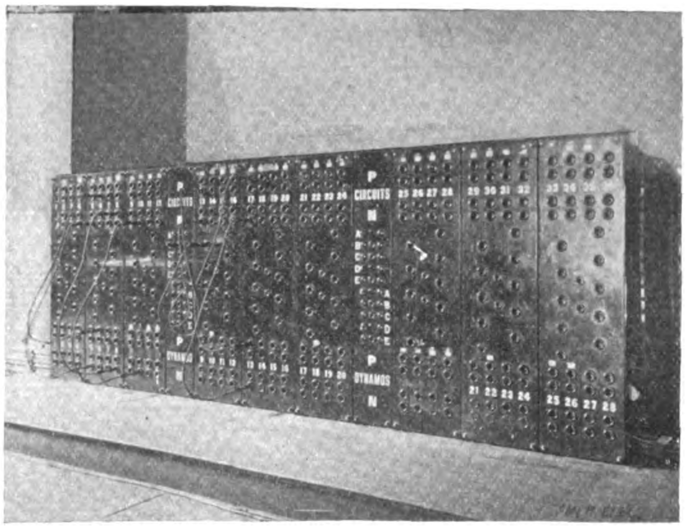

FIG. 11.—NEW ARC SWITCHBOARD, WITH FOUR PANELS CONNECTED.

This station is also the main center of distribution for the 6000-volt current from the Union station, not only to itself, but also to the Williamsburg and Pearl Street substations. The distribution board is erected in a fireproof vault, and consists of four panels of blue Vermont marble, carrying General Electric high-tension, quick-break switches, set on corrugated cones of hard rubber and separated from each other by high barriers of japanned maple in a manner similar to those on the main board. They are pulled open by a hooked stick. This vault is shut off from the room by an iron-barred gate.

The transformation in the interior will extend also to the exterior, and with the steam plant will also disappear the tangle of wires shown in Fig. 5. All incoming current from the Union station is transmitted through duplicate three-wire, lead-covered cables, drawn through earthenware ducts. These cables are paper and compound insulated, and were furnished by the Standard Underground Cable Company after test at from 12,000 to 15,000 volts. All the outgoing mains are also carried underground, the high voltage and low-tension Edison wires in their several conduits. The high-tension series arc wires run underground for a distance of three-quarters of a mile, when they rise, and are carried on poles to the arc lights.

In this remodelled station almost all the benefits conferred on the electrical lighting industry by the introduction of modern methods may be seen and appreciated.

Reference to Figs. 2 and 3 shows clearly the great economy effected in the floor space occupied, while Fig. 10 shows the mass of belting from engine to countershafting and from countershafting to generator formerly necessary, eliminated by the adoption of methods dictated by long experience in the art.

In hardly any other case are the compactness of the devices and subsequent restriction of floor space occupied, simplification of the apparatus and the added flexibility to the general system more strikingly apparent than in this. And when we reflect that this change is being effected without the loss of light from one lamp for a single night the task accomplished reflects high credit on the engineers and electricians who planned and are carrying it out.

MECHANICAL DRAFT..

THE ADVANTAGES OF MECHANICAL DRAFT.

BY WALTER B. SNOW.

The economic progress in steam engineering which has marked the past quarter century has been largely the result of greater refinement in the design and construction of the engine in which the steam is utilized. Future improvement along this line is to be sought principally in the increase of the steam pressure and the expansion ratio. But experimental results which, with a quadruple expansion engine and steam of 500 lbs. pressure, have already shown a steam consumption of less than 10 lbs. per hour per indicated horse power, are indicative of the fact that we are closely approaching the maximum practical efficiency.

Until the recent past, however, the steam generator or boiler and the manner of its operation have received far less attention than they deserve. Although, under the best conditions, over 80 per cent of the full calorific value of the fuel may be utilized in the production of steam, yet it is true that this high standard is seldom reached in ordinary practice. Hoadley showed an efficiency of nearly 88 per cent in his tests of a warm-blast steam boiler furnace equipped with air heaters and mechanical draft. Bryan has reported eighty-six tests conducted under common conditions with ordinary fuel, upon boilers of various types, which indicate an average efficiency of only 58 per cent, and have a range between a minimum of 34.6 per cent obtained with a small vertical boiler, and a maximum of 81.32 per cent resulting from the test of a water tube boiler with improved setting. The possibliities of increased economy in ordinary boiler practice are thus rendered clearly evident.

Of the losses in the efficiency of the fuel used in connection with a steam boiler some are inevitable, while others are to a greater or less degree avoidable. It is with these latter that we have to deal, and it is interesting to note to what an extent the application of mechanical draft is of assistance in their reduction.

The loss resulting from the escape of unconsumed carbon in the form of smoke is probably one of the most noticeable losses, although seldom exceeding 1 per cent in good practice. Even this loss may, however, be almost entirely eliminated and the smoke nuisance may in most cases be practically avoided by such regulation of the air supply and the intensity of the draft as is possible under the conditions of mechanical draft.

In a similar manner, the loss by carbonic oxide—the result of imperfect combustion—may be reduced to an almost infinitesimal amount under proper draft conditions.

The direct loss which ensues from the dropping of small pieces of coal through the grate, and from the presence of incompletely burned coal in the ash, may be greatly reduced by proper grates, having small air spaces, and by the application of mechanical means to produce the draft, which is absolutely required where small-sized coal is employed.

Although, in theory, the amount of air required for the combustion of one pound of coal is about 12 pounds, in actual practice with chimney draft the amount supplied is usually greatly in excess. In the case of sixteen different plants tested by Donkin and Kennedy it was shown by gas analysis that the air supply ranged from 56 to 328 per cent in excess of the chemical requirements. Such an excess brings

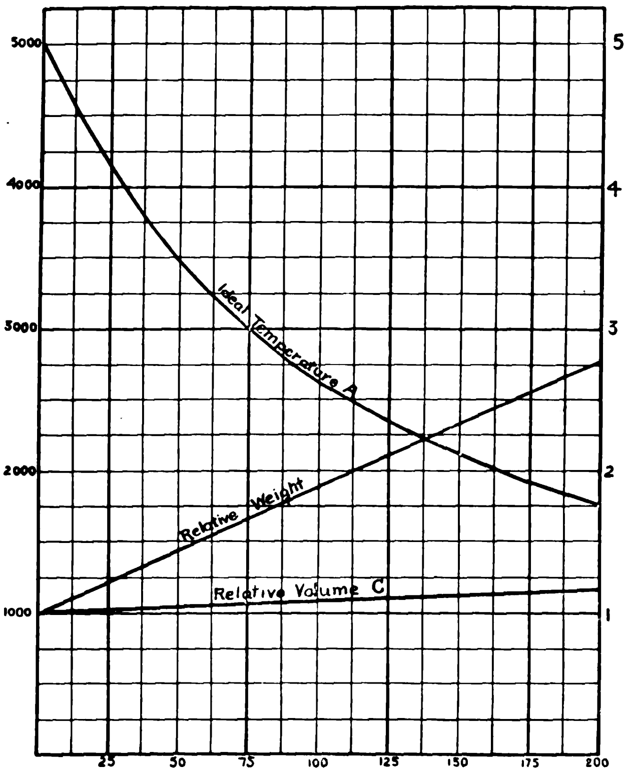

FIG. 1.—CURVES OF TEMPERATURE, WEIGHT AND VOLUME.

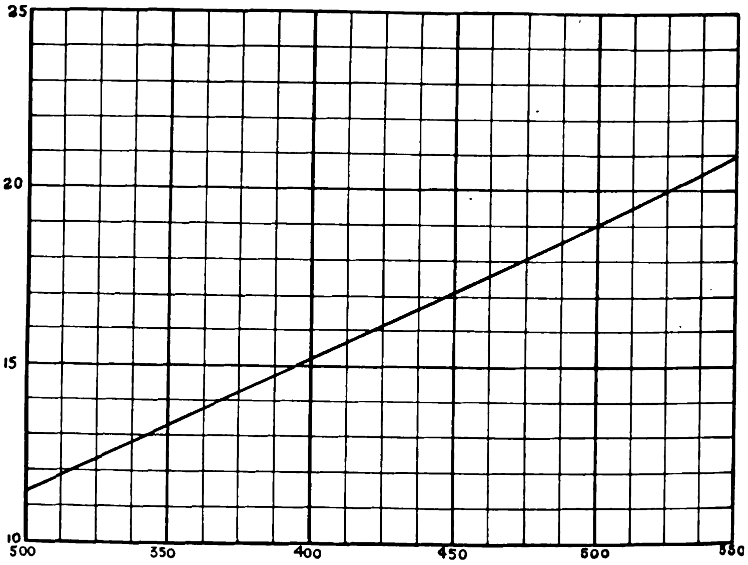

FIG. 2.—CURVE OF LOSS DUE TO HIGH TEMPERATURE

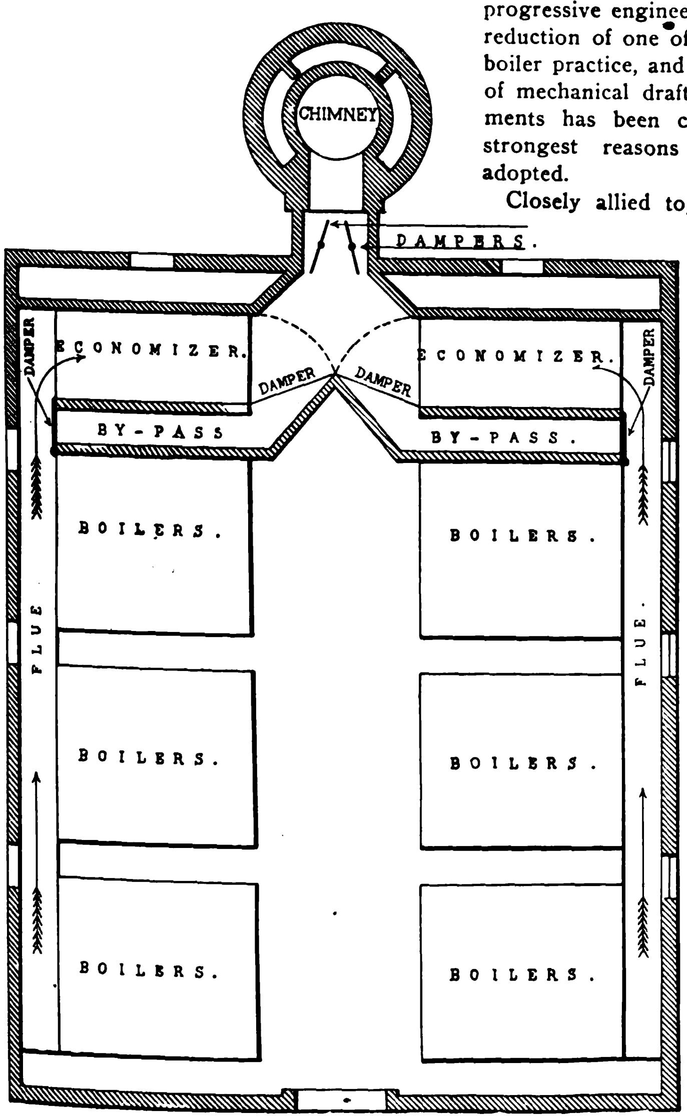
about a two-fold loss: First, the temperature of the furnace is lower; second, paradoxical as it may seem, the gases, because of the lower furnace temperature, their larger volume and higher velocity, actually leave the boiler at higher temperature than with a less excess of air.

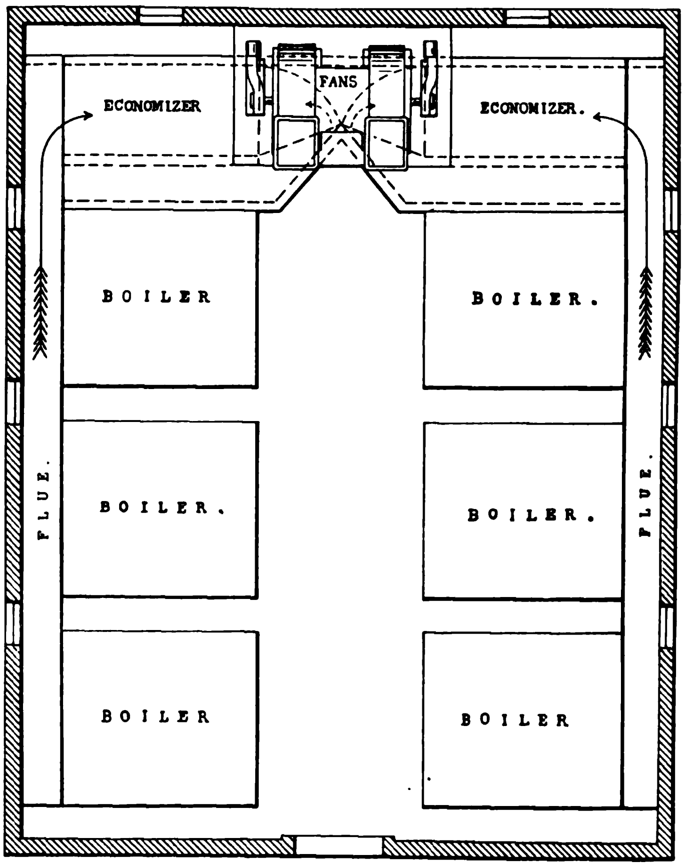
The conditions in the furnace chamber are shown by the accompanying curves, Fig. 1, of which A indicates the ideal temperature for an ordinary anthracite coal; B the relative weight of the products of combustion, and C their relative volume at the ideal temperature.

TABLE I.

EFFECT OF DECREASED AIR SUPPLY ON TEMPERATURE OF ESCAPING GASES.

Day.	Cubic Feet of Air at 62 degrees per pound of Coal	Average Temperature of the Gases Leaving the Boiler.
First	272	624°
Second	198	601
Third	163	550
Fourth	124	497





FIGS. 3 AND 4.—TYPICAL BOILER PLANT, NATURAL AND FORCED DRAFT.

The actual results obtained by M. Burnat, in the case of a boiler provided with special heaters, are shown in Table I..

A high furnace temperature and low stack temperature, other things equal, are evidently conducive to greater efficiency, and the preceding results serve to show that such conditions are incident to a reduction in the excess of air supplied. But perfect combustion with small air supply will only result when it is intimately distributed throughout the fuel. For such intimacy of contact, intense draft and a clean and reasonably thick fire are necessary—conditions which may be most readily maintained by means of mechanical draft.

It appears that if, with a given boiler, the grate area be reduced and the rate of combustion thereon be increased so as to maintain a constant consumption of coal, the air actually required to be furnished per pound of coal will be reduced. Years ago D. K. Clark stated that "the proportion of surplus air required appears to diminish as the rate of combustion and the general temperature in the furnace are increased," and that "the system of forced draft opens the way for increase of efficiency in facilitating the adoption of grates of diminished area in combination with acceleration of combustion." It is along this line that all progressive engineers have sought for the reduction of one of the greatest losses in boiler practice, and the ready adjustability of mechanical draft to the exact requirements has been considered one of the strongest reasons why it should be adopted.

Closely allied to, and, in fact, largely dependent upon the loss due to excess of air, is that resulting from too high a temperature of the flue gases. In the case of the chimney, a certain temperature is absolutely necessary to produce the requisite draft. If economizers or other devices for extracting heat from the gases are introduced, the chimney has to be just so much higher to produce the necessary draft to overcome their resistances. With mechanical draft, on the other hand, the intensity of the draft produced is independent of the temperature of the gases; and in the case of induced draft the lower that temperature the smaller the fan required, the slower the speed and the less the power expended.

The loss due to high temperature of the gases ranges from 10 per cent in the best practice to 30 per cent and upwards in common and poor practice. The theoretical losses with 100 per cent excess of air and different temperatures of the escaping gases above the atmosphere are clearly presented in the curve, Fig. 2, for an ordinary coal having a calorific value of 11,720 B. T. U. This heat may in most cases be abstracted by proper forms of air or water heaters, retarders, ribbed tubes or the like. By means of feed-water economizers Roney reported an average saving of 14 per cent in the case of nine plants equipped therewith and with mechanical draft. Hoadley succeeded in reducing the total waste in the flue gases to 5 per cent of the calorific value of the fuel, only 1 per cent of the total steam generated being required to operate the blower employed to produce the necessary draft.

The methods of application of mechanical draft, by means of fan blowers, may be broadly classified under two heads—the plenum and the vacuum methods. Except upon shipboard, the plenum method is employed only under the conditions of a closed ashpit into which the air under pressure is forced. Various methods are adopted for the admission and regulation of this air. A special form of damper placed in the bottom of the ashpit or in the face of the bridge wall generally serves the purpose. It must, however, be so located as to prevent direct impingement of the air currents upon the grates and fuel.

Under the vacuum method there is practically only one means of application—that by the introduction of an exhausting fan in the place of the chimney. This is commonly known as the "suction" or "induced" method. The fan serves to maintain the vacuum which would exist if a chimney were employed, and its capacity can be made such as to handle the gases which result from the process of combustion. A short and comparatively light stack usually serves to carry these gases sufficiently high to permit of their harmless escape to the atmosphere.

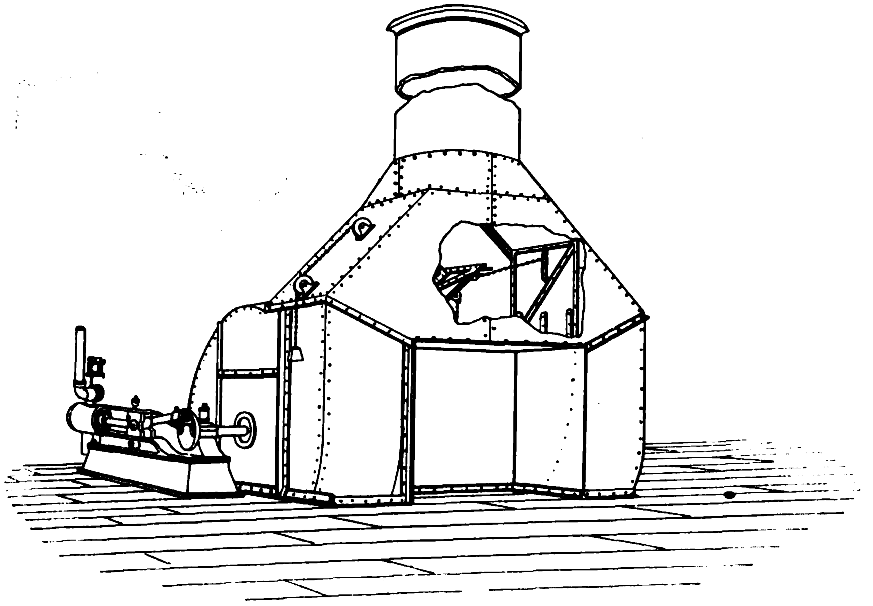


FIG. 4.—APPARATUS FOR FORCED DRAFT.

The method of application which is most suitable must depend upon the circumstances. In fact, it cannot be said that either of these two principal methods is the better. Each has its peculiar advantages.

The efficiency of mechanical draft must, of necessity, be judged from a commercial standpoint. The two principal factors in commercial efficiency are the first cost and the operating expense. The relative cost of a chimney and a mechanical draft apparatus for producing the same results can best be shown by the consideration of a typical boiler plant. Such is shown in the accompanying Fig. 3.

The plant consists of twelve modern water-tube boilers set in pairs upon either side of a substantial boiler house. Each boiler is of 200 rated h.p., making the total 2400 h.p. An economizer of suitable size is provided for each battery of six boilers and the gases pass either through these economizers or by-pass around them to a chimney 9 ft. in internal diameter by 180 ft. high.

In round numbers, the cost of the plant is, in detail, as follows:

12 boilers	$37,000
2 economizers	10,500
Boiler and economizer settings and by-passes	9,000
Automatic damper, regulators, and dampers	400
Chimney, including foundations	10,200
Boiler house	11,500
	$78,600

Of course these figures would vary somewhat with the locality and conditions, and the chimney cost might be vastly increased if built upon unstable ground.

Fig. 4 serves to show the method of application to the same plant of an induced mechanical draft apparatus. The chimney, of course, is omitted, and the duplex fan—representing a most complete equipment—is placed overhead between the economizer ends and entirely within the boiler house.

The general form of such an apparatus is as indicated in Fig. 5. Two steel plate fans are supported side by side upon a steel beam framework carried by the boiler and economizer settings and the end wall of the building. Each fan is driven by an independent horizontal engine, automatically regulated by a special device so that the fan speed increases as the steam pressure falls. Between the fans is an enclosed space to which the gases pass. By means of a swinging damper these gases may be caused to pass to either fan, and by a similar damper in the breeching above the fan outlets, either fan may be entirely shut off. As each fan is of sufficient capacity to operate the entire plant, the other may serve as a relay. All necessity for stoppage due to accident is thus avoided and access to the disabled fan is made simple and comfortable.

An apparatus such as is here represented could be installed complete with supporting framework, inlet and outlet connections and short stack, for about $4700. Evidently this cost would be far less if only a single fan were employed. As it is, the damper regulator and flue dampers are omitted and the actual cost of the draft producing apparatus is as follows:

Chimney Draft.		Mechanical Draft.	
Cost of chimney	$10,200	Cost of mechanical draft plant complete	$4,700
Cost of damper regulator and dampers	400	Saving by using mechanical draft	5,900
	$10,600		$10,600

There would be a further saving in first cost due to decreased space occupied, which in the case of valuable land in a city would be an appreciable item. This factor is also of account when a larger output is obtained from a given plant by means of mechanical draft instead of chimney draft. For this amounts to a smaller plant and less space occupied for the same output when mechanical draft is used.

Fig. 6 represents another example of the application of induced draft.

A problem that has to be faced sooner or later in most boiler plants is that of increased capacity. This may be secured in two ways, either by increasing the output of the existing plant or by adding additional boilers. Suppose, for instance, it is desired to increase by 16 2-3 per cent. the capacity of the plant shown in Fig. 3. With chimney draft, supposing the chimney capacity to be sufficient, it would be necessary to install more boilers, in this case, two, which would in turn require the enlargement of the boiler house. On the other hand, at the sacrifice of a slight percentage of efficiency (which might be more than offset by the ability to burn cheaper fuel) the original plant of twelve boilers might be made to do the increased work by the aid of a fan applied for forcing the draft on the closed ashpit system. Such a fan, with engine, ducts and dampers, could probably be installed for about $1200. Taking the figures first given the relative costs of the two plants would be about as follows:

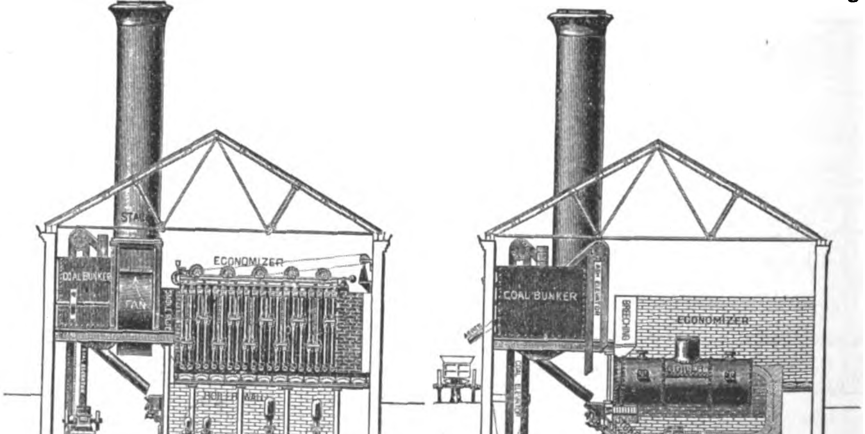

FIG. 6.—BOILER PLANT FITTED WITH FORCED DRAFT.

LIBRARY

Chimney draft, with 2,800 rated horse-power plant—		Mechanical draft with 2,600 rated horse-power plant—	
Cost as in Fig. 3.	$78,600	Cost as in Fig. 3.	$78,600
Cost of 2 additional boilers...	6,250	Cost of mechanical draft plant complete.	1,200
Settings, &c., for 2 boilers........	1,250	Saving in expense by mechanical draft plant	9,000
Cost of adding to building, &c	2,700		
	$88,800		$88,800

Such an increase in output as is here contemplated may be easily secured by mechanical means. It is evident that counting interest, insurance and taxes at 7 per cent on the investment, the annual fixed charges would be increased under chimney draft $714. In an economical arrangement this might cover the cost of operating the fan, if the exhaust steam should be thrown away. If, however, it should be utilized, as would be the case in any well arranged plant, this saving would be practically all clear gain.

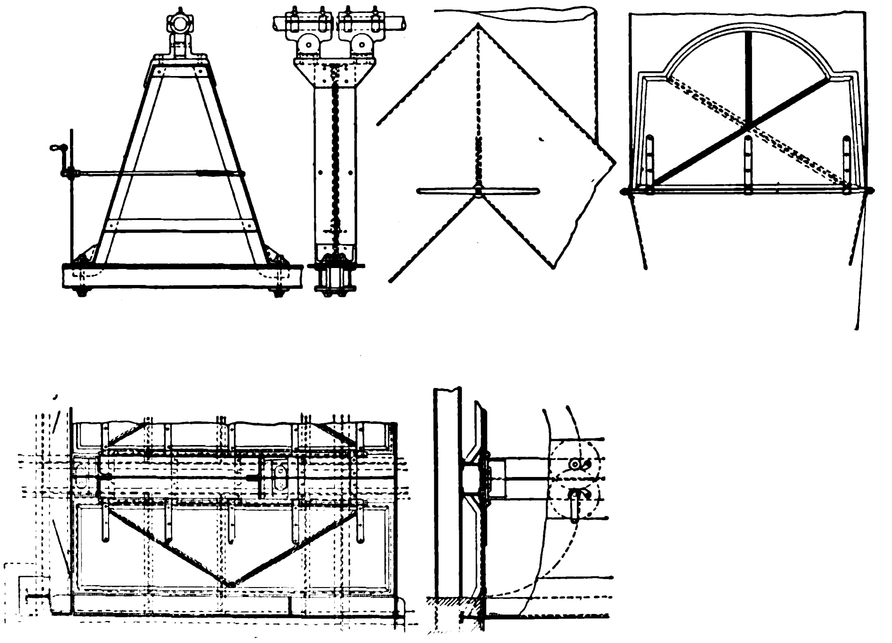

FIG. 7.—DETAILS OF DAMPER ARRANGEMENT, ELECTRIC RAILWAY PLANT.

The question of operating expense, which is the other factor in commercial efficiency, is most largely dependent upon the cost and character of the fuel; although the fixed charges are of only secondary importance. The value of a coal is not to be judged alone by its cost per ton, but by the number of available heat units which can be obtained for a given price. In this price should properly be included the transportation charges, the expense of getting the coal into the boiler house and putting it into the furnace, as well as taking out and carrying away the ash.

As the cost of transportation is practically dependent upon the weight and independent of the character of the coal, the proportional difference in price which may rule at the time may be almost extinguished when an equal charge is added for the transportation of each. Thus, a No. 2 buckwheat may prove an economical fuel at the mine where it may be purchased at 25 cents per ton. But its efficiency is so low that at a distance from the mine it may prove to cost more per 1000 lbs. of water evaporated than a coal costing considerably more per ton. As a rule, however, with proper appliances and mixtures, the low grade fuels may be made to show good financial results when burned with mechanical draft.

Based on the cost of the coal and the firing, the following will serve to illustrate the economy that may be secured by burning a cheaper fuel of lower efficiency. In a certain plant equipped with horizontal tubular boilers and down draft furnaces, an evaporation of 8.5 lbs. of water from and at 212 deg. was regularly obtained. The coal was Illinois slack, costing $1.40 delivered under the boilers. This makes the cost about 8.3 cents per 1000 lbs. evaporated under these conditions. Had the best picked anthracite coal, costing $4.80 per ton under existing market rates, been used, and had it evaporated the generous amount of 12 lbs. of water from and at 212 deg., the cost would have been 20 cents per 1000 lbs.

In another plant consisting of three water-tube boilers of an aggregate of about 1000 h.p., there was burned with chimney draft a coal costing $4.00 per ton delivered, and it was found impossible to burn a low grade fuel. Upon the application of mechanical forced draft, the fuel was changed to a mixture as indicated below. The result of thirteen weeks run, during which the average power developed was 1562.36 indicated h.p., was as follows:

	Weight in Lbs.	Cost.
Dry buckwheat coal containing an average of 17 per cent. of dust or anthracite culm that would pass through a 3-16-in. square mesh screen......	1,613,217	$2,019.91
Dry dust or anthracite culm.	287,781	215.48
Low grade Cumberland........	170,983	313.11
	2,071,891	$2,548.50

This covers all coal used for banking fires at night and getting up steam in the morning. The average cost per i.h.p. per hour is .21 of a cent. The average actual saving resulting from a change in fuel amounted to $126 per week, enough to pay for the fan and its engine in about six weeks.

Fig. 6 serves to show a duplex induced-draft apparatus, which was recently installed in connection with the boilers of an electric railway power plant. The two fans, each driven by an independent engine, are placed upon the top of a brick chamber to which the gases pass from the economizers. An arrangement of dampers similar to that shown in Fig. 5 serves to control the discharge of these gases. The plant as at present installed consists of only three boilers of 200 h.p. each, although the draft apparatus is designed for twice that number—the eventual size of the plant. Each fan is of sufficient capacity to operate the entire future plant. The expense of a tall chimney and expensive foundations which would have otherwise been necessary, was avoided by the employment of the fans in connection with a very short stack extending just above the roof. Under the circumstances the draft apparatus does not, of course, operate at its highest efficiency, for all three of the present boilers are seldom used. Nevertheless, the advantage of instant response to sudden demands has proved the greater advantage of the mechanical method.

The average results of operation during a single summer month are given in Table II. The plant is usually started up about 5.15 a.m., and stopped at 12.15 a.m.

TABLE II.

AVERAGE RESULTS OF ONE MONTHS' RUN OF ELECTRIC RAILWAY STEAM PLANT.

Items.		Average for month.
Total time in operation	hours	569
Total coal consumed..........	pounds	415 591
Total ash....................	"	30,897
Total combustible consumed. 1	"	384,694

Average temperature of water entering boiler.......... . ..	"	242.7
Total electrical output	watts	154,165,(00
Average electrical output per hour	"	270,900
Equivalent electrical horse-power per hour.... . ..	"	363.1
Average coal per electrical horse-power per hour.....	pounds	2.12

In addition to the general economic advantages of mechanical draft which have been presented, there are those which relate primarily to the convenience of installation and operation. Prominent among these is the feature of adaptability. The fan, which is usually of steel plate, may be constructed in any shape to meet specific requirements; may be located as desired with regard to the position of the boilers and without expensive foundations; may be used for either forced or induced draft; and because of its portability may be relocated or exchanged for another of different capacity. In its operation the fan is perfectly flexible, may be run at high or low speed, independently of the chimney temperature, and is always susceptible of instantaneous change in response to sudden demands. A mere change in engine cut-off produces an effect only secured with a chimney by adding to its height at great expense.

External temperature changes have no appreciable effect upon the operation of mechanical draft, which, above all else, is independent of climatic conditions. The fan is a most important factor in smoke prevention, its value under such conditions being that which is due to the ability to continue the operation of a boiler plant when, without smoke prevention, its operation under stringent laws would have been impossible.

Briefly summarized, mechanical draft has here been shown to be capable of reducing the avoidable losses, of decreasing the first cost of a steam generating plant and of reducing the fuel expense. In addition, it presents certain marked conveniences in the matter of installation and operation.

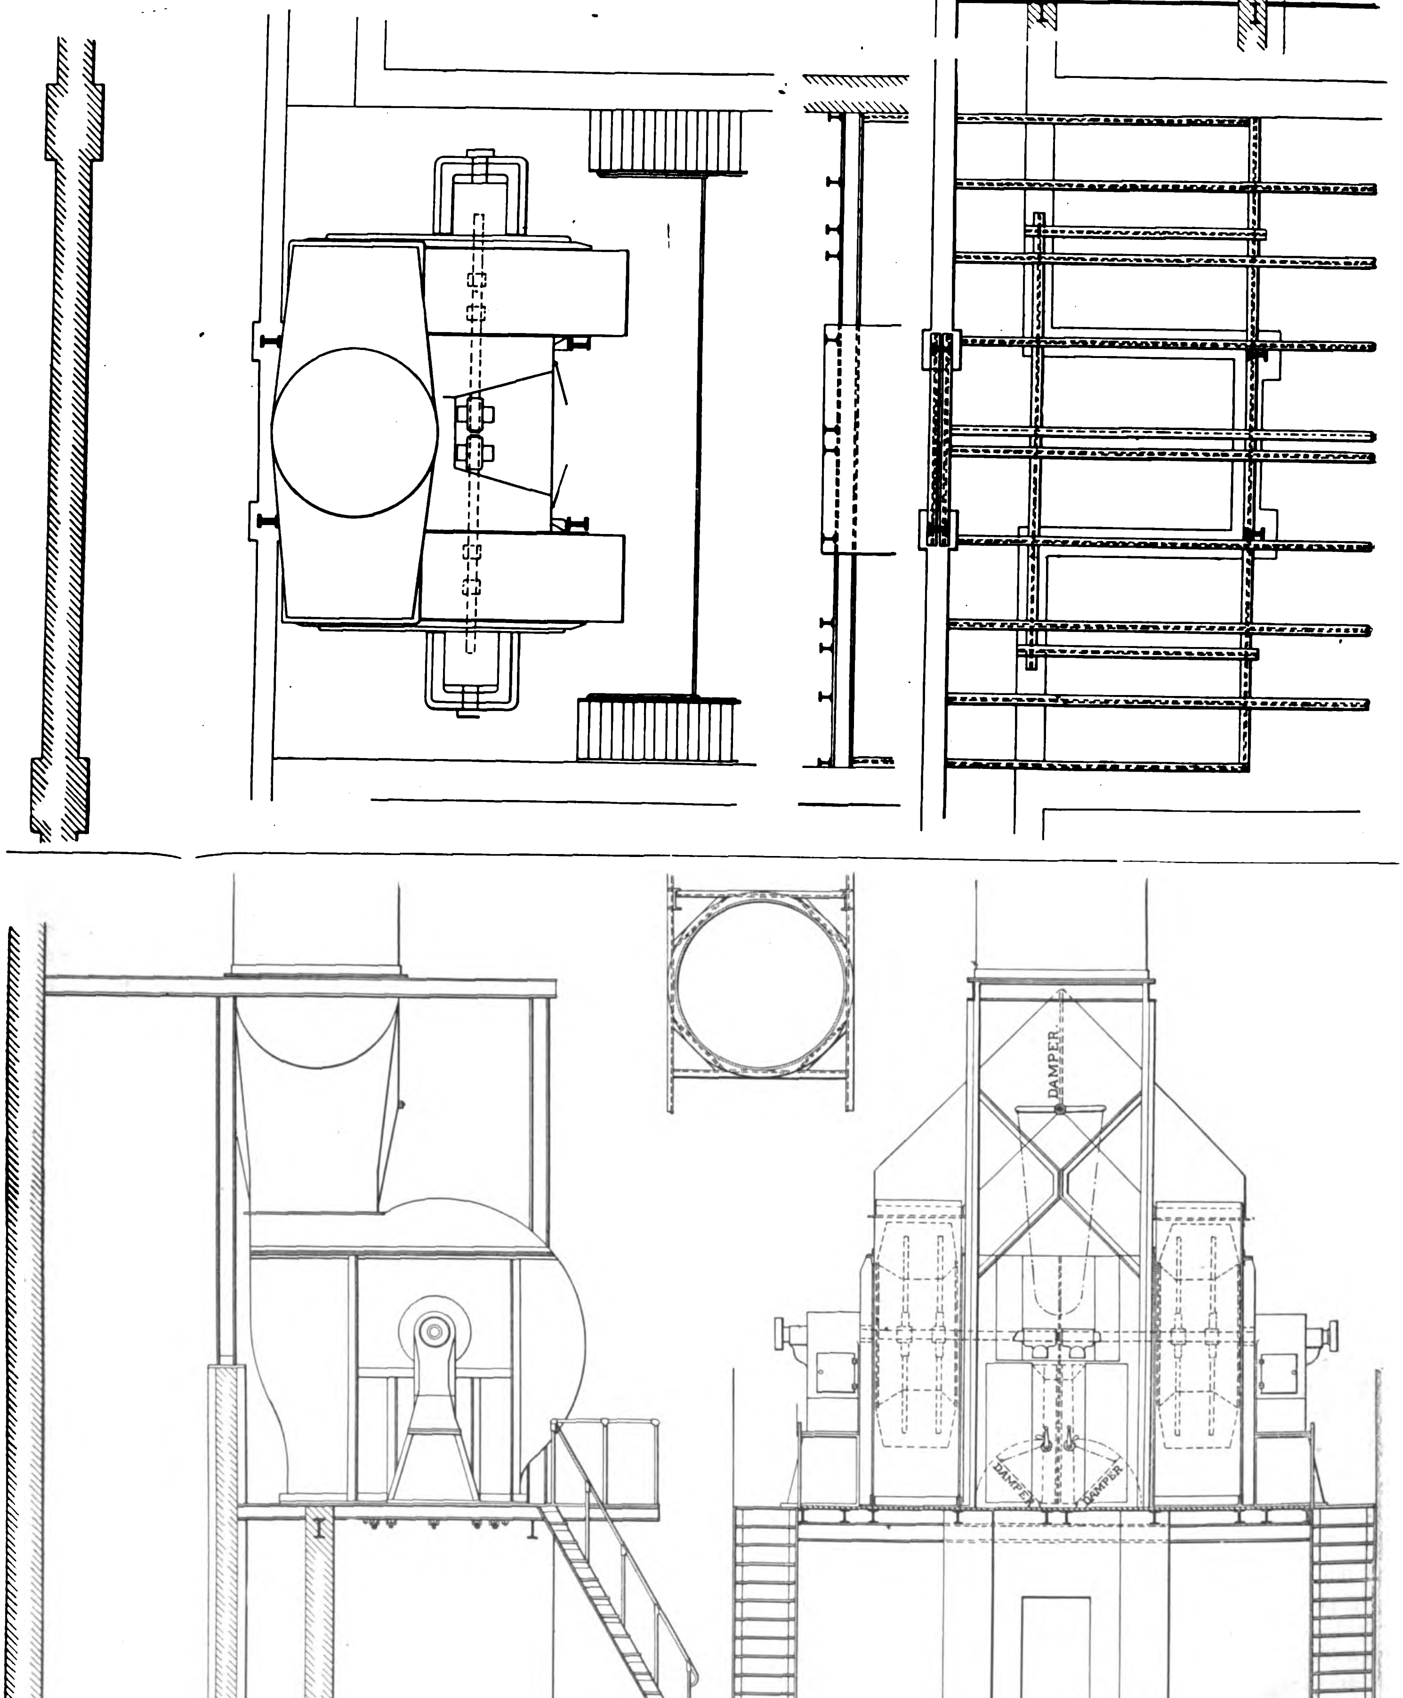

FIG. 8.—DUPLEX INDUCED DRAFT PLANT FOR ELECTRIC RAILWAY SERVICE.

In these days, when every step in the process of steam generation and utilization is being scrutinized in the attempt to reduce the cost by even a single per cent, the opportunity presented by the employment of mechanical draft cannot be, and is not, overlooked. The economical necessity was not so great a quarter of a century ago, when its advantages were first definitely realized by thoughtful engineers. And the future was first dimly discerned when, only fifteen years ago, Seaton referred to the chimney as a rough and ready but exceedingly wasteful way of inducing the air to flow into furnaces with sufficient velocity to cause the fuel to burn, and prophesied that it would some day be superseded by a more scientific and economical device.

THE 220-VOLT SYSTEM.

220-VOLT AND ALTERNATING CURRENT SYSTEMS.

BY PROF. GEO. D. SHEPARDSON.

In the last few years a large number of plants have been installed for lighting by incandescent lamps at 220 volts. Although the reasons for and against the use of high voltage lamps have been discussed to some extent in various papers, there seems to be some uncertainty as to whether it really pays to use the 220-volt lamps as made at present. This is a question that has two sides, and the present writer does not hope or intend to settle the question, but simply aims to clear up some hazy ideas that seem to be prevalent.

In brief, the main argument in favor of the use of higher voltages is the great saving in copper required in the wires and the greater distances that may be reached. The various points will be considered in detail later in the paper.

First, consider why less copper is required as the voltage rises, by simple calculations for a common case. Suppose that it is desired to transmit 10,000 watts to a point 1000 ft. distant with a loss on the line of 10 per cent. Calculate the size of wire and the weight of copper required for different voltages.

Suppose the energy is to be delivered at 100 volts; since the energy equals the product of current by pressure, the current may be obtained by dividing watts by volts; whence current is 10,000 divided by 100, or 100 amps. The resistance of the line is found by dividing the drop on the line by the current; the loss is to be 10 per cent, or 10 volts; whence the resistance is 10 divided by 100, or 0.1 ohms; since the total distance out and back is 2000 ft.. the wire must have a resistance of half the above, or 0.05 ohms per 1000 ft.; reference to a wire table shows that the nearest size wire is No. 0000, having a resistance of 0.049 ohms per 1000 ft. The table also shows that 2000 ft. of this wire weighs 1240 lbs. if bare, or 1460 lbs. if covered with "weather-proof" insulation.

Next try the effect of raising the voltage to 110 volts instead of 100. Following the same method of calculation as above, the current is found to be 91 amps., the drop on the line 11 volts. Size of wire No. 000, weighing 1014 lbs. if bare, or 1176 if weather-proof. It is thus seen that by using lamps at 110 volts instead of at 100 volts, the same amount of energy can be delivered with the same loss on the line, although the weight of copper used in the line is 226 lbs. less if bare, or 284 lbs. less if weather-proof insulated. In other words, by raising the voltage 10 per cent we have saved 18.3 or 19.5 per cent of the copper. This is on the assumption, of course, that the lamps in the second case are suitable for the higher voltage and are of equal efficiency.

By sending directly to the lamp makers we could even get lamps for 120 volts equally as good and efficient as those for 100 volts, so let us see what saving would be effected by using 120 volts at the point of delivery. The current is 10,000 divided by 120, or 83.5 amps.; the drop on the line is 10 per cent of 120, or 12 volts; the resistance is 12 divided by 83.5, or 0.144 ohms, which requires No. 00 wire. This will weigh 804 lbs. bare, or 952 lbs. weather-proof. By using 120 volts instead of 100, we have thus saved the necesity of buying and erecting 32 per cent of the bare copper, or 35 per cent of the insulated wire.

If so much copper can be saved by increasing the voltage only 10 or 20 per cent, the question at once arises, Why not boldly double the voltage, or even go even higher? Hopkinson, Edison and others answered the question by evolving the "three-wire system," which is practically two two-wire systems coupled in series so that the common wire is the positive side of one and the negative side of the other. The voltage between the two outside wires is thus twice that of either dynamo and the energy is transmitted at double the voltage of either. By the use of the common or "neutral" wire, the lamps on each side get their proper current at the proper voltage as if the other side were not in existence. The three-wire system requires three wires and two dynamos, and moreover is or has been controlled by one company. Competitors have been driven to some substitute or else pay royalty. The two competitive methods are the 220 two-wire and the high-tension alternating system.

Consider the saving of copper effected by the three-wire 110-volt or the two-wire 220-volt system, as compared with the 100-volt.

For delivering 10,000 watts at a point 1000 ft. distant with 10 per cent loss as before, but using 220 volts, the current is 45.5 amps.; the drop is 22 volts; the resistance of the wire is 22 divided by 45.5, or 0.484 ohms; this requires a No. 4 wire, which weighs 250 lbs. bare, or 320 lbs. insulated. This means a saving of 988 lbs. bare, or 1140 lbs. insulated; or 79.7 per cent bare, or 78 per cent insulated, as compared with the 100 volt system. Comparing it with the 110 volt system we have a saving of 762 lbs., or 75 per cent of the bare wire, or 856 lbs., or 73 per cent of the insulated wire.

For the three-wire system there is required a third wire that is either the same size as the outers or one-half their size, according as it is one of the distributing mains or one of the feeders. The principal objection to the 220-volt two-wire system is that the 220-volt incandescent lamp requires more energy for the same amount of light than does the 110-volt lamp.

The principal competitor of the systems named above is the alternating current system using high potentials for transmission and transformers which reduce the voltage for distribution and use. The voltage commonly used for transmission has usually been about 1100 volts for transmission and 110 volts for distribution. To compare the amount of copper required for transmission at 110 and at 1100 volts, we may calculate as in the preceding examples. Ten thousand watts would mean 9.1 amps. at 1100 volts; 10 per cent loss would mean 110 volts; to carry 9.1 amps. 1000 feet and back with a loss of 110 volts requires a line with a resistance of 12.1 ohms, which would be a No. 18 wire; this would weigh 10 lbs. bare or 22 lbs. weather-proof. Thus by transmitting at 1100 volts with the same loss as with 110 volts, we save 1004 lbs., or 98 per cent. of the wire if bare, or 1156 lbs. or 98.1 per cent of the wire if weather-proof. As good engineering practice would not allow any wire smaller than No. 10 to be used for pole line work, unless hard-drawn, we would not use the small wire indicated. Calculating the loss incurred when using the No. 10 wire, we find that it has a resistance of 1.0 ohm per 1000 ft.; therefore, the resistance of the line would be 2.0 ohms, the drop would be the product of current by resistance, or 2.0 multiplied by 9.1, or 18.2 volts; which is 1.63 per cent of the 1100 volts. Allowing 5 per cent loss in the transformer, we still have 3.4 per cent loss in favor of the alternating system. The weight of the No. 10 wire would be 63 lbs. bare or 102 lbs. weather-proof insulated.

Combining the above results in a table for easier reference, we have:

WIRE FOR DELIVERING 10,000 WATTS 1,000 FEET AT 10 PER CENT LOSS.

Volts delivered	Size wire.	Weight of wire.	
		Bare.	Weather-proof.
100	0000	1240	1460
110	000	1014	1176
120	00	804	952
220	4	252	320
1100	18	10	22
1100	10	63	102

From the above case it is seen that the saving in wire required by the 1100-volt transmission would more than pay for the transformers, when compared with the 110- or 120-volt system, and would go far toward it when compared with the 220-volt system. When the distances approach a mile or more, the comparison is far more in favor of the alternating system.

Having now seen why engineers prefer to use high voltages when possible, let us note the arguments advanced for and against the 220-volt system by its advocates and opponents, without vouching for their accuracy.

Comparing the 220 with the 110-volt system, we hear:

(1) Less copper is required.

(2) Greater distances are within practical reach; hence

(3) The power plant may be in a more convenient location, and

(4) A larger district may be covered and more business obtained.

(5) The lamps are stronger, being about 20 c.p. instead of 16.

(6) The lamps give more steady light; hence

(7) The customers are better satisfied.

(8) The lamps do not blacken so much as 110-volt lamps.

(9) The lamps last longer; and hence

(10) The customers are still better satisfied and take more lights.

Comparing with the three-wire system, we hear:

(11) The wiring is simpler.

(12) There is no trouble from unbalanced load.

(13) The neutral wire being omitted, means less copper required.

(14) Only one dynamo is required instead of two; hence

(15) The first cost of machine is less; also

(16) The dynamo is more efficient than two smaller ones of equal aggregate capacity; also

(17) Less space is required in the power house; and

(18) The one machine requies less attention and less repairs than the two.

(19) The system is not controlled by one company; hence

(20) The purchaser has the benefit of competition and lower prices.

(21) Arguments 5, 6, 7, 8, 9 and 10 hold equally true here.

Comparing with the alternating system, we hear:

(22) All the 220-volt plants claim to be making money, while most of the alternating current plants claim to be losing continually, having never paid expenses, etc.

(23) The 220-volt system gives better regulation; hence

(24) The light is better; hence

(25) Better satisfaction is given both to owner and to customers; hence

(26) The business builds itself up.

(27) The lamps do not blacken as with alternating (or direct) 110-volt.

(28) The lamps give more light, being more nearly 20 c.p. than 16.

(29) Arc lamps may be used indoors where alternating current arc lamps would be intolerable on account of their noise.

(30) Storage batteries may be charged without being taken to the power house.

(31) Motors of any size and of high efficiency may be operated without difficulty.

(32) The system of distribution is simpler.

(33) No loss in transformers.

(34) No extensive transformer repairs.

(35) Less trouble from lightning.

(36) Less danger from fire.

(37) No danger from shocks from high potential circuits.

(38) The all-day efficiency is higher; that is, the total watt hours delivered to customers is more nearly the total watt hours developed at the power house.

(39) If meters ars used, the low efficiency of the 220-volt lamp does not work against the central station man, since he gets paid by the watt-hour, and not by the lamp-hour.

(40) Bare wire may be user for pole lines in prairie towns and on streets without trees, thus saving much expense for insulation. The practice of running bare wires through the streets would not be allowable with high tension alternating currents. Hence a saving not only in first cost, but also in maintenance; hence, also,

(41) The wires on the poles always look well, not having any decaying insulation hanging from the wires.

(42) The 220-volt plants are simpler, hence less trouble to run; and

(43) Less expert help is required.

(44) One can always test his plant for efficiency without such uncertain elements as angle of lag, power factor, etc.

(45) There is no induction to disturb telephone circuits.

(46) The 220-volt dynamo may be coupled directly to the engine, thus avoiding the loss of from 2 to 5 per cent in the belting, which is nearly always used with alternators, except those of very large size. This saving largely offsets the lower efficiency of the 220-volt lamps.

Against the 220-volt system we hear other arguments, some of which are as follows:

(1) The 220-volt lamps are of low efficiency, requiring 55 to 80 watts when new, as against 45 to 60 watts for 110-volt lamps.

(2) The 220-volt lamps rapidly drop off in candle power.

(3) They gradually take more and more current; consequently

(4) The unproductive load becomes greater if charging by the lamp hour or flat rate by the month; or

(5) The load quickly increases beyond the capacity of the plant.

(6) On account of the low efficiency of the 220-volt lamps, the lines will have larger drop than calculated; hence

(7) The watts lost on the line will be greater, or

(8) The lines must be larger for the same number of lamps on account of their inefficiency, thus losing a considerable part of the benefit from the higher voltage.

(9) On the same account, the dynamo and engine must be larger for the same lamp capacity.

(10) This increases the first cost of engine and dynamo from 10 to 20 per cent.

(11) The larger amount of energy demanded by the inefficient lamps requires the consumption of more coal.

(12) Any improvement in the 220-volt lamp must be equally applicable to the 110-volt lamp, so that the balance must continue to be against the 220-volt lamp.

(13) The 220-volt lamp costs about 25 per cent more than the 110-volt.

(14) The switches and other fittings must be special or extra good.

(15) The filaments of the 220-volt lamps are so slender that they cannot be used in a horizontal or inclined position without great risk of the filament drooping over and touching the glass bulb, thus breaking the lamp.

(16) The lamps cannot be used with key sockets with drop cords, for the filaments are liable to bend over and touch the glass when turning off the key.

(17) Many of the lamps explode when first put into service; thus

(18) Frightening the user and

(19) Causing increased cost for renewals.

(20) The 220-volt system is not so suitable for arc lamps as the 110-volt direct or alternating system, since four or more lamps must be run in series for economy.

(21) Four arc lamps in series on a constant potential circuit area are a source of constant trouble both to user and to station man.

(22) It is not practicable to use a single arc lamp on a 220-volt system without using an "enclosed arc."

(23) The enclosed arcs are not satisfactory for 220-volt circuits, since the current is so small that the largest part of the light comes from the arc rather than from the carbons, thus making a violet tinge that is not agreeable.

(24) It is not practicable at present to get an enclosed arc light of more than 1200 nominal c.p., which is too small for some purposes.

(25) It is not so easy to arrange incandescent street lights for economical operation from a 220-volt system as with the series alternating.

(26) A street incandescent system requires far more copper than a series alternating system.

(27) With street incandescent lamps on the 220-volt multiple arc system, it is not easy for the station operator to tell whether all his street lamps are burning, as it is with the series alternating with lamp board and ammeter.

(28) Stations equipped with modern alternating current apparatus are operating very efficiently, more so than the 220-volt plants, and are also making good earnings.

(29) A town can be equipped with an alternating current plant for less money than with a 220-volt plant, if the town is scattering, or is at some distance from the source of power.

The writer disclaims all responsibility for the truth of the arguments detailed above, but gives them as those used by the advocates of the different systems. He believes they are all true so far as they go, but his experience does not fully cover arguments 8 and 10 for the 220-volt system, or arguments 23 and 24 against.

Some remarks may well be added concerning some of the arguments. Of those for the 220-volt system, we may note that the truth of 5 and 28 depends upon the make of the lamps. The 220-volt lamps of two prominent makers give nearly 20 c.p., although marked 16; those of some other companies are about 16, some being as low as 13 c.p. when new. All of these drop off as they burn, so that in a few hundred hours they are no stronger than 110-volt lamps of the same age and rating.

The better regulation claimed in argument 23 for the 220-volt system should be taken with allowance when applied to well engineered modern plants. The noise of alternating current arc lamps mentioned in argument 19 is greatly reduced if the globe fits tightly against the lamp case so as to hold in the noise. With enclosed alternating current arc lamps the noise is hardly noticeable.

The difficulty of charging storage batteries from alternating current lines may sometimes be of importance, yet this difficulty is removed by the use of a rotary transformer. Small batteries may be taken to the power house and charged by the exciter. The alternating current has a compensating advantage in that it is possible to increase the volume of the current indefinitely by the use of a transformer which will reduce the voltage proportionally. Conversely, it is easy to get a very high voltage by the use of a "step-up" transformer.

Motors may be operated with success from a two-phase, or "monocyclic," or three-phase plant. In fact, for transmission of any considerable amount of power the alternating current is conceded to have no superior. For small motors, the ordinary single-phase current is quite satisfactory.

The loss in transformers and the necessary repairs from lightning and other burnouts is greatly reduced by the modern methods of construction and operation.

The troubles of the telephone man are by no means all traceable to induction from alternating currents. He can neutralize such induction by careful arrangement and maintenance of his lines. In one city known to the writer, most of the telephone troubles from other currents come from direct current plants that make some use of the ground in common with the telephones.

Referring to some of the arguments against the 220-volt system, we may note in connection with objections 9, 10 and 11 that the great saving in the investment of copper for feeders may more than balance the added cost of engine and dynamo and may also reduce the annual added cost of coal. The higher first cost of the 220-volt lamp is more than compensated by its longer life, although the high mortality in infancy (if we may so term the premature explosions that used to be more common than now) may offset this. The difficulty of the filaments touching the glass when lamps are used in horizontal or inclined positions may be diminished by so turning the lamp that the plane of the loop is vertical, in which position it is stiffer. Better methods of anchoring the filament have also reduced this trouble.

One of the great advantages of the alternating system is the ease of raising or lowering the voltage by the use of adjustable transformers or boosters. To be sure, the motor and dynamo combination usuallv known by the same term accomplishes similar results, but at the cost of two moving armatures with the attendant care and expense.

Attention might be called to another point that is sometimes mentioned by advocates of the 220-volt system, "but secretly, for fear of the Jews"—namely, that the efficiency of the direct current 220-volt dynamo is higher than that of the alternating current machine. This may be true when comparison is made with the alternators of years ago, but hardly so with the late ones. Records of tests of recent alternating and direct current generators of equal output made by the same company show that for sizes above 50 k.w. the efficiencies of the two types of machine are practically the same. With the smaller machines the inefficiency of the small exciter has a larger effect and the total efficiency of alternator and exciter is slightly less than that of the self-excited direct current generator. The cost of machines of the same maker is also practically the same, except also that in the smaller sizes the exciter raises the cost of the alternator slightly.

W. I. Gray & Company, of Minneapolis, have kindly furnished the following figures showing the relative cost of certain plants upon which they have made bids for both alternating and 220-volt specifications. There is some uncertainty as to the exact basis upon which the specifications were drawn so far as relates to the calculated losses on the lines, but it seems fair to presume that they were upon the same basis in each case, so far as practicable.

For one plant with 60 k.w. machine, about 3600 ft. from the center of distribution, the bid for alternating system was $5100, while that for 220-volt was $5742, with belted generator, and $6242 with direct connected 220-volt generator. In this case, there was a difference of over 3000 lbs. of copper in the feeders alone.

Upon another and smaller plant in which the power house was 2000 ft. from the center of distribution, the bid for alternating system was $2195, as against $2435 for the 220-volt.

At another letting their bid for 220-volt system was $3396, while their two bids for alternating systems, not covering quite the same ground, however, were $3340 and $2858. Comparing two cases nearly alike, the wire for the 220-volt came to $1359, while the wire for alternating lines was estimated at $715, to which should be added about $380 for transformers, or a total of $1.095 compared with $1,359.

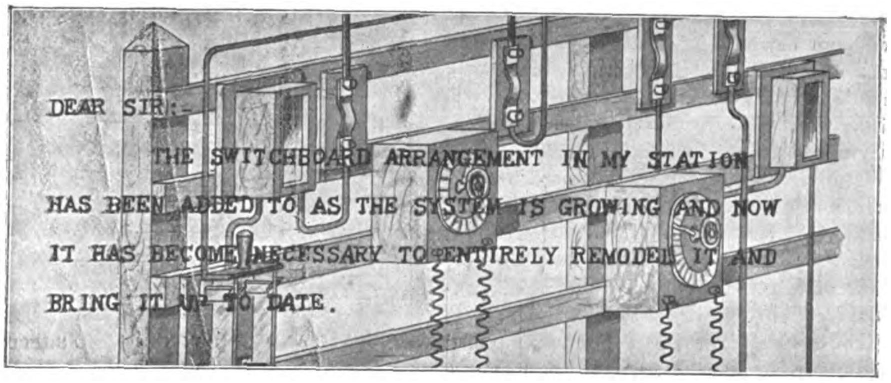
At another letting the bids of various parties for 220-volt plants were $9800, $9300, $9400, $9240 and $8485. The contract was let for an alternating system at a figure between $7500 and $8000.

The above figures are all exclusive of steam plant and building. They seem to indicate that for equally well made apparatus, the alternating systems are cheaper in first cost.

In the face of all that precedes, it should be remembered that a large number of 220-volt plants have been sold and are operating very satisfactorily. Moreover, they seem to be paying excellent dividends.

SWITCHBOARD RECONSTRUCTION.

BY ALBERT B. HERRICK.



DEAR SIR:—

THE SWITCHBOARD ARRANGEMENT IN MY STATION HAS BEEN ADDED TO AS THE SYSTEM IS GROWING AND NOW IT HAS BECOME NECESSARY TO ENTIRELY REMODEL IT AND BRING IT UP TO DATE.

The above is a type of letter I receive very often. The salient features and modern methods adopted in switchboard construction may be of general interest.

Where radical reconstruction is undertaken it should be borne in mind that it does not necessarily follow that the best position for the new board is where the old one was located.

In a small station where the engineer is also the dynamo tender, the valve of the engine, the commutator of the dynamo and the dynamo regulator and switch, should be so arranged that the engineer does not have to pass near moving belts or squeeze by the engine in order to reach them; in short, do not place the attendant under physical hazard if the right thing is to be done under all conditions of service.

The materials used in switchboard construction should necessarily be fireproof, as the conductors leading to the switchboard are covered with semi-inflammable material makes the switchboard a center to which fire will naturally travel.

Materials of a fireproof nature should be used for the support and insulation of the instruments and busbars. The skeleton frame of wood even when covered with asbestos paper or filled with the so-called fireproofing compounds has not been found to reduce the fire hazard enough to make their use advisable. Slate and marble slabs and iron verticals cost only slightly more, and insure a good mechanical and absolutely fireproof construction.

The use of slate and marble for this work would be universal if the constructor knew how easy it was to handle and drill the slabs. First, the switchboard is laid out and divided into slabs not larger than 4 ft. x 2 ft., as they are more awkward to handle and more liable to break when of larger size. In laying out, do not place the apparatus so that a number of holes for their support come on the same straight line, as the least pressure will crack the slab through this line of holes. If it is necessary to break the slab, the best way to do it is to drill a number of holes along the line of required fracture and then, by driving in taper iron plugs, the slate can be fractured.

The slate can be drilled by a twist or flat drill run at a slow speed, but be careful not to let it choke up with dust. Where the proper sized drills are not at hand, use a gaspipe having the outside diameter the same as that of the hole required, and file a set of teeth on one end of the pipe; if this is rotated slowly and fed emery powder and water, it will quickly cut a hole through the slate or marble. Always provide a support directly under the hole which is being drilled, so that no traverse strains are supported by the slate.

In the selection of slate, the uniformly colored brown or dark gray having a clean fracture will afford, as a rule, a good insulation; while the variegated variety and those having strong veins and metallic blotches should be carefully tested for their insulating qualities.

The supporting of the slate and marble boards are best done by steel angle or channel verticals. Figs. 1 and 2 show some of the methods of supporting. These slabs can be bolted directly to the verticals, but the precaution should be used to have washers between the slate and steel member at the points of support, so the slate will not be made to conform to a warped or irregular surface. Do not have these verticals carry any compression strains, as they often tend to bow, throwing an abnormal strain on the slate surface.

The bottom of the switchboard can be either on foot plates 16 ins. or 18 ins. high, or supported on pillars. There are split pillars made which surround the iron vertical, thus giving it a very neat and inexpensive finish.

The iron framework of the switchboard should be insulated from the ground where held on a cement or structural iron floor and in high tension switchboards this becomes very necessary. Fig. 3 shows one method where the vertical has an insulated footing on an iron floor member. Stone pedestals can be set in cement when this is used as flooring. This framework should also be insulated from the wall, which can be done by means of the insulated coupling and turnbuckle shown in Fig. 4.

The best location of the board is largely a matter of local conditions, and it is often advisable to use some of the later day appliances and instruments from the old board in the reconstructed switchboard, which will again modify the plans. The rheostat should have the preference as regards location, as it should be easily adjusted when the attendant stands in front of the board and can see the dynamo ammeter and voltmeter.

The ordinary practice is to arrange the dynamo switch at the bottom of the board, then the rheostat, then the voltmeter or dynamo galvanometer switch, then the amperemeter in the same vertical line for each generator.

The connecting together of the apparatus electrically should be done on the back of the board and following the above method of arrangement of apparatus gives the vertical method, the only horizontals being the busbars.

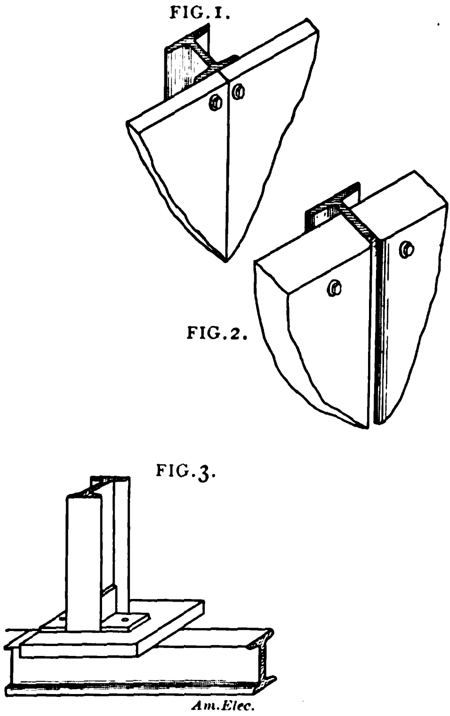
Where face connection switches have been used, these can be made into back-connecting switches when they are refinished, by drilling out the hole provided for the lug and tapping this out for a copper stud with a shoulder, and fitting it with a threaded nut on the front. This makes a stud connection like that shown in Fig. 5.

Where two copper conductors are secured together, use iron bolts and nuts for securing them, for the reason that when the conductors heat they expand faster than the bolts holding them, and thus increases the contact pressure and reduces the contact resistance.

FIG. 1.

FIG. 2.

FIG. 3.



FIGS. 1, 2 AND 3.—SWITCHBOARD SUPPORTS.

So far the constructional features have been common to both high and low-tension switchboards. The low-tension board will be taken up in those details especially pertaining to its construction. The busbars and vertical connections can be bare copper rods or bars if they are arranged so that each potential is on a separate vertical plane, making an accidental short circuit impossible. These busbars can be supported and insulated on cast iron brackets secured to the vertical iron members and pieces of marble placed on the bearing surfaces for insulation. Some of this construction is shown in Fig. 7, where a number of buses are used in multiple, and in Fig. 8, where only one bus is to be erected.

In low-tension work, where the current volume is large, the making of contact where the different conductors are to be connected together is one of importance, but the element of the truth of the surfaces in contact and the pressure of contact both play a very important part, as well as the metals that are brought together. Copper bus to copper bus, and 180 to 200 amps. per square inch in general practice. A thread with a nut forced on it which has a good fit will carry 160 amps. per square inch of thread area. A cable soldered into a lug if well soldered will carry 160 amps. per square inch. Switch blades carry, at a fair rating, 60 amps. per square inch available contact area. Commercial brass has about 22 per cent of the conductivity of copper. A copper busbar table is given below.

It is generally the aim in assembling to give the front of the board an appearance of neatness, but the backs of some of the boards I have come across are unfathomable mysteries in the maze of their connections. The back connections can be laid out with just the same simplicity as the front, if time is taken to make a creditable job. In order that the connections can be followed, it is usually the practice to carry all the positive connections to the right and above.

In three-wire work the neutral system is sometimes connected together at the dynamo, and a common neutral brought up for the feeders. This reduces the switches on the switchboard and saves one-half the weight of copper in the dynamo leads.

The equalizer in railway and isolated plants is often permanently connected at the dynamos, saving one-third, approximately, in weight of copper.

The ground returns run directly to the negative bus in this case, the positive or trolley bus only being connected to the feeders through the switch and circuit breakers.

In re-designing switchboards, it is often desirable in order to cover an expanding territory with the low-tension system, to supply feeders with different potentials during different periods of the load to compensate for the feeder losses, which may be due to too little copper or too great distance. If too little copper, the investment in further copper would probably be dictated by economical considerations, and the maintenance of the maximum economy of generation by still maintaining one potential. These matters are foreign to the present topic, but are touched on in order to show that to increase the bus potential of a constant potential system always increases the losses of that system and neutralizes the maximum station economy, which occurs at the same period, and these questions become very pertinent when re-designing the switchboard to cover future developments.

For two potentials double-throw switches can be used, which can be all thrown on the common bus when the current density on the copper system is too low; and the feeders can be thrown on the high potential bus when the loss in pressure is such that they cannot deliver the current at normal voltage at the mains.

A three-potential system can be devised by using a double-throw switch only, if the common bus is the one carrying the mean pressure; and by then grouping the inlaying, mean and outlaying feeders into three groups, they can be connected as shown in Fig. 9. This of course requires that three different potentials be delivered by dynamos or boosters; the dynamo board in this case would have to be provided with a three-way switch, which is generally made up of two double-pole double-throw switches.

Sometimes long isolated feeders are supplied with equalizers, or lamps of lower voltages are used on this service; but for general regulation of pressure, equalizers have long since been abandoned and more copper laid down to reduce the unbalanced pressure on the mains.

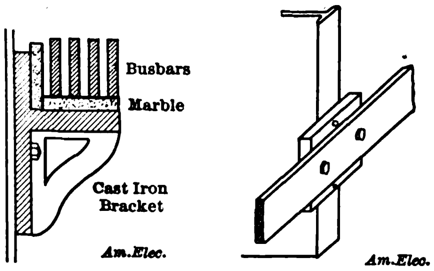

FIGS. 7 AND 8.—BUSES.

In order to determine the pressure on the mains, pressure wires are brought back to the station and connected to a pressure switch, and the pressure at the mains in this way compared either with the bus bar pressure for losses or a standard pressure for regulation. This switch places across the pressure arms from each feeder the voltmeter terminals. It is generally desirable to have a voltmeter for the standard feeder permanently connected in, and a separate voltmeter for feeder pressure. If the feeder pressure switch is conveniently located, enough additional terminals can be added for the dynamos, and it can also be used with the same voltmeter for throwing the dynamos on the system, in this way saving the investment of a dynamo pressure switch and dynamo galvanometer.

The field rheostat or regulator being mounted on the switchboard, requires that one leg of the field be brought from the generator to the switchboard; the other leg can be connected to the dynamo side of the dynamo switch, if self-excited, and the busbar side, if separately excited.

The dynamo can also be independently excited, and of the different methods the best to adopt depends entirely upon local and distribution conditions as they all have their friends. Another wrinkle is to so have all fields that they can normally be self-excited, and also independently excited from a separate generator, which normally operates on the system. The reason of this is that when a dead short comes on, the shunt generator flunks and refuses to maintain the potential to burn out the short circuit, and the field rheostats have resistance all out to make them deliver enough current to burn out the short circuit; when this does let go, the potential takes a jump that is liable to break the lamps. When this occasion does arise, it is very easy, where a double-throw switch is placed on the board, for each generator, to open the field wire and throw over and feed the field from an idle generator; in this way the excitation is independent of the armature reaction and all the generators can be held up to their load and be controlled by one rheostat.

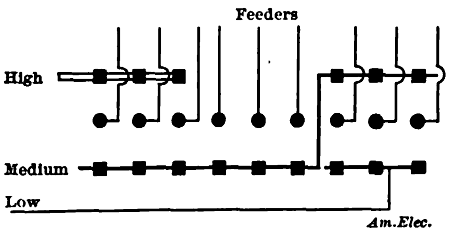

FIG. 9.—THREE-POTENTIAL FEEDERS.

There are a number of other useful adjuncts, such as pilot lamps for generators, alarms for open circuit breakers. In the case of compound generators where the equalizer is operated by a switch at the generator, if this is left open when the generator is thrown on the circuit, trouble will arise. A good practice is to have a double-pole switch at the generator, and to bring the equalizer, as well as one leg of the circuit, through this switch so the generator cannot be thrown in until this switch is closed.

In the three-wire system any dynamo can be used on either side of the system by means of a double-throw switch on the switchboard. Where the dynamo is also compound, the equalizer must also be brought to the switchboard and a triple-pole double-throw switch used.

Where an equalizer is brought into a switch used also for a dynamo switch, the terminal from the equalizer clips should be a trifle longer than the other clips, that the dynamo may be equalized before it is thrown on the system.

The reading of amperes at stated intervals and multiplying the average by the voltage does not give a figure in watts output which is reliable enough to figure the economy of the plant operation from. An integrating wattmeter inserted in the main bus, generally between the dynamo and feeder board, is very desirable where accurate records are to be kept.

Arc light switchboards involve but very little variation, and experience has shown that a flexible cable having its end terminating in plugs by means of which the different circuits are connected, gives the best satisfaction.

In the construction of these boards marble and slate should not be depended on, as the insulation for the terminals of the board at this point should be reinforced by, preferably, micanite or built-up mica. All bare conductors should be heavily taped or have glass or hard rubber tubes fitted or slipped over them, so the flaming arc which occurs when these circuits of 4000 volts is pulled, will not flare up and start a general flashing behind the board.

No matter how well the framework of the board or the flexible conductors are insulated, have a rubber mat or insulated flooring in front of the switchboard for the attendant to stand on.

Lightning arresters are sometimes placed on these boards, but it is not the proper place for them; they should be connected to the circuit on its entrance to the building and choke the discharge off to ground at this point, if possible.

Ground detectors and testing arrangements are generally also arranged on the arc light boards so that the circuits may be tested out each day for opens and grounds.

An ammeter should be provided for each circuit, and also polarity indicators, so that if the lamps are burning upside down the matter may be rectified, as the lighting of the heavens is not as a rule satisfactory to the city fathers.

UNDERGROUND DISTRIBUTION.

EUROPEAN METHODS OF UNDERGROUND DISTRIBUTION.

BY FRANCIS JEHL.

European electric light engineers, and especially those living in Germany, Austria or Hungary, often wonder why the Americans and the English employ and build such expensive underground subways, conduits, etc., into which to place their electric light mains and cables. Mr. E. de Fodor, one of the directors and chief engineers of the "Budapester Allgemeine Elektricitats Actien-Gesellschaft," and which company has about 270 kilometers of double armored cable simply buried in ditches, said to the writer some time ago: "It seems to me that Americans invest too much money and time in underground conduits and the like, and too little on cables. You build wooden conduits, iron pipe conduits, cement lined pipes, terra cotta ducts, brick subways, and, in fact, every Tom, Dick and Harry has a system of his own. You have over there perfected conduits, and we on this side have improved our cables to such a standard that we have found it sufficient to simply employ the old Edison method — that is, simply lay the armored cable in a ditch, giving it a good bed of washed sand, on the top of which common bricks are laid, which are a sufficient safeguard against picks, etc. By spending a little more money on insulation and armor such a cable does away with all kinds of ducts, etc., and as the protection and insulation is executed at the cable works, it is self-evident that it can be better performed there than work that is done in a street, as when building conduits. Besides, the protection and insulation of an armored cables takes up but a minimum amount of space as compared with the space occupied by a subway and its accessories."

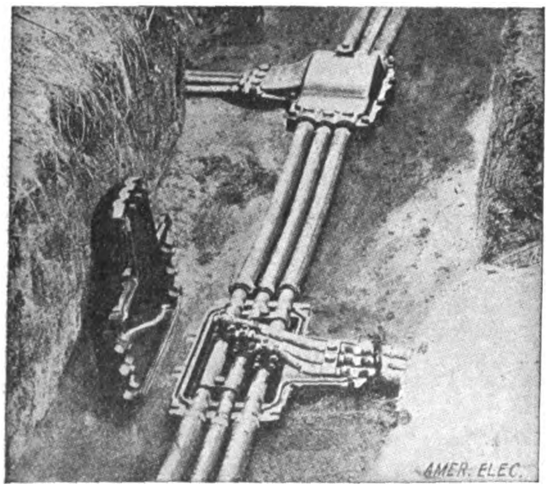

FIG. 1.—ELECTRIC LIGHT MAINS IN BUDAPEST.

Fig. 1 gives a good idea of the general practice here in Europe, and shows part of the electric light mains (three wire system) existing in Budapest. The cables are laid in a ditch dug under the sidewalk, which has a depth of 2½ to 3 ft., and is from 3 to 5 ft. from the house front. They are then covered with a layer of sand, on the top of which bricks are placed, which not only guard the cables against picks, but serve also as a warning to the excavator; and every laborer knows in this country (Austria) that when he comes or strikes on bricks that a cable is near by, and then takes extra precaution in working further.

The cables of the Budapest A. E. G. were made by Felton & Guilleaume, who have a factory there, and consists in this special case of a core of stranded copper insulated by their special composition, over which two lead sheathings are pressed; over these there is a layer of jute that is well impregnated with a sort of asphalt composition, and on this two iron bands are wound that serve as armor, while over the armor another layer of impregnated jute is placed.

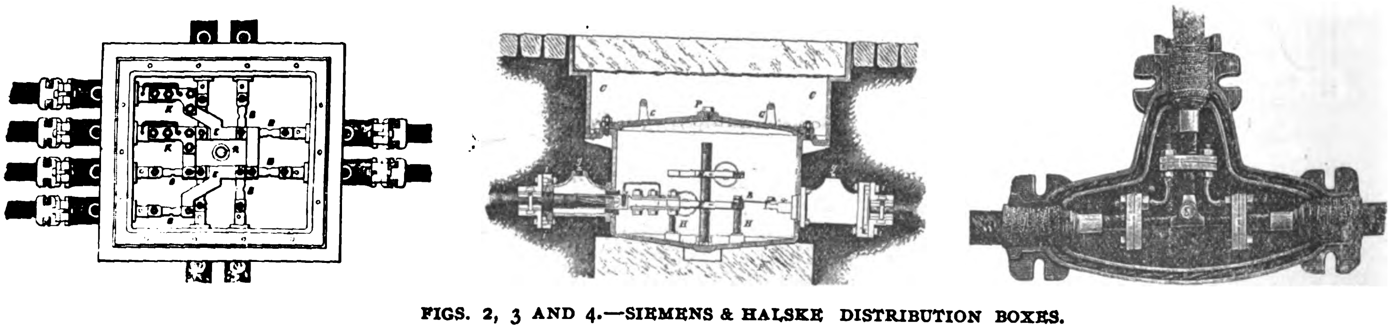
When considering the mechanical strength that such a cable possesses, and its high insulating qualities, together with the simple mode in which it is laid underground, there can be no doubt but that it will stand a lot of strain and hard usage, and that it is entirely self-protective; while on the other hand it gives us one of the best and cheapest methods of underground distribution.

Fig. 1 also gives us a view of two junction boxes, one opened and the other sealed, and it will be seen that they resemble those of the Edison system brought out in 1881. Another advantage in using cable is that it forms one long complete circuit, and does not necessitate a joint or connection every 16 ft. as in the old Edison system.

The distribution boxes at Budapest are generally placed on a solid brick foundation. Each of these boxes contains three insulated rings of copper which correspond to the three poles of the three wire system, and contains as many fuses as there are cables that enter it. The box is closed by a cover that is air and water tight, while access to it can be had by simply lifting an iron lid which is on a level with the footpath and forms a sort of manhole.

Siemens & Halske were among the first to construct lead and armored covered cables for electric light purposes, and their cables are in extensive use everywhere, and they, too, adopt the system of laying cables in trenches excavated under the sidewalk.

The Siemens & Halske system of underground distribution bears much evidence of careful design and study, particularly in matters relating to details. Figs. 1 and 2 represent one of their distribution boxes in plan and cross-section. Here the armored cables, which are simply buried in the ground, enter the box firmly clasped by means of small stuffing boxes that are bolted on to the main box, as seen. By means of the screw plug, g, insulating compound is poured into these boxes. It may be mentioned that this compound consists of waterfreed Swedish pine tar not containing any creosote, mixed with a heavy oil. Coal tar has not been found satisfactory for insulating purposes. The main box, which is shown in plan and cross section, is covered by an air and water tight lid (rubber packing being used). G represents handles, E E bus bars, K copper connections, B fuses, F



FIGS. 2, 3 AND 4.—SIEMENS & HALSKE DISTRIBUTION BOXES.

foundation, H H supports for the bus bars, while C is the pit covered by a flagstone. Joints and service connections are made as represented in Fig. 2, showing a concentric cable.

That armored cables are a success will be seen from the following table, which is a list of the cities that use the Siemens & Halske type:

Halske, told the writer that his firm considers the average life of their armored cable as 30 years, and that it reckons in all its estimates 1.94 per cent. of its cost as the yearly amount to be put aside in the redemption fund. Siemens & Halske have electric light cables that have been in the earth over 13 years, and they still show no signs of deterioration.

Fig. 5 will give a good idea how armored cable is laid in a ditch, and represents the laying of the high tension mains in Cassel, Germany. Mr. Hanns Scheinig, an engineer connected with Siemens &

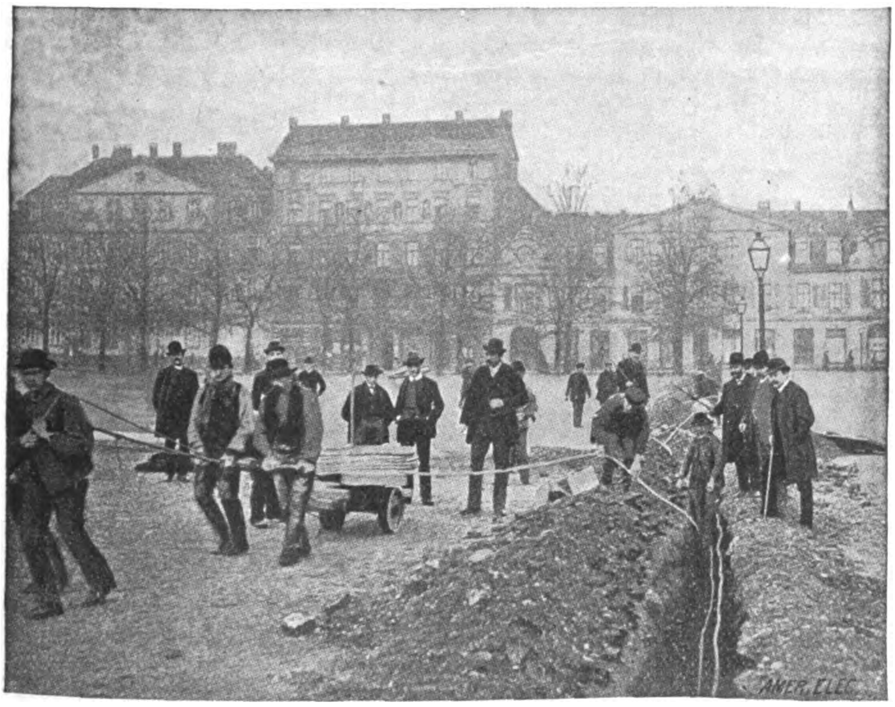

FIG. 5.—LAYING UNDERGROUND CABLE AT CASSEL.

Here in Brünn, where the writer is at present residing, there is in course of erection a three-phase station that will work at a pressure of 2,000 volts, and the underground mains are at present being laid. The cables are of the stranded conductor, three-core type, and are provided with two layers of lead and armor to make them self-protective. This type of cable is now a standard type, and made largely by Felton & Guilleaume.

The cable manufacturers, it may be mentioned, also undertake to lay the cables they deliver, and sublet the work of excavation to a contractor, who in this case (Brünn) has a gang of about 150 men, and with them lays and finishes about 4,000 feet (ditch length) of cable per day. The process of tearing up the sidewalk, digging the trench, laying the cable and then putting the street in order again takes but a few hours. Truly this method of underground distribution may be called a flexible-inflexible system. Armored cable can be laid or taken up quicker than by drawing in or taking out a cable or main from a conduit or subway.

The cable arrives from the cable factory wound on a large wooden drum, having a diameter of about 6 ft., the drum being strengthened by means of iron bolts, while its center contains a heavy hollow shaft. This drum as it comes from the railroad station is raised by means of a hoist attached to an iron tripod, and put on a low, heavy truck in a horizontal position. The truck is then taken and pulled by a gang of men to the distant end of the ditch, and here the cable is unwound from the drum and carried by the men (often as much as 60 to 70 men in a line) to the point of commencement, or to the end of the cable already laid.

Washed sand or sieved earth is then thrown on the cable to a depth of 3 to 4 ins., and on the top of this common bricks are laid, as shown in Fig. 6, where, a, represents the sand and, b, the brick. When the cable is laid in a street where there is a heavy traffic it is usual to lay also bricks *b*, *b* at the sides, as shown in the central view of Fig. 6. This precaution is also taken at all crossings, etc.

The Government or State here in Austria requires all cables that are laid in State roads (as distinguished from municipal or county roads) be provided or encased in a special conduit. In Brünn this extra protection is provided for at a few crossings, as shown in the cut to the right in Fig. 6, and consists simply of two U-shaped iron troughs bolted together, into which the cable just about fits, while two layers of bricks are sometimes used in this case instead of one. As there is generally only one or two Government roads running through a city, and as the cables are mostly laid under the footpath, there are only very short lengths to be taken in consideration where such extra precautions are necessary.

Fig. 7 gives a view in Brünn while laying polyphase cables. The wooden drum on which the cable is coiled, resting on the low, heavy trucks, is clearly seen in the foreground. The view represents a gang of men who are in a ditch and are hauling the cable across a roadway. The iron tripod to which the hoist is connected is also plainly seen in the background, and shows

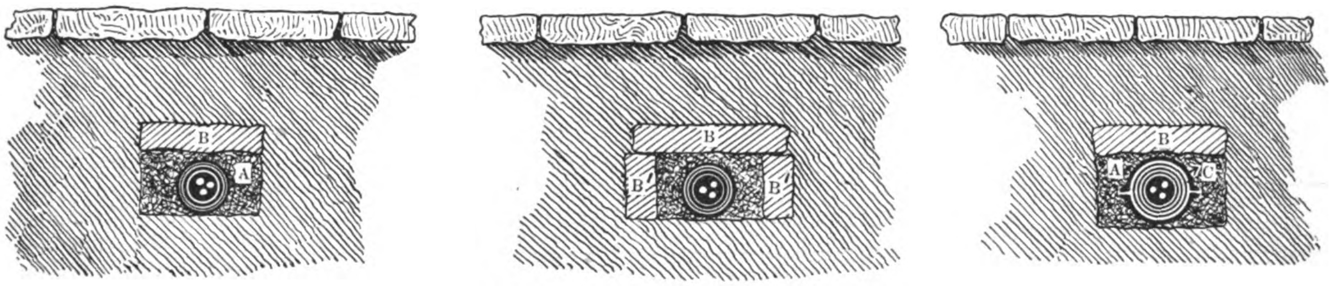

FIG. 6.—ARMORED CABLES IN THE GROUND.

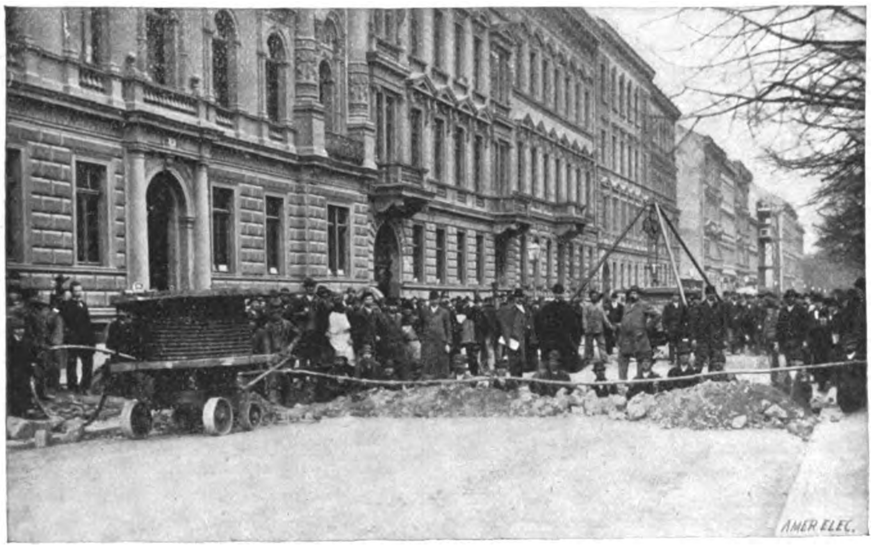

FIG. 7.—LAYING UNDERGROUND CABLE AT BRÜNN.

how the drum is hoisted on to the cable trucks. It may be mentioned that a heavy pin (the eye of which is seen in the picture) is inserted into the hollow iron shaft of the drum and keyed at the bottom; the hook of the hoist is then locked into the eye and the drum raised from the wagon that brought it from the railroad station and lifted, or rather placed, on the cable truck. The body of the cable truck revolves on ball bearings and with it, of course, the drum. Near the first lamppost in Fig. 7 will be seen two small smokestacks belonging to stoves that are placed on a small wagon, and serve to melt, or rather to heat up, the insulating compound that is used to fill up the junction boxes.

In Fig. 8 we have another view of the men hauling a cable in a ditch, and it may be well to notice the sieve and small mounds of sieved earth or sand that provides a comfortable bed and casing for the cable. Armored cable is never laid in such a straight line as pipes, conduits or ducts, etc., and this can be clearly seen from Fig. 5. Mr. Guiseppe Pagliari, who is the contractor laying the cables here in Brünn, remarked to the writer the other day: "See what a difference there is between the laying of light cables and gas pipes; here in Brünn I will lay about 23 miles of cable in about as many days, while if I had that length of gas pipes to lay with the same number of men I have now it would take over a year. Then again, with cable we can dodge obstructions; for instance, here we have just circled the manhole of a sewer which would have caused us lots of trouble if we had had pipes."

The International Company in Vienna, which uses high pressure, first laid its armored cables in simple wooden boxes, or troughs, lined with a coating of asphalt. The writer has, however, been informed that such boxes offer no protection, and decay in the course of four or five years and fall in. In Cologne the high pressure armored cables were laid in a wooden box suspended at intervals of about one meter by a sort of iron strap, after which the box was filled with a sort of asphalt compound, thus completely surrounding the cable.

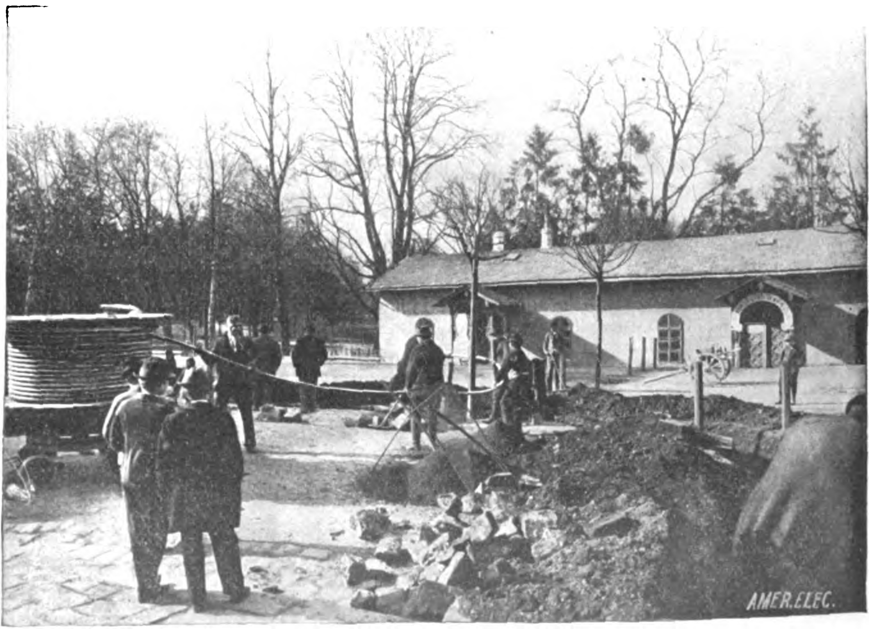

FIG. 8.—LAYING UNDERGROUND CABLE AT BRÜNN.

Fig. 9 gives a cross sectional view of this system, and it may be mentioned that the cable is of the concentric type, well armored. A German engineer told the writer lately that the above methods have been discarded, as the wood decays soon, and that the armored cables are now simply laid in the earth. The same may be said of other electric light companies in Germany and Austria, which also formerly built some kinds of concrete conduits and culverts, which, however, were found unnecessary to use with the high standard of armored cables manufactured to-day.

Fig. 11 represents a conduit that is used in connection with the Chevres-Geneva station. The conductors (bare copper) are laid in a concrete conduit that has a depth of about 12 ins. and a width of about 16 ins., while the flooring is about 30 ins. below the level of the soil. In this conduit the inside is first coated with an insulating compound of tar, after which the copper mains are stretched over porcelain insulators placed at a distance of about 2 feet from each other. The conduit is then fillled with an insulation compound of asphalt, which is poured in hot. Pilot and telephone wires are also laid in the conduit, as shown in the illustration.

In Fig. 10 is given a cross-sectional view of the conduit used in some parts of Zurich, and which consists of a stoneware trough placed beneath the footpath. The outer dimensions of the trough are about 7 by 7 ins. It is made in lengths of about 3 ft., which are connected together by cement joints. The protection of the conductors at Zurich consists of two lead coverings, and the cables are of the concentric type. After the cables are laid in the troughs they are covered with sand and further protected by means of a stoneware cover, which seals the conduit.

In Paris many of the cables are laid in the large sewers, while the Cie. Continentale Edison also employs a concrete conduit, as shown in Fig. 13. The cables laid in the conduit are generally of stranded copper, and supported upon porcelain insulators, as shown, which are held or carried by means of iron pins secured in the concrete. Armored cable is also largely used in France.

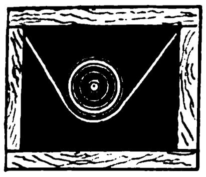

FIG. 9.—COLOGNE UNDERGROUND SYSTEM.

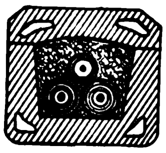

FIG. 10 —ZURICH UNDERGROUND SYSTEM.

In England opinion seems divided on the question of underground distribution, but there are many electric light stations that have armored cable simply buried in the ground. In fact, as may be seen from the data below, probably the majority of stations employ such a system. There are, however, many stations that have or use iron pipe, stoneware or earthenware casing or ducts. The following data were compiled by the writer from a statistical sheet published by the London Electrician:

Twenty-seven stations have armored cable simply buried in the ground and 46 have armored cable, but with no statement as to how it is laid; 28 have insulated mains in earthenware casing, pipes or conduits, and 22 bare copper in culverts, etc., the type not being stated; 48 have insulated mains in iron pipe, 7 insulated mains in iron troughs on the solid system, 6 insulated mains in iron troughs or conduits, and 13 insulated mains in bitumen casing or conduits.

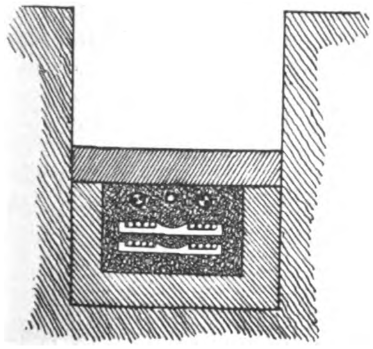

FIG. 11.—CHEVRES-GENEVA UNDERGROUND SYSTEM.

From the above it is seen that many English stations employ a mixed system, as some of the mains are simply buried in the ground, while others run through iron pipes or stoneware conduits, some stations having two or more kinds of underground distributions. It seems probable, however, that the item referring to armored cable should be classed with that relating to armored cables laid in the ground, in which case we obtain 73 examples, as it is not probable that armored cable is still further protected by laying it in pipes or conduits. The same is the case with insulated mains in stone conduits, etc., and bare copper in culverts; no doubt both these items belong under one heading as far as earthenware or stone conduits, culverts, etc., are concerned.

We thus see that in England armored cable also takes the lead, while the stoneware and iron pipe systems are about equally divided as far as systems go, and it would be interesting to obtain data regarding the relative lengths of these various methods.

FIG. 12.—DOULTON CONDUITS.

The advocates of armored cable all claim it affords the greatest security against gas explosions, electrolytic action (which sometimes takes place in conduit systems where bare copper is laid); nor is an armored cable liable to act as a drain pipe or be subjected to overflooding as in the case of a conduit system. However, it is just to assume that many of the so-called drawbacks of the conduit systems are more of a theoretical nature than anything else.

One thing which the armored cable men claim with justice is the ease with which they can lay the mains, as they can dodge all underground obstructions; while in building conduits or culverts in ground that is full of gas and water pipes, pavements undermined by coal cellars and the like, necessitates much work and expense.

Of the various earthenware conduit systems used in England, the Doulton type takes the lead, and much time and money have been expended in making this system a standard one. Over 40 electric light stations use the Doulton conduits, which speaks for itself, and there is no denying that this admirable system presents many favorable features. For feeders the advantage of the drawing-in system is a real one, as cables can be withdrawn and replaced by larger ones when necessary.

These conduits are manufactured of hard-burnt and glazed stoneware, and possess great strength and toughness; they are an insulator in themselves, are unaffected by heat, are proof against chemical action and gases found in the ground, and may be regarded as imperishable. As the interior surface of the ducts is smooth and hard, they present exceptional facilities for drawing in cables without any risks to the insulation. The ducts are generally laid under the footways at the bottom of a trench 12 to 18 ins. from the level, and in roadways subject to heavy traffic a depth of 3 ft. is usually adopted.

They are also laid near the surface on a bed of concrete, and this method is frequently used where the conduits are carried from pavement to pavement across roadways. The lengths are laid with a small space between them on shallow cast iron bearers, as shown in Fig. 12. A mandril with India rubber head is then introduced into each of the ducts, as shown, and when opposite the joint it is expanded by a few turns of the thumb nut at its end. A removable iron mould, open at the top, is placed over the joint, and then filled with a special rapidly setting bituminous cement, which hardens in two or

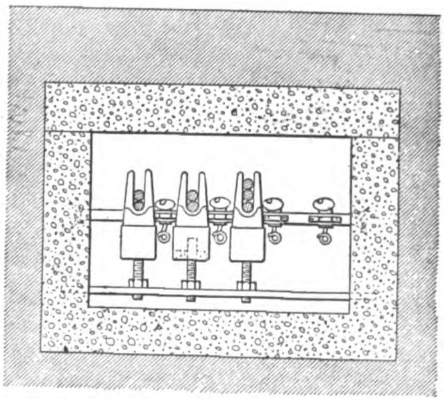

FIG. 13.—PARIS UNDERGROUND SYSTEM.

three minutes, when the mandrels are unscrewed and withdrawn and iron cover removed.

For house service connections a special split-length is used. Fig. 14 represents a system of house service boxes designed by Prof. A. B. W. Kennedy, and of which over 2,000 have been used at Edinburgh. The box consists of a short length of casing, the body of which is partly divided longitudinally in such a wav that the upper and lower portion may be easily separated by means of a chisel when required. The box is laid in the same way as the ordinary casing, or it may be subsequently introduced into the line of conduit, in which case it is substituted for an ordinary length, which may be removed at any required point. When it is desired to make a house connection both halves are removed from the line of conduit, and thus ample access to the cables is afforded.

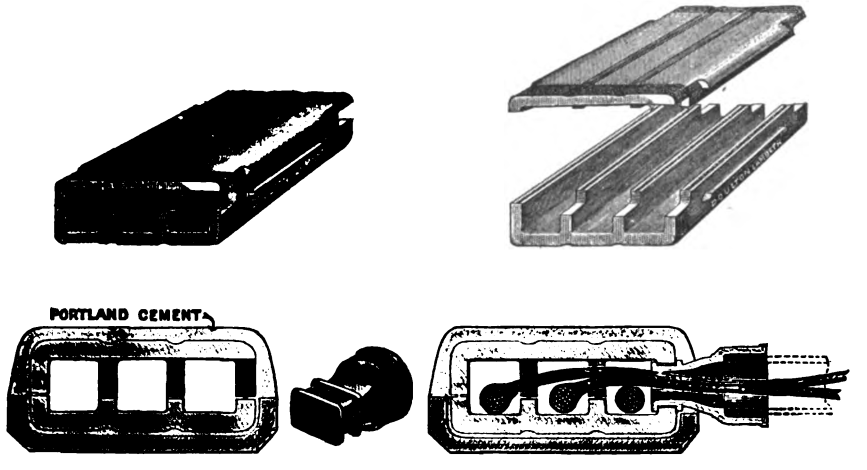

FIG. 14.—EDINBURGH SYSTEM.

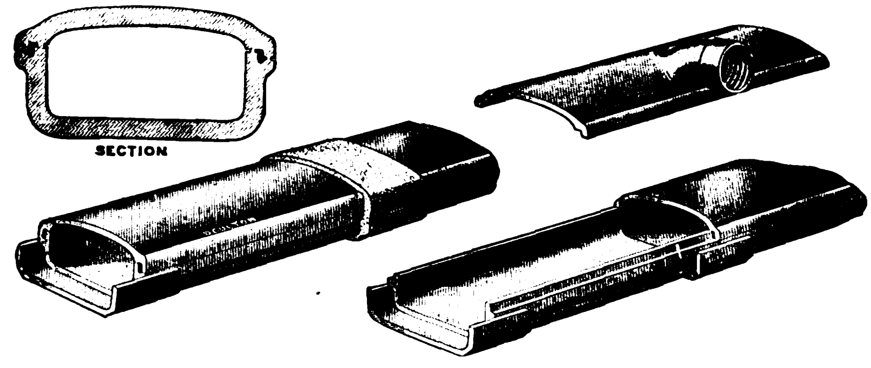

FIG. 15.—DOULTON SYSTEM.

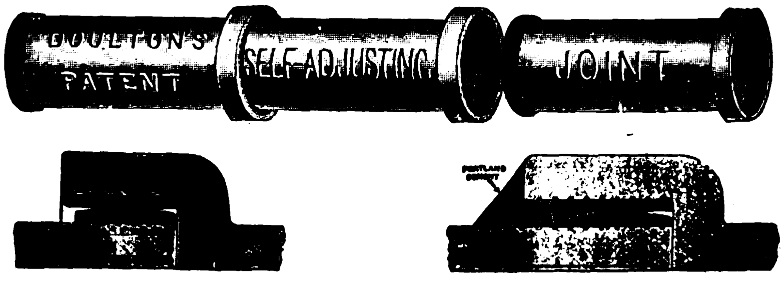
The cable connections having been made, the box is replaced, and in making the joints with the adjacent lengths of casings a special cast iron collar is used, provided with an outlet through which the branch cables are conveyed. When the casings are jointed with Portland cement the same type of box can be used, the slots at the end being enclosed within a cement joint, as shown in Fig. 14. When a house connection is required the upper and lower portions of the box are readily divided, and the cast iron connection socket shown inserted in the outer slot. The socket takes an iron pipe which leads into the consumer's premises. Another illustration of the Doulton conduit system is shown in Fig. 15, which explains itself. The ends of the lengths are laid on stone chairs and jointed with Portland cement, as already described. The conduit is supplied with cover attached, which can at any time be detached by means of a chisel and replaced by a special cover provided with socket for branch cables, as shown above.

Several cities in England have also the Doulton glazed stoneware pipes with self-fitting joints, as shown in Fig. 13, for underground distribution. The joint in the Doulton pipes is a sort of artificial "bored and turned" joint, formed by casting on the spigots and in the sockets of the pipes rings of a durable material, which, when put together, form a mechanical fit without the use of cement. The pipes can be laid very rapidly and the ground filled in at once. Many miles of these pipes are to be found in Manchester, Stafford, Oswestry, Leeds, Preston, etc. It may be mentioned that the joints admit of deflection without leakage. Glazed stoneware pipes are obtainable at a fraction of the cost of iron pipes. The lower part of Fig. 16 gives a section of an ordinary joint and also a section of a composite joint, the latter having an addition of an exterior fillet of Portland cement.

Of the various subway systems in use in England none surpass the Doulton type. This type has been adopted in many of the principal cities of England, and finds favor, as they are much cheaper than iron subway, their cost being about the same as concrete ones, while, on the other hand, they are made of an insulating material (glazed stoneware), and can be quickly laid. The subway is made in two feet sections, the ends of which rest on stone cradles, and are jointed by cement, as shown in Fig. 17. During the process of manufacture a recess is cut out of every third section, into which an insulator is set in pitch, as seen in the Fig. 17. The copper strips are then laid into the slots of the insulators and the subway covered with flags or slabs with rabbitted joints. The subway is placed under the footpath, and in some cities insulated cables in iron pipes are used when crossing a roadway.

Messrs. Laurence, Scott & Co. have also designed a very neat form of subway that is laid in Norwich and elsewhere in England, and which is claimed to be much cheaper than the concrete system. This system is shown in Fig. 18, and consists of highly vitrified porcelain insulators cemented in nicks cut into the socket end of an ordinary drain pipe, as shown at right. As will be seen, the projecting ends of the insulators form but a small contact surface with the pipe, and there is plenty of space for water to drain and for the copper to sag. For a 9-in. pipe there are five ducts, each of which will carry 1 sq. in. of copper, three being used for distribution and two for feeders. The pipes are bedded in and covered with cement for about 3 ins. to protect them against damage. The copper is not drawn until the conduit is finished, while only copper for existing requirements is put in place, as more can be added at any time by pulling out the top strip with a draw-in cable attached, and then pulling it back with the additional copper required.



SELF-ADJUSTING JOINT COMPOSITE JOINT

FIG. 16.—DOULTON JOINTS.

A manhole is placed at every change of direction and connected to the sewer by means of a special trap. The ventilation is effected by means of vertical pipes placed at the higher points and carried up the sides of neighboring buildings; or by ven-

LIBRARY

tilation cowls close to the nearest wall. The cost of a 6-in. subway laid complete under macadam roads, with 3 ins. of cement concrete all round, including manholes, 1½-in. pipe for pilot wires, is about $2.25 per yard, while the corresponding cost for the 9-in. culvert is about $2.88 per yard. The cost of drawing in copper averages 2 cents per pound.

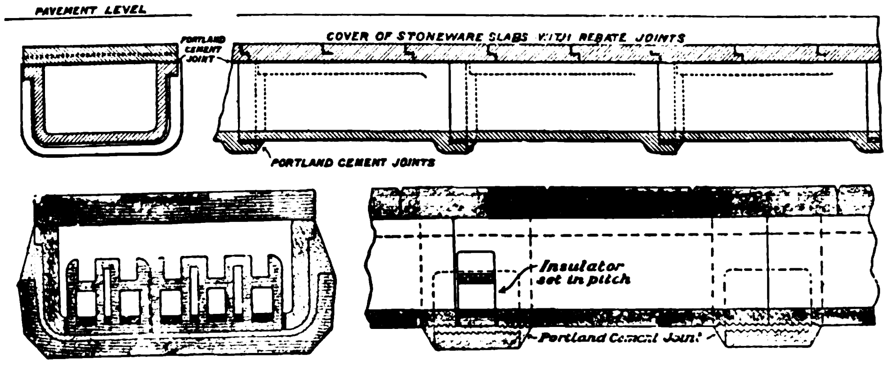


FIG. 17.—DOULTON SUBWAY.

The cost of a Scott 9-in. subway with the five ducts half filled with copper, 2¼ sq. in. section in all (copper at 16 cents per pound), is about $4.80 per yard. The cost of the subway complete, of drawing this copper in, and of connecting up, will come to $3.48, making a total of $8.22 per yard.*

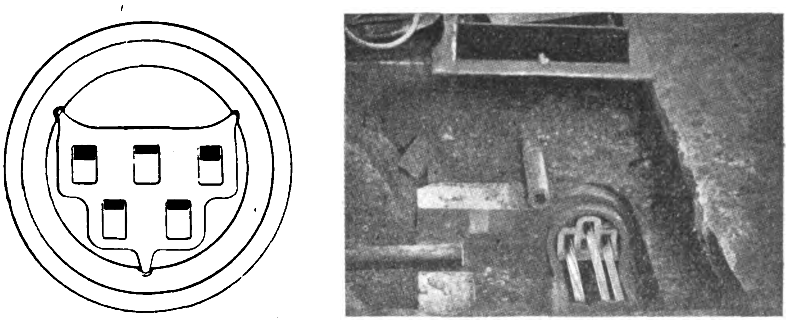

FIG. 18.—SCOTT SUBWAY.

Several cities in England use the Crompton conduit, which is made (in situ) of concrete and resembles the system shown in Fig. 13. In this system bare conductors are tightly stretched between porcelain insulators carried by cast iron bearers. The conduit is usually laid, or rather built, under the sidewalk, while at intervals of about 16 to 18 yards a manhole cover is placed, in order to take out service wires, and at intervals of about 100 yards large manholes are constructed that afford room for the workmen when drawing in or out copper.

The Westminster Company, of London, uses a concrete conduit designed by Prof. Kennedy, as shown in Fig. 19, which, it will be seen, is similar to the Crompton system. The bare copper conductors are here supported on solid porcelain insulators placed directly in the concrete flooring of the conduit. The manholes, etc., are placed at intervals as in the other systems already described.

TERMINAL BOX.

FIG. 20.—DETAILS OF BROOKS CONDUIT SYSTEM.

Many companies employ cables which are well insulated and possess lead coverings but not armor, and are simply drawn in cast or wrought-iron pipes laid under the pavement. At street corners, and at intervals of 80 to 100 yards, cast-iron surface boxes are inserted with the usual adjustable lids. Of the various iron pipe systems in use, none exhibit more careful design and thought than that made by Johnson & Phillips on the Brooks semi-solid method of underground distribution

In this system the copper conductors are covered with two helical bindings of fibrous material, impregnated with an insulating compound. The conductors are then drawn into iron pipes, which are afterwards filled with a semi-solid dielectric possessing high insulation qualities. This system comes under the class that is technically known as a draw-in and draw-out type, and appears to fulfill all the conditions that are required in high-tension circuits. Kapp, it may be mentioned, tested a line or main built on the Brooks system with 10,000 volts, and found that the line behaved much better than the testing transformer. This system is laid in Brighton, Chatham, Glasgow, Keswick, Rochester and Worcester, Great Britain, and in a large number of private estates.

The iron tubes, which have a length of about 15 or 16 ft. and are bell-mouthed at each end, merely require connecting together by means of the ordinary screw socket. As each successive length is added it is threaded over an iron wire, this wire being afterwards used for drawing in the steel rope for hauling in the cable. Every other length of tube is connected together by means of a T coupling closed at the top with an ordinary plug, the opening being required for filling in the semi-solid dielectric which, when heated to 300 deg. F., is quite liquid. When the line takes a bend, it is usual to use enlarging sockets and put in a tube one size larger than the normal. The tubes are connected up to cast-iron draw-in junction or terminal boxes when required. Fig. 20 shows a terminal box, junction box, joint box, draw-in and test box, and a service box.

The cable is hauled through the pipes by means of a winch, and roller guides are arranged where the cable comes out of a tube or box, so that the fibrous covering may not be injured by undue friction. After the cables have been pulled in and the joints made, the insulating dielectric is heated in cauldrons to about 400 deg. F. and poured into the tubes at the various points. It is of great importance that the whole of the air should be expelled and the tubes be perfectly free from moisture.

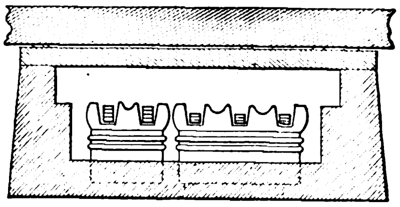

FIG. 19.—KENNEDY SUBWAY.

There can be no doubt that such a system has a long life, and the writer, who has had some experience with the Edison system (the type that was made in 1881), found that the iron pipe withstood the corrosive action of the organic acids that are sometimes found in the earth for over a period of 15 years. In Brünn he had a line about 1,300 ft. long, and after 13 years found that a portion under a crossing where there was always a heavy traffic, and consequently also a place where much animal refuse existed, tending to the formation in the earth of ammoniacal gases and saltpetre, the iron pipes were damaged and at some parts completely eaten away. The greater length of the line ran through a park and in clean earth, and here the tubes were still in good condition, showing no traces of deterioration.

---

*Taking the price of labor and conditions in England.

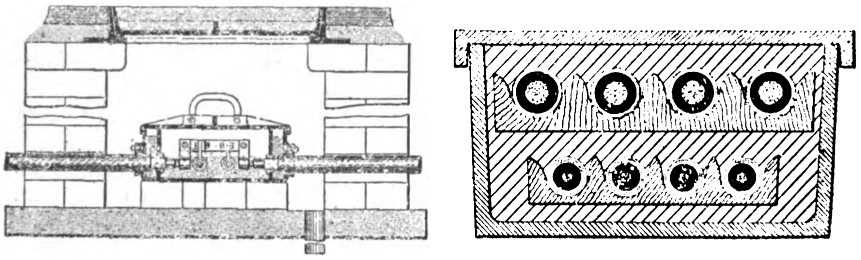

FIG. 21.—CALLENDER TROUGH SYSTEM.

It will be remembered that the iron pipes of the first type of Edison mains were not thick, and that later on stronger tubing was employed. The latter tubes will stand the damaging action in some kinds of earth much longer than those in the case cited above. The writer found that iron pipes wound or covered with a good layer of coarse jute cloth that is well impregnated with a thick paste of asphalt boiled in linseed oil, lengthened or increased their life about 5 or 6 years. The asphalt covering protects the iron against acids of the earth and lasts about the time stated before the iron is exposed at all to their action.

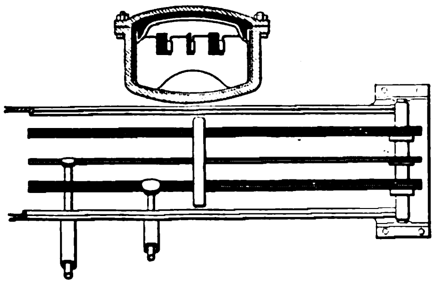

FIG. 22.—ST. JAMES AND PALL MALL COMPANY'S CONDUITS.

Other iron pipe systems are similar in many respects to the one described above, minus the filling-in part with heavy oil. It must be admitted that all such systems are to some degree complicated on account of the joints, etc., and the skilled workmanship required in the streets, where it is more expensive than in a factory.

Of the iron trough systems none is better known than the Callender solid system as shown in Fig. 21. In this system the insulated cables are supported by wooden bridges held firmly in a cast iron trough filled with Trinidad bitumen and covered by a cast iron lid. This system has given excellent results and seems to be able to exclude moisture well, while at the same time providing ample protection for the cables.

The troughs are in lengths of 6 ft. and laid under the pavement. The junction boxes and manholes all show careful design, but the system seems, on the whole, a very expensive one to employ. The Callender system is also employed at some places where the troughs are made from wood instead of cast iron. Iron troughs, it may be mentioned, are quickly and cheaply laid, but are objectionable on account of their high first cost and the possibility of short-circuiting or the occurrence of electrolytic action.

The St. James & Pall Mall Electric Light Company, of London, have some of their mains laid in iron troughs, a view of which is given in Fig. 22. The bare copper conductors are supported in this system by means of porcelain bridges held firmly in position and placed at intervals of a few feet. The troughs are covered by means of a well-fitting water-tight iron lid, which is secured by means of bolts and packing. Special precaution is taken concerning drainage, as water is apt to get in.

Another iron conduit system is the Johnstone, but of which little is now heard. no doubt on account of its first cost and the preference which now seems to be given to the earthenware systems already described. The Johnstone system consists of troughs made in sections so that a conduit of any capacity can be built, as shown in Fig. 23. At frequent intervals service boxes are placed, while at corners expensive manholes are built of iron. This system, like other iron trough methods, is open to the same objections as have been stated above.

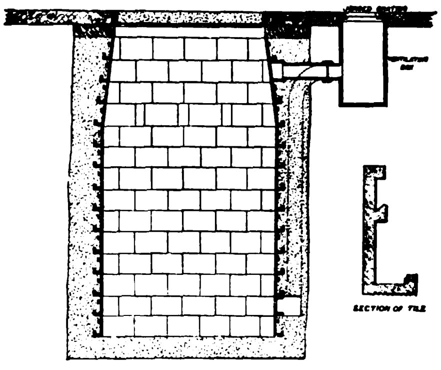

FIG. 23.—DOULTON TRANSFORMER SUB-STATION.

A few concerns have what is known as bitumen conduits or casings, which are generally made from bitumen or pitch concrete, moulded around mandrels and formed into tubular blocks. The ducts are jointed with a hot mixture of bitumen, and are exceedingly difficult to lay as regards alignment.

Having described the various systems of underground distribution used in Europe, it might be well to end with a few words on transformer chambers and pits.

In connection with Continental underground distribution, it is the general practice to place transformers, etc., above ground, in a sort of kiosk constructed of iron, and very similar to the newspaper kiosks seen on the Boulevards in Paris, which are accessible and permit easy inspection. Fig. 23 gives a picture of a kiosk of a kind used in Chemnitz, Germany, and made by Siemens & Halske. They are to be found in nearly all German cities and are about 13 ft. high and about 4 ft. in diameter. They rest on a solid brick or concrete foundation and consists of two chambers, the upper one of which contains the transformer and has three doors that permit easy access and inspection from all sides; the lower chamber contains the switches, fuses and cable ends and has one door.

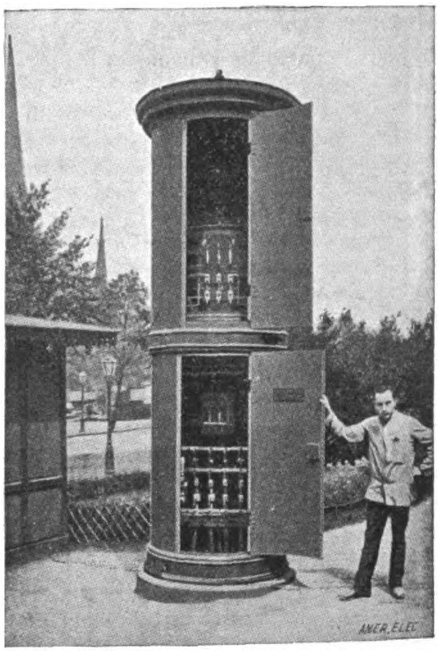

FIG. 24.—TRANSFORMER KIOSK.

These kiosks are self-ventilating, having a sort of open, bell-shaped roof that allows ample circulation of air, and yet so constructed that rain or snow cannot enter. This type of transformer sub-stations has proven very satisfactory, as they are not expensive, their maintenance costs hardly anything, and their form or appearance permit of any decoration that may be required to put them in harmony with their surroundings. It may be mentioned that such overground chambers are never troubled with water condensing inside, as in the case of underground chambers.

It is a common practice in England to build underground pits or chambers by erecting two walls, with a space between space filled with hydraulic cement or pitch. In some cases concrete pits are built lined with asphalt. Of late the Doulton system has been finding favor everywhere, and is generally adopted as a standard. Fig. 24 gives a sectional view of the Cockrill-Doulton pit, which is made of concrete and glazed tiles. By the use of such tiles, concrete walls are constructed without the aid of any wood or iron framing. The operation of building is performed by laying a course of tiles to form the face of the wall, and filling the space behind with soft concrete, the weight of which on the horizontal flange keeps the tile in a vertical position. This operation is repeated course by course. A glazed surface is obtained with fine joints in cement, so that on the whole it makes an ideal underground structure.

Walls built on this system are said to be monolithic, waterproof and durable. The ventilation is provided for, as shown in Fig. 24, by means of a box with hinged grating; it can also be provided by means of pipes ending in a grating standing against a wall about 10 ins. above the ground.

In conclusion, the writer desires to thank Messrs. Scheinig, Krugl, Goetz and Pagliari for the courtesy shown him in the preparation of this article.

ELECTRIC POWER ON WAR SHIPS.

ELECTRICAL POWER TRANSMISSION ON SHIPBOARD.

BY F. W. ROLLER.

The modern man-of-war, about which this article is mainly concerned, is, as is well known to the readers of this paper, a huge hulk of steel, dependent entirely for its propulsion, handling and fighting, on power generated within itself; the same being, almost without exception, coal burned in boiler furnaces.

Of course, the steam thus generated that is to be used for the propulsion of the vessel is best utilized by the main engines, usually two in number, which, owing to their size and steady load may be, and are, so designed by the use of multiple cylinders, high speed, high boiler pressure and other well known devices of modern practice, that a maximum of economy is secured.

The wisdom of this practice in view of the present state of the art cannot be questioned, but the operation of the various auxiliary mechanisms by steam-driven prime movers is another mattter.

To one not familiar with the facts of the case, the number and total power required by these auxiliaries is apt to be a surprise when first learned of.

Beside the usual feed, circulating and air pumps that would naturally go with a high pressure condensing installation, and the bilge, fire and flushing pumps, we have large ventilating fans, steering engines, capstans, hoists (both ammunition and for other work), apparatus for moving turrets, heavy guns, etc., etc., all of which are steam driven. These small engines are widely scattered throughout the ship, and in most cases require careful attention to keep them in order.

The question of conducting the steam to these and the exhaust away again is a serious matter. The steam pipes of all engines which might be used in action must be carefully protected in the best possible manner, not only because of their being so readily disabled by a shot and because of the difficulty of making any temporary or permanent repairs on such a pipe without great loss of time, but more particularly because the escaping steam would probably cause greater mortality in its compartment than the shot or shell which caused the break. The protection required is in a large measure gained by the course adopted of making the runs as far as possible below the protected deck. This, on the other hand, leaves them as a rule inaccessible, and further heats up spaces that are already far above living temperatures.

The inefficiency of these small engines is also great. In a man-of-war the points to be striven for are offensive power, defensive power, speed, and a large steaming radius. These are all inter-dependent and if, of a given supply of fuel, we are wasting a certain proportion in uneconomical engines, we are losers, not only by the value of the fuel, but by the decreased efficiency of the whole vessel.

The able paper read before the American Society of Naval Engineers by P. A. Engineer W. W. White, U. S. N., giving an abstract of the exhaustive tests made by him on the steam consumption of the various engines of the U. S. S. "Minneapolis," will give some idea as to how wasteful some of the engines are. Of course, in the case of the pumps, which are taking steam for the full stroke and running at a very low speed, the steam consumption would naturally be expected to be high, but when 250, and in one case 300 lbs. of water per hour are exceeded, even if less than of one h.p. is being developed at the time, the matter becomes graver. Even in the larger engines, like those for running the blowers, ice machine, dynamos, etc., where the average load is quite steady and the conditions favorable to fair economy, we find the water consumption running from 70 to nearly 110 lbs. per h.p.

Another point which prominently presents itself as against the use of small steam engines is the structural weakening of the vessel which they cause in many cases. Take the ventilating apparatus for instance. It is the usual practice to have two or three groups of large fans centrally located, and to lead the air to and from them through the various compartments by sheet metal air ducts often 4 to 6 square feet in cross section, which are carried through openings cut in the bulkheads for that purpose. Beside weakening them as above stated, this further introduces a large factor of uncertainty into the preservation of the other aim for which bulkheads are used—to obtain safety from sinking by the formation of water-tight compartments.

To be sure, automatic valves or shutters are used which are supposed to operate in case of flooding of the compartment, but there is some question as to their value. Where matters are such that it is still a matter of dispute between experts as to whether it would not be better to omit all openings whatever serving as a means of communication between compartments, sealing the present water-tight doors which are in plain sight, easily inspected and frequently tested, it becomes evident that such automatic valves in air ducts are still less worthy of confidence.

This difficulty could, however, be surmounted, provided that independent ventilating apparatus was employed for each compartment and the trunk air mains abandoned, but it has been decided that the increase in number of small engines thus necessitated would be the greater of the two evils.

From all the above, it will be seen that auxiliary steam engines have a minimum of good qualities, although even they have for most purposes marked advantages over hydraulic or pneumatic systems, both of which have been tested in small way.

An electrically driven installation would, on the other hand, seem to meet all of the objections raised. The units for the generation of the current would be amply large to give high economy with the use of the multiple-expansion high-speed condensing engines that would be employed, and they could all at the same time be located below the protective deck, like the main engines themselves, where they would be safe, and under constant observation by the expert engineer corps. It would be fair to assume from the results of data taken under modern practice that the efficiency of transmission from the cylinders of the dynamo engine to the point of application of the motor power would be such that the steam consumption per brake—not as in the case of the tests on auxiliaries cited, indicated h.p.—would average no more than 30 lbs., which is less than half of the best showing made by the steam engines, and less than one-tenth of the worst.

On the same test on the "Minneapolis'" engines that we are considering, the auxiliary engines were found to consume nearly 25 per cent. of all the steam generated or out of 5,200 lbs. of coal per hour, 1,300 lbs. were chargeable to them.

As the average steam consumption per h.p. hour of the auxiliaries was nearly 100 lbs., bringing this down to 30 lbs. by the use of electric transmission means a saving of 70 per cent of the fuel, or of the 1300 lbs.; 910 lbs., per hour, nearly 11 tons per day. It must be remembered that this is under cruising conditions where the load is comparatively light, and that the saving would be greater if the load were higher.

If electric motors are used, the objectionable heat and odor of corresponding steam engines for the work would, of course, be done away with, and the danger from burst or broken pipes also eliminated. We would further save largely in space, not only because of the much less bulk of the electric conductors, but because of their flexibility, which allows taking advantage of many breaks and recesses which a lagged steam pipe would have to jump over.

The motors themselves are also smaller and, more important, simpler, a single rotating piece being substituted for the numerous reciprocating parts, and they can be started, stopped, and, if required, reversed far more quickly.

In the use of electric transmission as above advocated, there is one arrangement which has never, we believe, as yet been used, which would seem to offer marked advantages and is as follows: In the first place, a number of the auxiliaries not only need never have their direction of motion reversed, but when in operation at all run at a constant speed. While the ordinary direct current motor would fill this condition admirably, the multiphase induction motor offers great advantages even over this, owing to its simplicity, unequalled among power generators, and its ability to withstand the roughest usage. In order to be able to utilize it, it is only necessary to add to the ordinary direct-current generator three or four collector rings acccording to the system selected, and take the current from there by stationary brushes in the well-known way and carry it to the motors. This would add only in the slightest degree to the complication in the engine rooom; certainly not enough to embarrass the trained engine room force, but will leave matters at the motor end, where unskilled men are often in attendance, in such absolutely simple shape that it would seem to be practically impossible to dearrange or disable the machinery.

Particular stress is laid on this point, as the writer has more than once seen even the simple direct current motors put out of commission in a few months' run, owing to improper brush setting and too rapid starting, both of which are impossssible with the induction motor.

In conclusion, the use of electric motors would not be experimental in any way, all of the apparatus that would be employed being standard material that is in everyday use all over the civilized world. Its advantages are manifest, and it is to be hoped that they will soon be recognized by the authorities and employed both for their own good and that of the profession.

THE MODERN STEAM ENGINE.

ECONOMICAL MANNER OF WORKING STEAM IN ELECTRIC POWER PLANTS.

BY PROF. WM S. ALDRICH.

Steam engines for electric power plants should be so designed and installed that they may be operated at any time under the most economical conditions consistent with the varied requirements of such electrical supply service. To-day the demand is heard on every hand for greater economy in operation, reduced cost of management and increased reliability of service. It is our present purpose to consider more particularly the increased economies to be obtained in the manner of working steam in the engine cylinders. This is the primary question. It is quite irrespective of the size of the plant or the character of the load. It is, therefore, necessary to understand the relative merits of the several possible methods of working steam in the modern power plant engines. Such an understanding will clear up many apparent difficulties. There will thus be established a rational guide, and the only safe one for central station managers and power plant engineers. Without it all else would be pure empiricism.

Central station men may have to decide between two almost equally good but rival methods of working steam; as, for instance, between compound and triple expansion engines, or between the use of jackets and reheating receivers in either case. Attention is again being directed toward the use of superheated steam, though the highest steam pressures have not yet been practically introduced, nor the corresponding available expansions all utilized. Nevertheless, the present day demand for greater economy in the use of steam must involve a recognition of the value of superheating.

There are questions of construction, of maintenance, and of subdivision of the steam motive-power into units requiring consideration, and which may serve to fix a reasonable limit to the pressure to be carried and the number of cylinders to be employed. Yet it is not a question of the number of cylinders alone, but of the number of expansions and of how many cylinders it is advisable to employ in order that the range of temperatures of the working steam shall not be too great in any one cylinder—that is, not more than 70° Fahr.

The question of the economic working of steam, on the other hand, is not altogether a question of high pressures, though this permits of two advances in the right direction—on the one hand a greater range of expansions, and on the other hand an increase of the temperature range within which the steam is to be used. The latter feature, however, may be realized by the use of superheated steam, but at the sacrifice of any economic gain by the increase of the number of expansions. Moreover, it will require a greater expenditure of fuel to superheat the working steam, say, corresponding to an additional 100° Fahr., than it would to raise its pressure to the temperature corresponding to this superheating. It is, therefore, quite probable that the American practice will continue to advance rather in the direction of higher steam pressures than of superheating, if it is only possible to provide for the increased strength required of all structural parts of the steam power plant.

If we look upon the steam engine as a heat engine, the conditions producing the highest efficiency of operation are high temperature of admission and low temperature of exhaust. No limit has yet been reached for the temperature of the admission of steam. But in no case is it possible, much less practicable, to push this utilization of the heat energy in the steam to its other extreme limit. That limit is early fixed by the temperature of the steam corresponding to its exhaust pressure and the highest attainable vacuum in condensing engines. While the high initial temperatures may be readily obtained by increasing the pressure of the steam or by superheating it at a lower pressure, it must be borne in mind that we are working with a condensible vapor in the first instance and a steam gas in the second instance highly sensitive to radiation losses. However, this is far from being the only dictum.

Experience has shown that the best economy is to be obtained only when there is no condensation of the steam due to the cylinder walls during its admission and expansion. That is, there must be no cylinder condensation throughout the stroke, and the cylinder walls must be dry at the point of release of the steam from the cylinder. These are entirely new conditions imposed upon the use of the steam in any case. All else about the steam engineering of the electric power plant may be as perfect as can be made by the refinement of modern engineering design, yet disastrous economical failure may await the operation of the plant from a mistaken notion of the unimportance of this question of moisture in the working steam. The additional heat in the superheated steam, therefore, gives us the second advantage in that the cylinder condensation may be quite fully counteracted, if not entirely obviated.

The two advantages of high pressure steam are an increase in the temperature range and a greater number of expansions. The two advantages of superheated steam are an increase in the temperature range and the counteracting of the cylinder condensation. We may combine these, it is true, by the use of superheated steam at a high pressure, and yet fail to obtain the highest efficiency and the best economy possible under practical conditions.

So far we have been examining the economic conditions imposed upon the use of steam only at the beginning of its cycle. Quite as important a relation has now been fully established respecting the condition of the steam at the point of its release from the cylinder—namely, the cylinder walls must be dry at the point of final release of the steam.

It is not to be expected that any reasonable amount of superheating of the initial steam will fully compensate for the cylinder condensation and other losses during its expansion to the point of release. There must be some external provision made for supplying the heat necessary to keep up the temperature of the cylinder walls and that of the working steam. This has been satisfactorily accomplished by steam jackets, either on the barrel of the cylinder or on its heads. Another method for supplying heat to the steam is that of the reheating receiver placed between the cylinders of compound engines.

If live boiler steam is used in the jackets as well as in the receivers, it will result in the expediture of a little heat, it is true, but in one of the most efficient ways yet discovered. The amount of heat is taken from the principal, but it results in a cumulative income. In no other way can a little extra fuel be expended to so great an economical advantage.

These guiding principles will be of equal service, whether applied to existing installations or projected power plants. Under any given condition, the criterion of economical working is that the cylinder wall should be dry at the point of release of the steam. The line of investigation is therefore backward rather than forward. What conditions will secure this in any given case?

In single cylinder engines, a little superheating of the admission steam combined with the use of steam jackets. In compound and triple expansion engines, a little superheating combined with the use of steam jackets and reheating receivers. In any case, if it is not possible to slightly superheat the admission steam, it must be delivered to the cylinder during admission as dry steam, and the cylinder walls must be kept sufficiently warm by a greater expenditure of heat in the live boiler steam and jackets. In the case of multi-expansion engines, however, it will be found especially advantageous to expend a large amount of heat from the live steam in the reheating receivers.

With reference to existing plants, for instance, an outlay for installing superheaters or economizers will be met with early and gratifying returns in the way of reduced coal bills. In fact, such an economic investment will be similar to that for non-conducting pipe covering; namely, it will probably pay for itself in the first year of use. Respecting reheaters, there is scarcely an existing plant that might not enjoy the advantages of these at slight outlay. If it is possible to raise the boiler pressure, securing higher temperature and greater range of expansions, it will even be found economical to take out existing high pressure cylinders and replace them by smaller but properly proportioned ones and install reheating receivers.

The conditions of electrical supply are so radically different in the isolated plant from those of the central station that it would really require a separate treatment. In the former the load is not so variable. The service is entirely local. It is largely made up of all-night electric lighting, combined with some day lighting, but more extensive motor and elevator service during that period. In the winter season the exhaust steam of the engines is required for steam-heating. This makes it very desirable to use non-condensing engines. The question of safety is more paramount in the isolated plants of department stores, office buildings and hotels, public and private buildings. Therefore, very high steam pressures are not to be recommended, however desirable from an engineering standpoint. We shall therefore confine this treatment to the economies indicated by best modern practice in the steam engineering of central stations for electrical supply.

Here the designing engineer has a freer range, but is confronted with more serious obstacles. It is the problem of equipment. This is not a question merely of sizes of units best adapted to the work in hand. It is rather a question of the selection of suitable types of motive power machinery, of accessories and of the appliances most conducive to economy, all of which are to be installed with due attention to the recognized economics of arrangement, and operated according to the now well-known methods of economic working of steam. A further analysis of this problem, as we have previously shown, leads to the primary question of the quality of the steam during admission and expansion and at the point of release. Indeed, all other things being equal, it may be said that it is that manner of working the steam which insures at the point of release dry cylinder walls, which is really the vital and determining factor.

From the condition of the steam which insures dry cylinder walls at the point of release, we may trace back the events and accompanying heat changes to the steam admitted to the cylinders in the first place. We shall find that a steam jacket on the low pressure cylinder will be conducive of greater economy, for instance, than if placed on the high pressure cylinder. Reheating receivers between the cylinders may also be found to be valuable adjuncts to the steam jackets. In the first case, the additional heat supplied by the reheater to the working steam is at that stage of the process when it is most beneficial; namely, in its passage from the high-presure to the low-pressure cylinder. In the second case, the heat supplied continuously by the jackets of either cylinder will be found to be of the greatest alvantage during the time of admission of steam to the cylinder; for even the unjacketed cylinder frequently shows a profitable heat interchange during the process of expansion when it imparts some of the heat in its cylinder walls to the expanded steam. Farther back than this, however, we shall find that it is quite possible to store such a sufficient amount of heat in the steam at the boiler that almost all condensation losses in the high pressure cylinder shall be prevented. This last consideration brings us to the question of superheated steam.

In American steam-boiler practice the degree of superheating that is reached is more frequently that due to the structure of the boiler itself than to any especial means provided for superheating. Almost all vertical boilers and several water-tube types will superheat the steam from 10 to 20 deg. F. Such are the standard types of construction adopted by nearly all makers of so-called superheating steam boilers. After the steam leaves the water drum it usually passes through a separate steam drum, or through tubes exposed to the hot gases and other products of combustion on their way to the chimney. This results in slightly superheating the steam and so far is an effort in the right direction. If engineers demand a higher degree of superheat, it will no doubt be provided by designs adapted to further utilize the heat of the chimney gases. Heretofore, practical defects in the design and construction of superheaters have resulted in their early abandonment, if they have not actually prevented their introduction.

Within the slight range of superheating of from 10 to 20 deg. F., there is scarcely any marked benefits. Superheated steam to be effective in increasing economy should have very much higher temperatures than that of the saturated steam from which it is formed. In fact, the superheating should be carried to such an extent (from 100 to 300 deg. above the temperature of evaporation) that the result is a true steam-gas. Of course, this cannot be effected in connection with existing devices. Such superheated steam cannot be formed in contact with the water from which it has been evaporated. The injurious effects of superheated steam on the cylinder walls, piston rods, valves and packing can now be more efficiently obviated than in the past. The question of lubrication at these high temperatures can be satisfactorily met by the use of mineral oils.

For some reason or other, builders of stationary engines generally prefer not to jacket their cylinders; however, they will do so to meet engineers' specifications. Many have experimented in this direction and have come to the conclusion, whether wise or otherwise, that the complications and increased attention required of cylinder jackets more than off-set the possible gain. In almost all cases in which jackets are used in compound and triple expansion engines, provisions are made for using live boiler steam directly or through reducing valves. This throws the efficiency of the jacket into the hands of the operating engineer. It will be seen, therefore. that conditions may arise in which the jackets will be positively detrimental, resulting in wetter cylinder walls at the point of final release of the exhaust steam than would otherwise occur without the use of jackets.

Partly to counteract the ill effects of cylinder condensation in the high-pressure cylinders and further to reheat (and possibly to superheat slightly) the steam before reaching the low-pressure cylinder, as well as on account of their practical operation being more conducive to economy than that of steam jackets, we find that reheating receivers have come into quite extensive use. Compound engines with efficient reheating receivers have repeatedly shown themselves to be almost as economical as triple-expansion engines working within the same limits of steam pressure and with the same number of expansions. This is not the only argument, however, for reducing the number of cylinders for electric light engines, for it has been determined by experience with variable loads, that the compound engines will meet these rapid changes with less reduction in economy than in the case of triple-expansion engines.

Moreover, the cross-compound condensing engine with reheating receiver is a type particularly well adapted to drive electric generators. The structural advantages are many, particularly of the horizontal type. All of the electrical equipment of such an outfit may be placed in one large generating unit mounted on the engine shaft between the two cylinders. In vertical types of compound engines this central mounting is not so desirable on account of oil and water drippings, so that the dynamos are preferably placed on the outside of the cylinders on the overhanging ends of the crank shaft.

The engineer can determine beforehand the probable economic performance of any proposed plant. In the case of pumping plants the duty can be so closely approximated that both parties willingly enter into a binding contract on such a basis. A subsequent contract trial serves to determine how far the installation satisfies the guarantee of a specific performance. The whole business of electric power plant design, construction, installation and management is in a formative period. It is, however, rapidly attaining its majority. The growth should be along recognized engineering lines, a careful predetermination of performance, a binding contract on this basis and a thorough trial for fulfilment of guarantees.

The electric plant, though operated in practice under extreme and rapidly-varying loads, may still have its economic performance guaranteed, contracted for and tested at certain specified and uniform loads. Such contract trials may be readily conducted without being made needlessly elaborate and expensive. It is only required to determine the electrical output at the switchboard, in kilowatt hours, for a given input of pounds of feed water or of heat units in the feed water. Extreme simplicity and a high degree of accuracy are attainable in making such measurements in electric power plants. Though the daily operation of the plant will be under widely different conditions from those under which the contract trial is made, still there is a possibility that at least the efficiencies, economies, guarantees and contracts now being realized in pumping stations should be much more nearly approached by the modern electric power plant. For beyond a thousand horse-power the variable charges become more uniform, notwithstanding the load variations which produce them.

A FACTORY POWER AND HEATING PLANT.

Among the recent additions to the list of electrical transmission plants is that of the McMullen Woven Wire Fence Company, which has just completed a new factory in West Evanston, Ill., for the manufacture of woven wire fencing. The plant comprises two buildings, a main factory building 540 ft. long by 110 ft. wide, and a power house 58 ft. long by 48 ft. wide. The power house is located some 40 ft. west of the main building, the intervening space being used for side tracks for receiving and shipping purposes. Coal is shoveled directly from cars into the coal-storage bins in connection with and made a part of the boiler room.

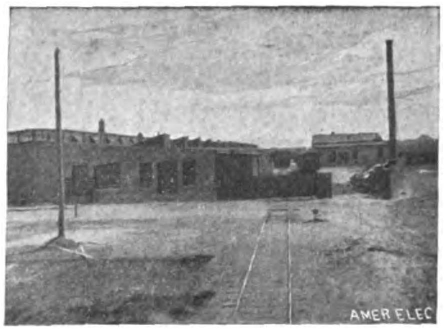

FIG. 1.—VIEW OF PLANT, SHOWING POWER-HOUSE ON THE RIGHT.

The power house is built entirely of brick, with an iron truss roof, and is divided into boiler and engine rooms. The engine room contains at present one generating unit and one ventilating unit used in connection with the heating system, together with all accessories. The generating unit consists of a 13-in. x 12-in. simple "Allfree" engine, directly connected to a 60-k.w. 120-volt "Excelsior" dynamo running at 275 r.p.m. The ventilating unit is composed of an 8-in. x 8-in. simple engine directly connected to a three-quarter housing, 120-in. bottom horizontal discharge fan, running at 225 r.p.m.

The engine room was laid out with space for another direct-connected generating unit for future expansion. Connecting the engine room with the main building is a tunnel 4 ft. wide by 4 ft. 6 ins. high, through which are carried the main steam supply and return pipes for heater stack, the mains leading from the switchboard to the center of distribution in the factory, and also the air discharged by the fan.

The boiler plant consists of two 66-in. x 18-ft. horizontal tubular boilers, fully equipped with all modern accessories, including "Roney" mechanical stokers. The latter, after a most severe test, have proved entirely satisfactory under all conditions of firing.

The chimney is self-supporting and of steel plate with a full lining of fire brick, having an internal diameter of 44 ins. and a height of 90 ft. above the grates. The general view of the factory and grounds, Fig. 1, showing power house in the distance, was taken with the plant in full operation.

The main building is of the ordinary mill construction with brick walls and roof and supports of wood. The large amount of window area makes the building very light at all points. At night the factory is lighted with twenty inclosed arc lamps manufactured by the Adams & Westlake Company, each lamp consuming 5 amps., with a difference in potential across the carbons of some 80 volts. These lamps have given excellent satisfaction throughout, giving a brilliant white, steady light. In addition, each machine is provided with a number of incandescent lamps for individual lighting, there being in all about 200 incandescent lamps.

The switchboard, which does not show in the cut of the engine room, is located about 3 ft. from the wall and a little west of the dynamo, it being intended that when

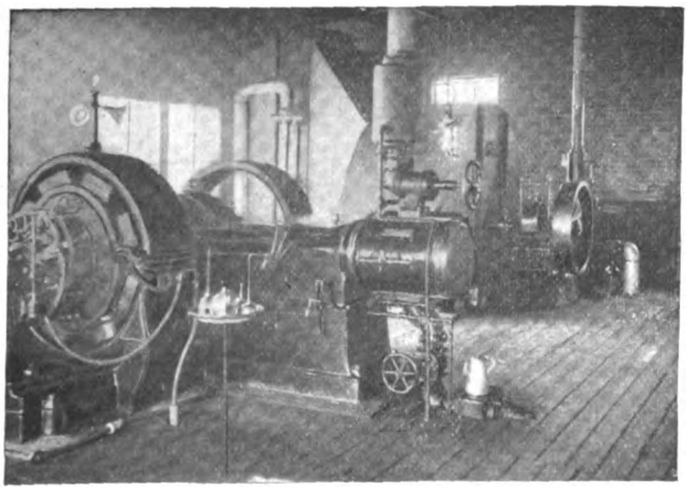

FIG. 2.—VIEW OF GENERATOR ROOM.

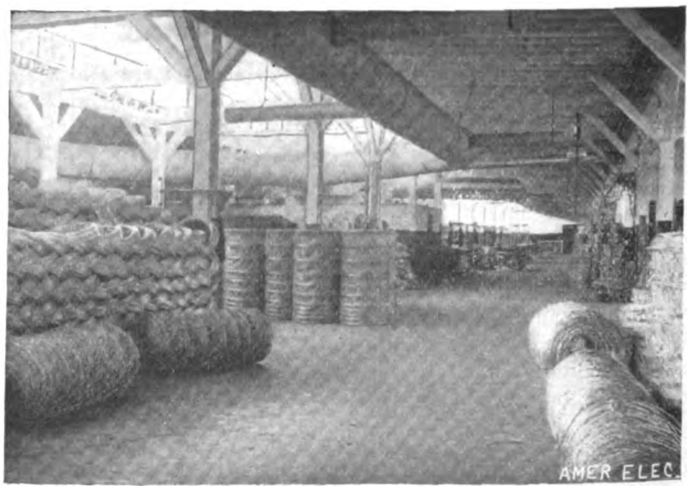

FIG. 3.—SHOWING HEATING SYSTEM.

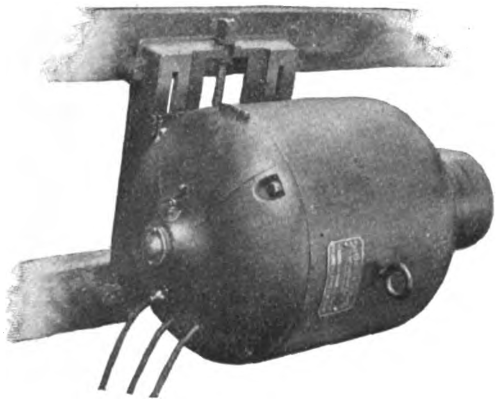
another direct connected generating unit is added the switchboard shall be equi-distant from both generators. From the switchboard two circuits are run to the center of distribution in the main building for power distribution and one circuit for lighting. From this point, four circuits are run for power, to one of which each motor is tapped indirectly, while for the lighting sub-centers are used. The maximum drop in voltage under full load to the most remote machine is 5 volts, and the dynamo is over-compounded to compensate for this drop.

The machines operated consist of looms and banks of "winders"; the product of the looms from the lightest poultry netting to the heaviest railroad fencing. This product is made in any width up to 96 ins. Stacks of so-called "railroad fencing" may be seen in the foreground of the cut showing the general interior. In most cases a 2-h.p. shunt motor is used to operate the machines, but the heavier machines require 4-h.p. motors. Each loom has an individual motor mounted on and a part of the machine.



The winders are arranged in groups and are operated by 4-h.p. motors of same type as is used for operating the heavy looms, the motors being mounted on platforms overhead and belted to line shafts about 18 ins. from the floor. The motors used throughout this plant are of the entirely inclosed type (Fig. 3), manufactured by the Thresher Electric Company.

The entire factory building is heated by a forced blast heating system, which was designed so as to maintain a temperature approximating to 70 deg. F. in the factory, with a minimum outside temperature of 10 deg. F. below zero. The fan, to which reference has already been made, has a capacity of delivering some 25,000 cu. ft. of air per minute through a system of ducts into the factory building. Before passing into the fan the air is drawn over a tempering coil containing approximately 500 sq. ft. of heating surface, which under the extreme conditions of temperature, will heat the air to some 20 deg. F., and at this temperature the air is forced through the underground tunnel underneath the railway tracks and rises through a galvanized iron duct in the factory building, running overhead to the main heater stack chamber.

In this heater chamber there are two heater stacks with a combined radiating surface of some 1450 sq. ft. Each of these stacks is subdivided into four separate sections, each individual section having its own steam and return valve; the entire arrangement being such that any section may be cut out or in independently of any other. A novel system of damper control has been devised, the arrangement being such that either one or both of the heater stacks may be by-passed, or in case of an accident happening to either of the stacks all of the air may be forced through the other stack and at the same time be evenly distributed, so that each end of the building will get its proper amount, or one end entirely cut out and the air forced through both stacks to the other end of the building.

After the air passes through the heaters it is distributed to all parts of the building, one main 36-in. duct leaving the north and south sides of the chamber respectively, these being subdivided as they leave the chamber into distributing ducts leading to branches on either side of the building. There is thus a complete system of main distributing ducts running the entire length of the building on either side. From these main ducts the heated air is delivered to the building by branch ducts, delivering the air toward the outside or coldest wall, with the exception of a few which are arranged to deliver the air into the lantern of the building. Each and every branch duct is provided with a damper which, by means of cords, can be controlled from the floor. A general idea of the heating chamber and distributing ducts can be had by reference to Fig. 4.

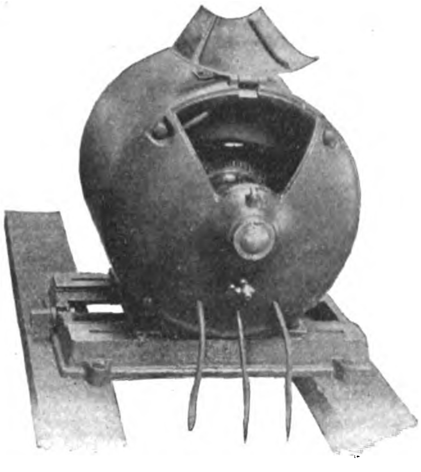


FIG. 4.—TYPES OF MOTORS EMPLOYED.

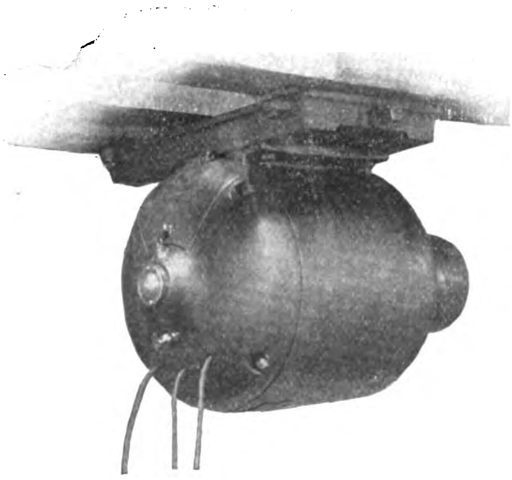
For heating the building, the exhaust steam from the dynamo engine, as well as that from the fan engine, is utilized and when this is not sufficient, as in extremely cold weather, the supply is supplemented by live steam. The exhaust steam from both engines and pump is first passed through oil separators and then enters the main exhaust header, carried underneath the floor of the engine room. This header is connected to an 8-in. pipe which is carried across to the factory building, where it rises and is connected to the headers of the heater stacks. In the exhaust header of the power station a pressure of 5 lbs. is maintained. The engines are thus working under a constant back pressure of this amount, the back pressure valve being set to open at approximately 5¼ lbs., while the pressure reducing valve connecting the high pressure header with this main exhaust is set so as to maintain the pressure in the heating mains at the predetermined pressure and is therefore weighted to open and admit live steam when the pressure falls below approximately 4¾ lbs. The return from the heater stacks in the factory building is connected to the return from the tempering coil in the power station, and the pipe is then led to and connected with a combined automatic pump and receiver, so arranged and connected as to deliver the hot returns either to the heater or to the boilers direct.

The entire plant has been so designed as to eliminate the possibility of delays due to accidents, as completly as possible, and is operated very smoothly and economically, for which credit is due the engineers, Messrs. Pierce & Richardson, who not only designed the entire system, but also have had complete superintendence over the installation. To these gentlemen we are indebted for the information contained in this article.



ALTERNATING-DIRECT CURRENT GENERATORS.

A system of current generation which is of comparatively recent growth is that in which an alternating current and direct current machine are combined into one. The chief advantages to be derived from the use of this system are found in connection with long distance electric railways where the power plant is located near the railway. In such a system it is desired to supply direct current from the power station, directly to the railway, and also to supply direct current from sub-stations at distant points on the line, the sub-stations being themselves supplied from the main generating station.

Direct current is supplied to the feeders from the "direct current end" of the generators; and alternating current, taken from the other end at a comparatively low pressure, passes through suitable step-up transformers and high tension lines to the various rotary transformer sub-stations, supplying the more distant sections of the railway.

The advantages in this case over the installing of both direct current machines and alternators in the power stations, are, uniform type and size of generators, less reserve machinery required, and more uniform load on generators and steam engines.

These machines may also be used when direct and alternating currents are required from the same station for power and lighting work. The generator is essentially a direct-current machine, with the number of poles and speed proportioned for the frequency of alternation required, and provided with suitable collector rings connected to the proper points of the armature winding for taking alternating current from the same winding.

The armature is of the same general form as that of a rotary transformer. The direct current voltage corresponds to the maximum alternating current voltage; while the mean alternating current voltage, as indicated by the voltmeter, is about .71 of the direct current voltage for two-phase machines, and about .61 of the latter for three-phase machines.

The first machines of this class were constructed by the Westinghouse Company in 1894 for the Citizens' Light and Power Company, of the city of Rochester, N. Y. These dynamos are provided with both shunt and series field windings, the shunt winding being always connected across the direct current brushes. When the machine is operated to produce direct current alone, the main current passes through the series winding as usual. When working as an alternating current generator, the regulation is effected by means of the rotary transformer at the sub-station, if the rotary is compounded, by having the direct current pass through the series winding. This increases the e.m.f. of the generator, as well as that of the rotary, thus giving an increased direct current e.m.f. as the system is located.

The armature core is built up of thin steel discs, and the coils are shaped and thoroughly insulated before being placed in the armature slots. The field core is built of thin steel plates, cast into the iron yoke or frame of the machine; thus producing an extremely powerful magnetic field, while the losses due to eddy currents caused by armature reaction, are eliminated by the use of laminated poles.

The generators are wound to over compound about 10 per cent, when used as direct current machines. They can be used to give both currents at the same time, but when so used, they will not of course regulate for both loads.

The Westinghouse Company has installed a large number of these generators and the results have been satisfactory. The latest application of the type is at the generating station of the Lewiston, Brunswick & Bath (Me.) electric railway. This road is to cover nearly thirty miles of steep grades and sharp curves, and the system here described is to be used exclusively.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Starters for Gas Engines.—In a short article in the (London) "Electrical Review" Mr. W. H. Booth speaks of the difficulties of starting large gas engines, and suggests that each be equipped with a small starting engine which can be itself started by hand. In electric light stations, etc., where there is a supply of electricity and the engines are coupled or belted to dynamos they may be started by using the dynamo as a motor, or they may be equipped with a starting motor. He objects to the compressed air starting mechanisms, depending on a store of air pumped up by a former run of the engine as likely to fail, especially in the case of engines using poor gases, and seems to think that the problem is one of great importance, as the difficulties of starting such engines promptly have limited their use.

A Singular Accident.—According to "L'Electricità," a singular and fatal accident recently occurred at Basle. Early one morning a young man walking along the street was struck in the neck by a fallen telephone wire that lay across the overhead trolley wire of the street railway and was grounded at the other end by a metallic structure. The wire was traversed by a heavy current and was at a low red heat. Between the burning and the shock the young man lost his footing, fell forward so that his weight rested upon the red hot wire, and was completely decapitated by it. Our Italian contemporary thinks that this accident will help the adoption of a two-wire alternating current railway system.

Frequency Measurements.—A very novel method of measuring the frequency of alternating currents is described by Mr. C. Kinsley in the "Philosophical Magazine." The apparatus consists of a telephone receiver and an air column of adjustable length contained in a drawn brass tube having a closely fitting piston. The telephone is inserted in the alternating circuit and the tube is placed in front of it, the distance between the receiver and the tube being about half the diameter of the latter. Whenever the length of the air column is suitable there will be a reinforcement of the note of the telephone, this applying as well to the harmonics present as to the fundamental. The frequency of the latter is always a simple function of the frequency of the successive harmonics, being the greatest common divisor of their various frequencies. Before calculating the final results correction must be made for the diameter of the tube (by adding 0.41*d* to the length) and for temperature. The author states that brass tubes about 1.5 inch in diameter are most durable and convenient. He found that the natural period of the diaphragm of every telephone on the market is too high to affect sensibly the alternating current harmonics.

A Simple Adaptation of the Coherer.—In the forms of wave-telegraph apparatus hitherto used a vibrating mechanism of some sort has been used to restore the coherer after it has "cohered." Usually this apparatus has taken the form of an electromagnetic vibrator or tapper, arranged to continually tap and jar the coherer tube. For various reasons this arrangement has not proven satisfactory, and Morse signals have been found to be too little separated by such a receiver for distinctness. Dr. H. Rupp describes, in "Elektrotechnische Zeitschrift," an arrangement for loosening the cohered filings, which is said to be as effective as it is simple. The coherer tube is provided with straight terminal wires and a small pulley, so that it can be rotated by the motion of the paper strip of the Morse register. The diameter of the coherer tube, for good results, must not be too small, and the quantity of filings should be such that they will roll around on the walls of the tube between the two electrodes. The diagram shows the arrangement of a receiving station. In circuit with the coherer tube F is a battery E, relay R, and resistance W. The plug switch U throws the calling bell L or the Morse register M into circuit with the relay. The local battery is indicated at B, adjusting resistances at W_2 and W_3, while W_4 is a resistance around the relay to prevent its sparking.

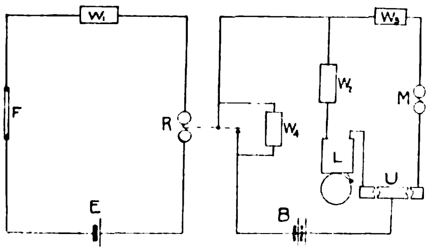


DIAGRAM OF COHERER CONNECTIONS.

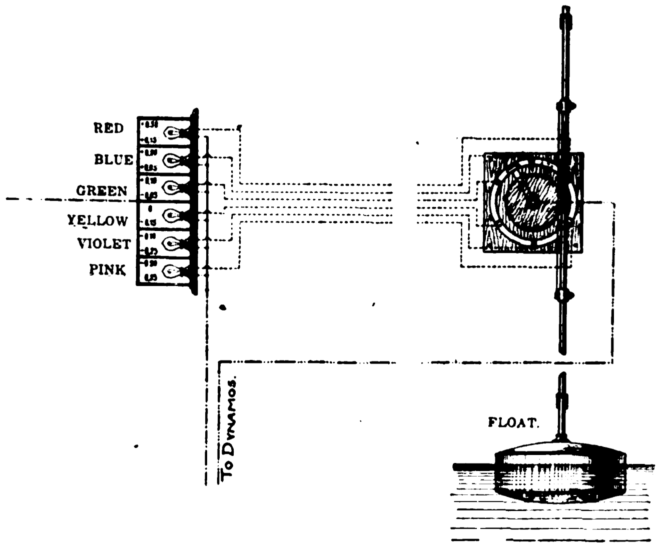
Alternating Current Arc Lamp.—An interesting regulating mechanism for an alternating current arc lamp has been brought out by a German firm and is illustrated and described in "Elektrotechnischer Anzeiger." At the top of the lamp a disc of aluminum turns on a horizontal axle to which is connected, through a train of gearing, a drum carrying a chain of which the two ends are attached to the upper and lower carbon holders. Two horseshoe electromagnets embrace the aluminum disc, one being energized by the main current, while the other is connected in shunt around the arc. The effect of the alternating field of these magnets is to cause currents displaced in phase from the main current to flow in the disc, which tends to revolve under the action of the two magnets and these currents. When the arc is of normal length the effects due to the two magnets balance and the mechanism stands still. When the arc is either too long or too short the disc rotates and moves the carbons into the proper position. Both the upper and lower carbons are of the same size and length, and the arc is maintained constantly at the same place. An enameled reflector having a hole in it for the upper carbon is suspended just above the arc, thus increasing the horizontal and downward intensity of the light.

Electric Water Level Indicator.—In a paper in "Zeitschrift für Elektrotechnik" describing the water-power installation for lighting Hermannstadt, Herr Oscar von Miller illustrates a simple water level indicator which is installed in the reservoir above the turbines and serves to continually indicate the water level to the switchboard attendant. The construction of the machine is clearly shown in the accompanying illustration. Attached to the vertical rod of the float is a cord wrapped around a drum to which is attached an arm sweeping over the switch sectors of a simple commutating arrangement. To this is connected a bank of lamps, of various colors, one of which is always burning. The color and position of the illuminated lamp are a continual index of the height of the water, an alarm apparatus also being included in circuit with the lamp that marks a dangerously low water level. An apparatus of this character is so simple and easy to make that it can be installed in almost any station worked by water power.



ELECTRIC WATER LEVEL INDICATOR.

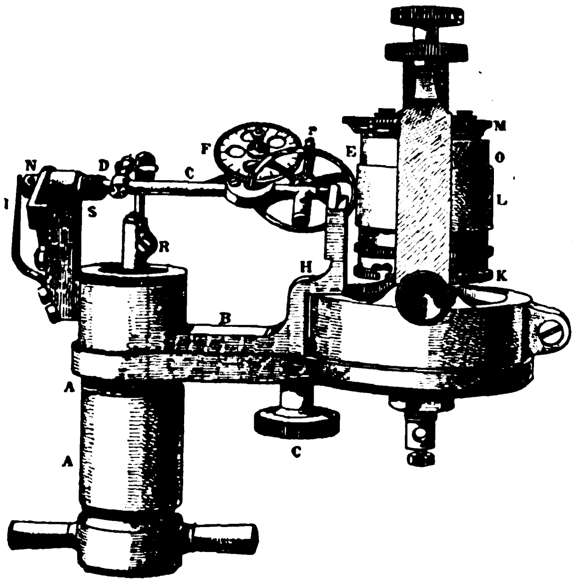
Electrolytic Glucinum.—This interesting metal possesses some properties which make the discovery of a commercial process for its reduction highly desirable. Its specific gravity is 2, electrical conductivity almost equal to that of silver, and it is practically unoxydizable. "L'Eclairage Electrique" contains an interesting note describing the various processes that have been attempted for its reduction. Of these the most recent is that of M. Lebeau. As electrolyte he uses one of the double fluorides of glucinum and sodium,

$$GF_2 2NaF \text{ or } GF_2NaF,$$

which he obtains either by mixing together concentrated solutions of the two fluorides which are then allowed to crystalize, or by dissolving glucinum hydrate and sodium carbonate in proper proportions in hydrofluoric acid. Of the two salts the one less rich in sodium is preferred, as its conductivity is the higher. The electrolyte is melted in a nickel crucible by means of a Bunsen burner, the heat being stopped when it is completely melted. A small carbon rod is used as anode and the crucible as cathode, the current being regulated so that the temperature does not exceed a dull red heat. A metallic non-adherent deposit forms on the crucible, which may be separated from the mass by boiling water. After many washings this deposit becomes completely dissociated as a powder of very irregular crystals of pure glucinum. By using a carbon crucible containing a stratum of a melted metal glucinum bronzes have also been made by this process.

Novel Properties of Rontgen Rays.—In a recent communication to the Berlin Academy Professor Röntgen described some new properties of the X-ray, which are of considerable interest. If a fluorescent plate is covered with a screen completely opaque to the rays a slight fluorescence can still be seen when the tube is in action. This is due to diffused X-rays proceeding from the air of the room, which itself emits the rays wherever it is exposed to their action. Of the rays which are given off by the platinum plate of a focus tube those are most effective for producing radiographs which leave the platinum at as great an angle as possible within a limit of 80 deg. The specific transparency of bodies is variable, being greater as the thickness of the body increases. The ratio of the thickness of two equally transparent plates of different material is dependent on the thickness and the material through which the rays pass before impinging upon the plates. The contrast between bodies of different transparencies depends upon the e.m.f. used to excite the tubes. A spark gap in the secondary circuit acts in the same way as an interpolated Thomson transformer, both producing more intense and less easily absorbed rays. With such a transformer and wire electrodes in a narrow tube X-rays can be produced with a vacuum of 3.1 m.m., the usual vacuum being about 0.002 m.m. Tubes requiring a very high e.m.f. for the production of the rays can be made active for lower pressures not only by heating, but also by passing through them a very powerful discharge. — "Electrotechnische Zeitschrift."

An Integrating Indicator.—It is often desirable to register the total power developed by an engine over a period of time. The usual method of taking many indicator cards and averaging these leads to troublesome calculation, with opportunity for error, and considerably increases the labor of the test. A new form of indicator that continuously registers the i.h.p. of the cylinder over the period of time during which it is in operation has been designed by Messrs. Little, and is described in "Engineering." Its construction is clearly shown in the accompanying illustration. The cylinder A and the piston working against a spring are similar to those of the ordinary type of indicator. Above the cylinder is an oscilating axle, C, carrying the counter F and a planimeter wheel, E. This is held in contact with the surface of the drum, O, by a spring and its inclination with respect to the elements of the drum surface varied by the motions of the piston. The counter consists of two wheels, one having 99 teeth and the other 100, engaging with an endless screw on the arbor of the wheel, E. This gives the apparatus a capacity for registering a large number of strokes. On the upper part of the drum is another counter, M, which registers the total number of strokes. It is stated that this ingenious apparatus has given excellent results in practice.



AN INTEGRATING INDICATOR.

Capacity and Discharge Rate of Accumulators.—A very interesting article in "L'Eclairage Electrique" give the results of the recent researches of Herr W. Peukert and M. F. Loppé upon the relation between the discharge rate and capacity of lead accumulators. It is well known that as the discharge rate rises the capacity of the cell in ampere hours falls, or that a cell having a certain ampere-hour capacity at a ten-hour discharge rate has a considerably less capacity when it is discharged in a shorter time. The relation between the time of discharge and the capacity can be expressed by the formula.

$$I^n t = k$$

where I is the discharge current, t the time of discharge and n and k constants of which the value is determinate for a given cell. The value of n depends upon the type of cell, while k depends upon the size of the element considered.

If for each type of accumulators the discharge current corresponding to a ten-hour discharge be taken as the unit, ten hours being taken as the unit of time, then for a time of discharge such that $t_1 = ta$ the current strength x will be given by the formula

$$x^n a = 1$$

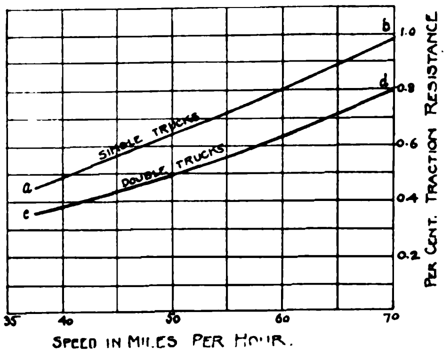
Similarly, an element having a capacity C for a time of discharge t, would have a capacity Cax for a discharge in time t_1.

As formulae requiring the use of exponentials are difficult of application, a table is given showing values of the capacity for discharge rates varying between 20 hours and 15 minutes for a number of values of n.

Time of Discharge in Hours.	Ratio of Capacities. Capacity at 10 Hours Discharge as Unit.									
	1.10	1.20	1.30	1.40	1.50	1.60	1.70	1.80	1.90	2
20	1.065	1.122	1.173	1.219	1.260	1.297	1.330	1.361	1.389	1.414
18	1.056	1.103	1.143	1.183	1.216	1,247	1.274	1.303	1.321	1.342
16	1.044	1.081	1.115	1.144	1.170	1.193	1.214	1.232	1 249	1.265
15	1.038	1.070	1.098	1.123	1.145	1.164	1.182	1.197	1.212	1.225
14	1.031	1.053	1 081	1.101	1.119	1 135	1.149	1.161	1.173	1.183
12	1.017	1.031	1.043	1.053	1.063	1.071	1.078	1.084	1.090	1.095
10	1	1	1	1	1	1	1	1	1	1
9	0.991	0.983	0.976	0.970	0.966	0.961	0.958	0.954	0 951	0.949
8	0.980	0.963	0.950	0.938	0.928	0.920	0.912	0.906	0 900	0.894
7	0.968	0.942	0.921	0.903	0.888	0.875	0.864	0.853	0 845	0.837
6	0.955	0.919	0.887	0.864	0.844	0.826	0.811	0.797	0.785	0.775
5	0.941	0.892	0.852	0.821	0.794	0.771	0.752	0.735	0.720	0.707
4	0.920	0.858	0.810	0.770	0.737	0.709	0.686	0.666	0.648	0.632
3	0.896	0.818	0.758	0.709	0.669	0.637	0.509	0.586	0.566	0.548
2	0.864	0.765	0.678	0.631	0.585	0.547	0.515	0.483	0.467	0.447
1	0.811	0.681	0.558	0.518	0.464	0.422	0.388	0.359	0.336	0.316
¾	0.790	0.649	0.550	0.477	0.422	0.379	0.344	0 316	0.293	0.274
½	0.762	0.607	0.500	0.425	0.368	0.325	0.291	0.264	0.242	0.224
¼	0.715	0.541	0.427	0 349	0.292	0.251	0.219	0.194	0.174	0.158

It is evident that the value of n for an ideal accumulator, or one in which the capacity does not diminish as the discharge rate rises, would be 1.

Traction Resistance.—For some time past experiments have been in progress in a French railway to determine the coefficients of traction of various types of cars at very high speeds, and these results have been published in the "Revue Générale des Chemins de Fer." The results of greatest interest to the electrical fraternity are those obtained for 4-wheel rigid truck cars and 8-wheel double (bogie) truck vehicles. Measurements were made under all sorts of conditions of track and weather, and the data below are the means of numerous results, taken in all cases on a straight and level track. A dynamometer between the tender and the train coupling on fast expresses in all sorts of service for six years gave the figures from which they were deduced. Where V is the speed in miles per hour the value of the traction coefficient in per cent. of the total weight is for the 4-wheel cars:



CURVES OF SPEED AND TRACTION RESISTANCE.

$$.016 + .074\ V \left(\frac{1.6\ V + 50}{10000} \right)$$

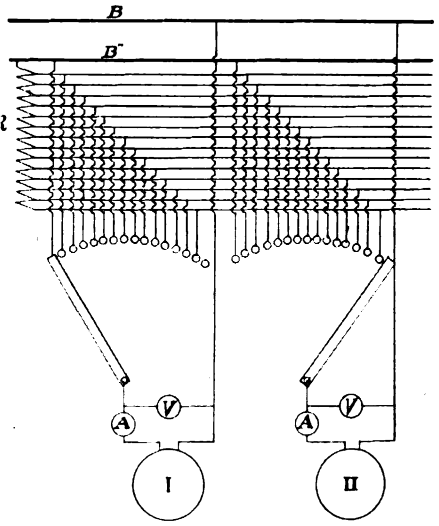
and for the double truck cars :

$$.016 + .074\ V \left(\frac{1.6\ V + 10}{10000} \right)$$

These are equations of parabolas, which are plotted in the accompanying curves, *a b*, representing the resistance of the 4-wheel type and *c d* that of the double-truck type at various speeds. The speeds are plotted as abscissas and the per cent. traction efforts as ordinates.

Electrical Conductivity of Glass.—Professors Andrew Gray and J. J. Dobbie recently read before the Royal Society a paper on the connection between the electrical properties and the chemical composition of different kinds of glass. Experiments were conducted to determine the circumstances that affect the conductivity and specific inductive capacity of glass, specimens being used that were richer in lead oxide than any formerly available. It had already been shown that potash and soda lime glasses have a higher conductivity than flint glass, and the experiments of the authors showed that the conductivity decreased with the increase of the lead oxide and the decrease of the soda, as had been expected.

Parallel Working of Alternators.—A simple method of paralleling single-phase alternators is described by Dr. J. Sahulka in "Zeitschrift für Elektrotechnik." The object of the method is to avoid increasing the load on the station by the use of an artificial load in the circuit of the machine that is to be connected to the bus-bars. A resistance, sufficiently high to permit the passage of only a few per cent of the output of one of the dynamos when short-circuited across the bus-bars is provided and connected to one of the bars as shown in the figure. This resistance needs not be entirely ohmic, but the part of it remote from the bus-bar connection can be inductive. The wire of which the part near the bus connection is composed should be large enough to safely carry the full output of one dynamo. From a number of points in this resistance wires are led along the switchboard parallel to the bus-bars, and these are connected to points as shown. One terminal of each alternator is attached to the switch lever and the other terminal is connected to the bus-bar. This apparatus permits the machines to be brought into the proper relations for parallel connection by simply advancing the switch of the incoming machine from point to point while reading the ammeter and voltmeter and manipulating the field rheostat so that the load is properly divided between it and the other machines at the time of its full connection to the working circuit. By this arrangement the load on the station is not increased. When the voltage of the incoming machine is properly regulated and all the resistance is in there will generally be a small current flowing due to phase differences between the machines. This current tends to bring the machines to synchronism, the tendency increasing as the resistance is removed, until the machines are in perfect synchronism when the resistance is all out. For disconnecting the same process is gone through in reverse order. A quick break switch would work well for this purpose, however. It is stated that the same apparatus works equally well for direct and three-phase currents.



PARALLEL CONNECTIONS FOR ALTERNATORS

E.M.F. of the Arc with Aluminum Electrodes.—It is known that an electrolytic cell having carbon and aluminum electrodes opposes the passage of current in the aluminum-carbon direction with an e.m.f. of 22 volts, while current passes in the other direction with only the opposition due to the resistance of the liquid and the polarization e.m.f. Herr V. von Lanz describes in "Wiedmann's Annalan" his researches upon the arc with aluminum electrodes. This arc is established under an e.m.f. of 19 volts. Between electrodes of aluminum and carbon the current passes more easily from aluminum to carbon, an effect contrary to that noticed in the electrolytic cell. This arc may be used, therefore, for the rectification of alternating currents, but the efficiency of such a rectification would not be higher than about 6 per cent.

Lead-Zinc-Cadmium Accumulators.—An article in "L'Industrie Electrique" gives the history of the lead-zinc accumulator and describes recent progress toward the perfection of this interesting type. In accumulators of this class the electrolyte is a solution of sulphates which deposits, under the action of the charging current, a coating of zinc and cadmium on the negative plate. The positive plate is the usual lead peroxide grid or formed plate. At full charge the liquid contains a solution of sulphuric acid, which redissolves during the discharge the metal deposited on the negative plate. This combination presents several marked advantages over the ordinary type of secondary batteries, among them a higher e.m.f. and a greater specific capacity, by reason of the diminished weight of the negative electrodes. As a consequence of these qualities the specific energy of this type is considerably higher than that of the all lead variety, and for certain applications this is a matter of extreme importance, as in the case of automobile vehicles. On the other hand, it is difficult in this type of accumulator to secure a good and solid deposit of metal on the negative elements, and the zinc thus deposited dissolves in the acid solution on open circuit with loss of energy. To stop this local action an early remedy was the reduction of the size of the negative element and its amalgamation. The recent improvements due to M. Werner seem to have made this type of accumulator very practical. As electrolyte he uses a mixture of the sulphates of zinc, cadmium and magnesium. During charge a deposit of zinc and cadmium is thrown down on the negative plate and a certain quantity of hydrogen is disengaged, which is said to enter into combination with the deposited metals, or, more properly, to be absorbed by them. During discharge the metals dissolve, the effective e.m.f. ranging from 2.3 to 1.9 volts. With a strong solution of zinc sulphate a good deposit of metal may be had, but the positive plate does not properly oxidize. With a solution of cadmium sulphate the oxidation goes on correctly, but the e.m.f. falls from 2.4 to 1.8 volts, after only 1/10 the total current is discharged. M. Werner found that in the presence of magnesium sulphate the deposit of zinc and cadmium is very regular and at the same time the functions of the positive plate are properly discharged. The charge is stopped when about 60 per cent of the salts are decomposed. On open circuit the losses due to local action depend on the nature of the bath and the quality of the metallic deposit. With a solution in which the cadmium salt is the largest element the loss is not more than 3 per cent. of the total charge per day. It is claimed that this type of cell has given results as good as 40 watt hours per pound of plates, or 16 watt hours per pound of complete cell.

Telephone Line Extensions.—In a rather elaborate article in "L'Eclairage Electrique" M. P. Heina gives a method of determining to what point of a system of cable main lines a subscriber's circuit should be connected. Taking first the case of a simple installation in which all the lines are overhead and no cable is used, each subscriber's line naturally runs direct to the exchange. If the crowding of the lines necessitates the establishment of a cable or substation, then the point of embranchment of the cable being selected, whether a given station should be connected to the exchange or the cable can be determined in the following manner. The average length of a subscriber's line is, for each installation, a definite amount greater than the air-line distance between the exchange and the station. Referring to Fig. 1, if P is taken as the ratio of these lengths, so that if C is the exchange and M the station, the actual length of the line is P. CM, the locus of points in which the relation

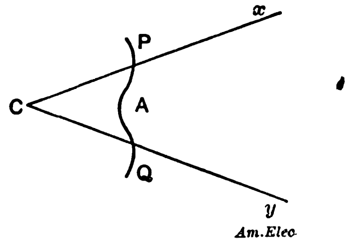


FIG. 1.—TELEPHONE LINE EXTENSIONS.

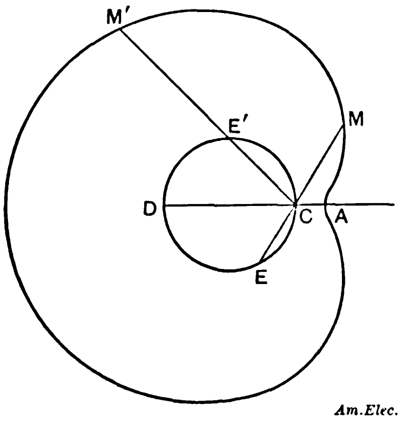

FIG. 2.—TELEPHONE LINE EXTENSIONS.

$$CA+AM=P.CM$$

holds good, where A is the end of the cable can be shown to be the curve AMM', which is a circular conchoid or Pascal's "limaçon." Its equation is, referred to C as pole and AC as polar axis,

$$r = \frac{2a}{P_2 - 1} \cdot (P - \cos \Theta)$$

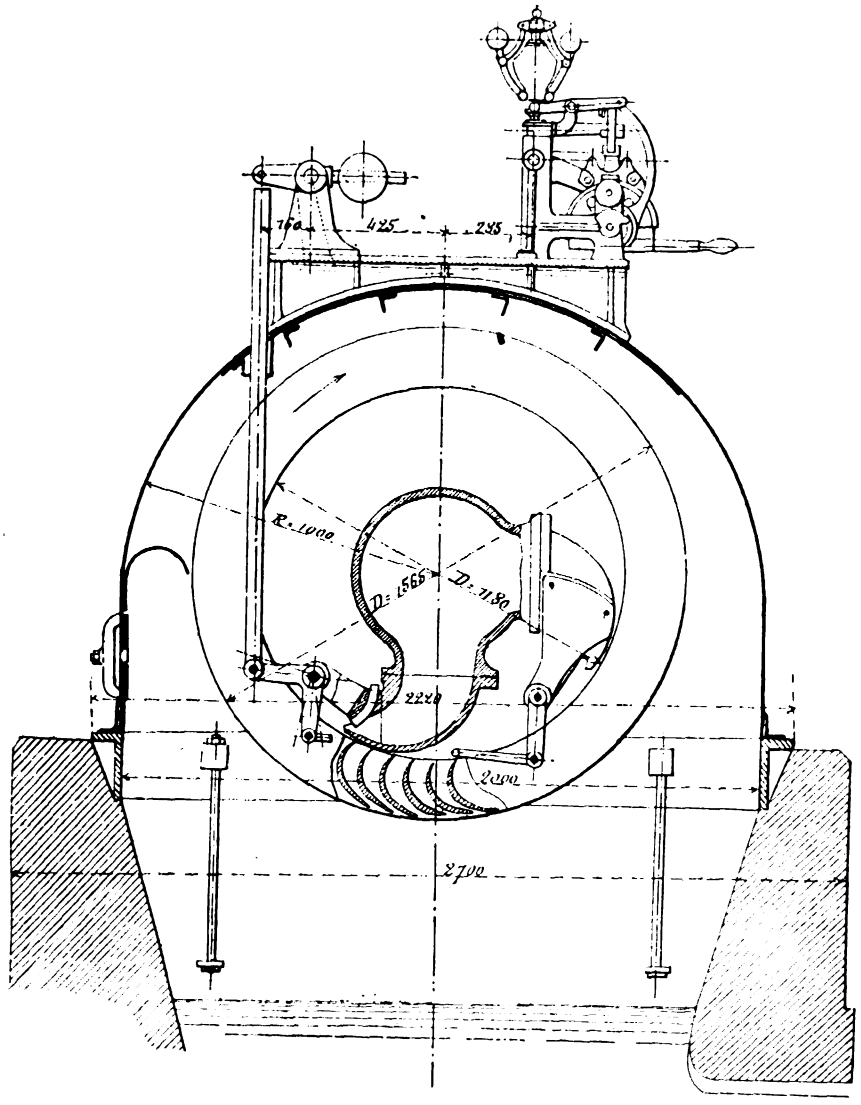
The circle CEDE' is the generating circle of the curve, and has for its diameter $\frac{2a}{P^2 - 1}$. In these equations a is the distance AC.

Referring now to Fig. 2 where xCy is any sector of the region served by the exchange containing a cable box A, the arc of this curve, PQ, can be easily constructed. All stations in the partxPQy should be connected to the box A and all stations in the area CPQ should be connected to the exchange. These principles can be readily extended to apply to a more complex system and furnish a guide that will easily determine the proper point for connecting in a subscriber so as to assure the maximum economy of line wire.

Lead Refining by Electrolysis.—Lead is never obtained in the pure state by the reduction of its ores. Apart from the bad effects that impurities have upon the quality of the metal, the foreign substances are frequently of value, as in the case of gold and silver. Two electrolytic methods for the separation of the foreign substances from lead are described by Mr. Sherard Cowper-Coles in the (London) "Electrical Review." By Keith's process the crude lead is cast into properly shaped anodes, which are inclosed in close fitting muslin bags. These are electrolysed in a solution of lead sulphate dissolved in an aqueous solution of sodium acetate. This mixture is made by electrolysing with lead anodes a mixture of 1½ pounds of sodium acetate, 2¾ ounces of sulphuric acid and 1 gallon of water, heated to 100° F. The lead deposited on the cathodes by this process is crystalline and continually separates from the plate, a space being left in the cell for its accumulation. When the anodes are dissolved the bags in which they were contained are emptied and the residual solid matter washed and remelted. The slimes suspended in the wash water are allowed to settle and the water drained off and filtered. These slimes usually contain antimony, arsenic, silver, copper, gold and iron.

The Tommasi process uses for electrolyte the double acetate of lead and sodium or potassium. The anodes are crude lead and the cathode, which is placed between two anodes, is a disc of aluminum alloy or copper half immersed in the liquid and revolving at the rate of one or two turns per minute. These discs are about 10 feet in diameter and ¾ inches thick. At the upper part are scrapers to detach the small, spongy crystals of lead, which fall into channels conveying them to wire gauze sieves, where they are drained and washed, the wash water being concentrated and again used as electrolyte. The lead is compressed, mixed with a few per cent. of charcoal powder and fused. The silver, with most of the arsenic and antimony, is separated at the anode and collected in trays to be fused with sodium nitrate and borax, by which the silver is separated from the other metals.. The cost of the process is estimated at from $1.60 to $2 per ton of lead when steam power is used.

A Spanish Lighting Station.—A very interesting electric light plant has recently been installed at Granada (Spain), and is fully described in "Génie Civil." Water power is used, the source being a torrent flowing from the glaciers of the Sierra Nevada. The power house is a little more than 6 miles from the city, at the foot of a gorge through which the stream descends. At a point about 3½ miles above a dam of concrete and masonry diverts the water of the stream into an open canal, through which it flows to a basin situated about 300 yards from the station. Thence it is conducted in a steel pipe 40 ins. in diameter to the turbines of the plant. These turbines are among the most interesting features of the installation. Working under a head of 325 feet, they develop 340 h.p. each at 350 revolutions per minute. The wheels are single and are overhung at the end of the wheel shafts. The water is admitted at two points in the interior of the moving part of the wheel, and acts both by impulsion and by the reaction of the outflow, as will be readily understood from the illustration. On the wheel shaft is a flywheel weighing 5,700 pounds. The couplings to the dynamos are of the Alioth insulated and elastic variety, and the alternators are very carefully insulated from the ground, being mounted on large blocks of porcelain. Around the dynamos the floor of the station is also insulated in the same way on porcelain blocks. Current is delivered by the generators at a frequency of 52.5 cycles per second (single-phase) and 4000 volts. The precautions against lightning and atmospheric discharges are very elaborate, as a singular phenomenon manifests itself daily. While it rains very rarely at Granada and the air is generally very dry, every evening at sunset there are strong atmospheric discharges on the high tension line. This is explained by the existence of a hill about 300 feet high near the middle of the 6 mile transmission line, the rest of the region traversed being flat. Great differences of atmospheric potential exist between the base and summit of this when the air on one side is warmed by sunshine, while the other is in shadow. The transmission line itself is of bare copper wire, about 0 gauge. At the outskirts of the town this is connected to a circuit of No. 4 wire, which runs completely around the town, and to which are connected 10 sub-stations transforming the current and feeding a three-wire system of 125 volts on each side. This circular feeder, notwithstanding the 4,000 volts pressure on it, is run entirely on house tops. It is to be regretted that our contemporary did not give more details of the method of mounting insulators and fixtures for this service.



TRANSVERSE SECTION OF GRANADA TURBINE.

A curious fact is noticed, on account of the larger part of the custom of the station coming from restaurants and drinking places, the load curve being unlike any other in Europe, and falling off very slowly until after 1 a. m. There are 5000 incandescent lamps fed by the installation and 40 arcs for street lighting, this being the whole extent of the lighting of a city of 75,000 inhabitants.

Submarine Cables in Time of War.—In an editorial the "Electrician" discusses at some length the question of the neutrality of cables in war with special reference to the probable attitude of this government and that of Spain upon the question of cables landing in the enemy's territory. It seems that there has been no war of importance since the establishment of the present widespread cable service to furnish precedents for the guidance of combatants in this very important matter, but the questions of neutrality that are concerned are out of place here. The most interesting feature of the article is the description of the cable lines landing in Cuba and Porto Rico and other Spanish possessions which it may be found necessary for our naval forces to destroy. It appears that there are four cables landing in Cuba, one from Havana to Key West, one to Hayti, and two to Jamaica. Porto Rico also has four cables, two to Jamaica, one to St. Thomas and one to the Danish island of Ste. Croix. The Philippine Islands possess one cable, to Hong Kong, which has already been severed by the American fleet, and the Canary Islands have two lines, one to Cadiz and the other to St. Louis in Senegal (Africa). It is pointed out by our contemporary that to cut this country off from communication with Europe it would be necessary to cut twelve cables in the North Atlantic, many of them ending in Canada, and three landing in Brazil, a contingency not in the least to be apprehended.

Electricity and Fire-Damp.—The safety of electric lights and other electrical apparatus in mines where there is much "fire-damp" and explosive coal dust has been studied at great length by MM. H. Couriot and J. Meunier, and the results of their labors presented to the Academie des Sciences. The general conclusions reached were that currents of methane, or mixtures of methane and air, cannot be ignited by an incandescent metallic wire or by the spark due to the rupture at an incandescent wire carrying a current. These mixtures are immediately ignited by a flame, and it was concluded that, for mine gases in motion, contact with a flame is necessary to determine ignition or explosion. With stagnant gases the results obtained were different. It was shown that incandescent wires cannot ignite even the most explosive mixtures, but that the spark due to the rupture of such a wire generally sufficed to explode the mixture. It seems that sparks of considerable volume and energy are required and that the incandescent light is the safest illuminant for dangerous mines.

A more important set of experiments was made recently by Herren Heis and Thieme in an artificial mine gallery supplied with gases from an abandoned working near Gelsenkirchen in Westphalia. The experiments on lamps were very complete. Naked filaments raised to high incandescence in an explosive atmosphere may or may not cause ignition, and may remain intact after the explosion. Lamps dropped to the floor and broken while burning sometimes caused an explosion and sometimes did not, though, with stout filament lamps such as are used with portable outfits, the filament sometimes survived the smashing of the bulb. The conclusion reached from some 200 experiments was that the ampere capacity of the lamps was the determining factor. Currents of less than 0.6 amp., continuous or alternating, did not cause explosion. Stronger currents mostly did. The advice given by these experimenters is to use stout globes and cages around the lamps for protection and to use low amperage lamps, but not to exceed 150 volts tension, as all excessive voltages are dangerous. Especial care should be taken with leading-in wires, etc., to avoid short circuits with their incidental flash. Arc lamps will not ignite coal dust, even in an atmosphere of methane unless the latter exceeds 6 per cent of the mixture, when an explosion is caused. Notwithstanding, arc lamps should not be used in fiery mines. Switches are dangerous when the current or e.m.f is excessive. Wire resistance coils are safe unless the wires touch and lead to internal sparking. For motors carbon brushes are safer than those of copper. A motor protected in a box with a fine wire gauze cover ignited the explosive mixture in the box on starting, but the explosion did not strike through the box. Induction motors were found to be very satisfactory and free from danger. The full report appears in "Elektrotechnische Zeitschrift" and an excellent abstract of it in "Engineering."

◆

ELECTRICAL PERIODICALS.

To the Editor of American Electrician:

I have read with interest the comments of Thomas D. Lockwood in your last issue on the subject of "Electrical Journals," giving the history of the three telegraph magazines published between October, 1852, and October, 1855. In one particular I think Mr. Lockwood is in error. Referring to "Shaffner's Telegraph Companion," the third and last of the publications mentioned, he says: "The first number is dated January, 1854, and the last October, 1855." This statement is correct only with reference to the octavo quarterly published by Shaffner between these dates in New York City. But during the previous year, 1853, Shaffner had issued two numbers under the same name in quarto form at Louisville, Ky. I quote from page 46 of the first number issued in New York, dated January, 1854:

> "The Telegraph Companion, as now issued, is an improvement on the old series, or original issue. The quarto form was inconvenient."

Also from p. 47, same number:

> "Old Subscribers.—The subscribers to the Companion during the last year can have their choice," etc.

In the next paragraph reference is also made to the change of publication office from Louisville to New York, and an apology offered for the delay, which had evidently been more than six months, as I find on p. 292 of the "American Telegraph Magazine," Vol. I., No. 6, dated July 15, 1853 (the last number published), the following:

> "After this issue 'Shaffner's Telegraph Companion' (of which two numbers were issued at Louisville), will be merged in the 'American Telegraph Magazine.'"

This plan of consolidation, however, was not carried out, as it is so stated in "Shaffner's Telegraph Companion" for January, 1854, on p. 48; but its publication was continued separately until October, 1855, as Mr. Lockwood states.

In this connection it may be of interest to present a table which I have compiled giving the "vital statistics' of American electrical journals that have ceased to exist. The causes of death are not stated. No doubt some died of natural causes, such as depletion of the bank account; others are said to have committed "journalistic suicide," a disease which seems to have had many victims, while not a few are reported to have been put to death by their charitable contemporaries.

I have included in the list no electrical periodical now published. The dates given have been obtained from the periodicals themselves in my own library, by correspondence with their former publishers and from contemporary references to them. I have included the telegraph journals, of which Mr. Lockwood has given the full history, so as to make the list more complete.

In addition to the above I append a list taken from the "Magnet" of Sept. 1, 1880, p. 113, giving the names of several infantile telegraph publications which were so short lived that it is doubtful if a single copy has been preserved. It is therefore impossible to verify names or dates. The list gives the following:

The Esquimaux (monthly; published by American Telegraphers in Russian America), 1866-7; eight or nine issues.
Telegraphica, New York, 1874; four or five issues.
The Fraternity, New York, 1874; two or three issues.
The Switch, Chicago, 1874; less than half a dozen issues.
The Plug, Cincinnati, 1874; one issue.
The Electric, St. Louis, 1875; two or three issues.
The Southern Operator, Bolivar, Tenn., 1878; one issue.
The Magnet (executed with the electric pen), Cincinnati, O., 1878; one issue.

If I am not mistaken, the editor of the "Esquimaux" was the late Franklin L. Pope, who was connected with a telegraph expedition to Alaska at that time. I have found several quotations from it and references to it in the contemporary volume of the "Telegrapher."

EDWARD CALDWELL.

New York, May 24, 1898.

---

[1] From Jan. 6, 1883, to April 28, 1883, the "Operator" was not issued as a separate periodical, but formed a part of the "Operator and Electrical World." On May 1, 1883, it was resumed as a separate issue. After Sept. 19, 1885, it was continued as "Johnston's Journal."

[2] I have seen no later date than this, although a few more issues may have appeared.

[3] I have at hand for reference only one number, "Vol. I., No. 3, Oct., 1853, Quarterly."

The National Electric Light Association.

THE twenty-first annual convention of the National Electric Light Association is the seventh meeting of that body in the West, and the third in Chicago, its birthplace. The association was organized in Chicago, Feb. 25, 1885, with Mr. J. Frank Morrison as president, and its ninth convention was held there in February, 1889. The other Western cities in which conventions have been held are Detroit, August, 1886; Kansas City, February, 1890; St. Louis, February, 1893, and Cleveland, February, 1895.

A. M. Young,
First Vice-President.

Samuel Insull,
President.

George R. Stetson,
Second Vice-President.

Geo. P. Porter,
Secretary.

C. O. Baker, Jr.,
Master of Transportation.

Among the social features of the Chicago convention will be a reception at the Auditorium on Monday evening, June 6, an excursion on Lake Michigan, Tuesday, and coaching parties for ladies through the parks and boulevard system and suburbs, with luncheon, on Tuesday and Wednesday during hours of meeting.

The meeting of the executive committee will be held at 9 a. m. of Tuesday, and the convention will be opened at 10.30 a. m., with an address by President Insull. The remainder of the programme is as follows:

Tuesday morning—A paper by Mr. Calvin W. Rice, Brooklyn, on the "Cost of the Generation and Distribution of a Unit of Electricity." Topic for discussion, "Prices and Discount for Electric Current and Methods of Billing Current to Customers."

Tuesday afternoon—A paper by Mr. Alex. Dow, Detroit, on "Public Lighting with Relation to Public Ownership or Control." Topic for discussion: "Legislative Policy as to Public Service Corporations."

Wednesday morning—A paper by Mr. Herbert A. Wagner, St. Louis, on "General Distribution from Central Stations by Alternating Currents," to be followed by a paper by Mr. Louis A. Ferguson, Chicago, on "General Distribution from Central Stations by Direct Currents." Topic for discussion: "Standardizing Apparatus for Central Station Use."

Wednesday afternoon—A paper by Mr. W. McLea Walbank, Montreal, on "Cost of Producing Electric Power by Water Power from Lachine Rapids, Canada." Report of committee on standard candle-power of incandescent lamps, Dr. Louis Bell, Chairman. Topic for discussion: "Questions and Answers? What Is It You Wish to Know?" Executive session.

Wednesday evening—Lecture by Joseph Wetzler, New York, on "Electricity Direct from Coal," to be illustrated by stereopticon views.

Thursday morning—A paper by Prof. W. E. Goldsborough, Purdue University, Lafayette, Ind., on "Transformer Economy." Reports of committee on "Amendments to the Freight Classification," and committee on "Legislation Concerning Theft of Current," Mr. Jas. I. Ayer, chairman.

Thursday afternoon—Discussion of topic, "Freight Rates on Electrical Apparatus." Report of committee on finance, Mr. John A. Seely, chairman. Executive session. Election of officers.

NOTES.

Electrical Burns.—The remedy used in the remarkable case of electrical burn, reported in these columns last month, may be obtained from G. F. Harvey & Company, Saratoga Springs, N. Y., the preparation being known as "vitogen." We make this announcement in view of the value of the preparation to those subject to electrical accidents.

A Worthy Object.—The Paul Quinn College, of Waco, Tex., is about to institute an electrical course of instruction, and appeals to the electrical industry for contributions to an electrical laboratory. The Paul Quinn College is a negro institute which ranks only second to that at Tuskegee, Ala., which Mr. Brooker T. Washington has caused to be so widely known. Electrical apparatus suitable for experimental demonstration is particularly desired by Prof. William H. Dammond, Professor of Mathematics, who at present is in charge of the organization of the course.

St. Anthony Falls Water Power Plant.—In the article on the St. Anthony Falls water power plant in the May issue, it is stated that the water wheels operating the two 100-k.w. exciters were built by the D. S. Morgan Water Wheel Company, of Dayton, Ohio. This is an error, the wheels having been supplied by the S. Morgan Smith Company, of York, Pa.

Questions and Answers.—That the examination papers of beginners in electrical science should contain an occasional amusing blunder is not surprising, in view of the fact that the new student most probably shares the general opinion that electricity is a mysterious thing, and is therefore apt to be off his guard logically. As several specimens of such answers we quote the following: Question.—What is the temperature coefficient of resistance? Answer.—a = temperature coefficient = number of degrees of resistance per square centimeter. Question.—What do we mean when we say "A charge of electricity?" Answer.—A charge of electricity is an indefinite something, having various properties which are measured in different ways. Question.—A 110-volt dynamo is connected to a circuit. The ammeter in this circuit reads zero. What is the condition of the circuit? Answer. $C = \frac{E}{R}$, $o = \frac{120}{\infty}$ The resistance is minus infinity; i. e., the dynamo is on a dead short circuit, which is a circuit without resistance.

Electricity in Germany.—At the April meeting of the Societe Internationale des Electriciens, M. J. Laffargue read a paper giving statistics concerning the central stations and electric railways of Germany. There are 265 central stations of a total capacity of 67,900 k.w, of which 204 are continuous current, 26 alternating current, 16 polyphase currents, 14 polyphase and continuous current, and 5 alternating and continuous current. On Sept. 1, 1897, there were 96 cities having a total length of 1530 miles of electric railway track, and electrical capacity of 21,465 k.w. Some statistics are given concerning the cost of lighting current. At Frankfort the entire cost, including interest and depreciation, is 6 cents per k.w.-hour. At Cologne and Dusseldorf the cost is 3.85 and 2.52 cents respectively, not comprising interest and depreciation. The consumption of fuel is about 6.6 per k.w.-hour, coal costing from $2.40 to $3.60 per ton. The charge for electrical energy varies from 16 to 20 cents per k.w.-hour for lighting, and from 5 to 6 cents for power, with discounts for quantity, which in some cases range as high as 50 per cent.

Telegraph Tournament.—The Morse National Telegraph Tournament, which was held at the New York Electrical Exhibition May 14, was excellently conducted by Mr. Fred. Catlin, manager; Mr. T. J. Smith, master of ceremonies, and Mr. A. E. Sink, timer, not a hitch occurring in the programme. The prizes amounted to $1350, of which the Western Union Telegraph Company and Postal Telegraph Company each contributed $250. The championship sending contest was won by Mr. W. M. Gibson, who sent 254 words in five minutes with but one error, Mr. F. L. Catlin winning the second prize on 253½ words with one error. Both cases broke all previous records, which had been 248 words, or 252 words including a record not generally recognized on account of its imperfect Morse. In the code sending class the first prize was won by Mr. G. W. Conkling (345 words in five minutes), and the second prize by Mr. W. M. Gibson (330 words), the former breaking previous records. In the ladies' sending class Miss J. McManus and Miss Emma R. Vanselow won the prizes, the former on 239 words with eight errors (superior Morse), and the latter with 241 words and eight errors (good Morse). In the 230-word sending class, the prizes were won by Mr. Charles F. Edney (233 words, excellent Morse), and Mr. F. M. McClintic (242 words, good Morse). The prizes in the 240-word class were won by Mr. J. D. Hinnant, 252 words, and F. M. McClintic, 243 words. At this writing the prizes for the typewriting receiving contest have not yet been awarded. Almost one hundred contestants participated in the tournament. Phonetic records in duplicate were made in the championship and code classes, which can not only be reproduced at any time in the future, but multiplied at will.

Heavy Electric Railroading.—At the May meeting of the New York Electrical Society at Madison Square Garden, New York, Prof. S. H. Short read an interesting paper on "Heavy Electric Railroading," in which he gave a review of the development of electric traction up to the present time, and considered the probable future in this field. He noted the general adoption in large cities of the underground conduit system, and predicted a close competition with the overhead trolley in the near future. Taking up the subject of suburban and interurban roads, he illustrated by examples how seriously the latter have affected the traffic of parallel steam roads, even when the latter reduced fares below those of the former, this being commented upon as furnishing the best proof of the advantages of electric traction. Several cases were spoken of in which steam roads have had much financial success in handling local traffic by an electric service. Prof. Short said that the trolley system of Cleveland is the largest in the world, there being no less than six roads from 10 to 40 miles in length, all using heavy cars and running on printed time schedules. As an illustration of the heavy work done, a stereopticon view was given of a heavy excursion train on the Akron, Cleveland & Bedford road, hauled by a four-motor equipment aggregating 200 h.p. As an illustration of the financial possibility of suburban electric roads, he quoted the case of the Chicago Northern & Pacific Railway, which, after a struggle with electric competition, leased its lines to the Suburban Railway of Chicago, after which the entire system was electrically equipped and the lost patronage regained. Prof. Short went into the details of the construction of the third-rail system and explained the main features of the multiple-unit system of control. He made an interesting statement that some 70,000 or 80,000 h.p. will be required to operate the Manhattan Elevated system of New York alone, and as Prof. Short has very carefully worked out the engineering details of elevated roads, his figures have, therefore, considerable significance. Among the views thrown on the screen was one showing the characteristic curves of a No. 15 L Walker motor, the Professor apologizing to the non-technical portion of his audience for the technical nature of the exhibit; the curves, however, were sufficiently remarkable to justify their being shown—representing, as they did, an efficiency attaining 92 per cent. As the motor weighs only 3900 lbs. and has an armature speed of 550 r.p.m., the showing is one of which Prof. Short, the designer of the machine, might well be proud. As to long distance traction, Prof. Short seems to think that the immediate prospects are bright for a system in which the current is transmitted at from 30,000 to 40,000 volts over distances of 50 or even 100 miles, the current being taken from the high-tension feeders at substations from 25 to 30 miles apart and transformed by means of static and rotary converters to the regular railway direct current pressure. He reviewed what has been done in the heaviest kind of electric railway work, referring to that of the General Electric Company on the Baltimore & Ohio belt line. The value of the gearless motors used there was mentioned, and here, as throughout the lecture when referring to pioneer and other work, Prof. Short's modesty forbade him to add that this construction was applied to the Baltimore & Ohio locomotives under his patents.

Electrical Conventions and Exhibitions.

The present month will witness the ending of the Electrical Exhibition, the conventions of the National Electric Light and the Northwestern Electrical Associations, and the opening of the Trans-Mississippi Exhibition, at which latter Prof. Owens has seen that electricity shall play a leading part. The electrical show has been a decided credit to the industry represented, and though handicapped by unparalleled adverse weather—there were but four favorable evenings during the month of May—the attendance showed that electricity still retains its popularity. The plan of the Northwestern Electrical Association to hold its convention afloat is a decided novelty, the outcome of which will be attended with much interest. If successful it will establish a precedent that may perhaps lead to convention excursions on ocean steamers, for a convention trip to Bermuda in the Winter or to Newfoundland in the Summer would have enticing features.

The programme of papers for the Chicago Convention is a strong one, and particularly so with respect to the interests of large central stations. The papers by Mr. Wagner and Mr. Ferguson give promise of being very important contributions to central station engineering, the writers having had exceptional opportunities in the branches which they will treat. The papers of Mr. Walbank and Mr. Rice are also extremely apropos, dealing as they do with the question of costs, the analysis of which is a matter of the greatest importance in these days of graduated charges for electrical energy. Transformer economy and municipal ownership complete a convention programme, which from its extreme appropriateness, reflects great credit upon those who had charge of its preparation. Of the committee reports, that on a standard candle power of incandescent lamps will be awaited with much interest. Though first taken up by Dr. Bell in 1891, and definitely brought before the American Institute more than two years ago, thus far no progress seems to be made toward the end in view beyond a report of a committee of the latter body, laying down certain principles upon which a commercial standard should be based. It is sincerely to be hoped that action will be taken at Chicago definitely establishing a commercial method of standardization.

Regulating Alternating Current Line Voltage.

On another page will be found an article which explains in a simple manner how, by means of an over-excited synchronous motor or rotary transformer in circuit, the inductive drop of an alternating current line may be neutralized, or both the inductive and ohmic drops neutralized, or even a voltage obtained at any point of a line in excess of the generator voltage. As will be seen, this curious result is produced through the motor or converter being so designed as to take a current leading the impressed e.m.f., thus having an action similar to a condenser. The e.m.f. set up in a condenser acts in a direction opposite to that of an e.m.f. set up in an inductance, and therefore if each of these is of the same value, the one will neutralize the other, which is the condition when the inductive drop alone is neutralized in the case above quoted. If the ohmic drop is also to be neutralized, or if the line immediately beyond the motor or converter is to be compounded, then an inductance or choke coil must necessarily be introduced into the generator side of the line. In this case, while the inductance and capacity may neutralize each other, the voltage between the terminals of the motor or the converter will be higher than that between the far terminals of the inductance and capacity by the amount of the ohmic drop or over-compounding thus provided for. It should be remembered that the neutralization or over-compounding refers to the terminals of the motor or converter; that is, the voltage there is the impressed e.m.f. of the line beyond, which is subject to drop, both ohmic and inductive, as if that were the original source of e.m.f. Consequently, to regulate the voltage of a long line, a number of motors or converters will be required, depending upon the closeness of the regulation desired.

Series and Shunt Machines.

We frequently receive inquiries how to change a series dynamo or motor—usually a small arc dynamo or a railway motor—to a shunt machine. If there is to be no change of voltage, the process is very simple, for it is then merely necessary to substitute a field winding that will give the same ampere-turns as the series field winding at normal load. If the voltage is also to be changed, this will require a change of the armature winding, which, however, may be made at the commutator if the voltage is merely to be halved. Of course, the voltage may be still further reduced by lowering the speed of the machine, but this will also reduce its capacity at the same rate.

For example, suppose it is desired to make a 125-volt shunt machine of an old-style five-light, 250-volt arc dynamo. By counting the series field turns as they are taken off and multiplying by the normal arc current—say 10 amps.—the ampere turns will be determined. But as an arc machine is run with its field over-saturated, an allowance must be made for this, and in the absence of a characteristic curve we may assume that 80 per cent of the former ampere turns will bring us to the right point on the curve of magnetism for the shunt machine. As in this case we would probably not care for a high efficiency, we will assume that about 7 per cent of the current will be used in the shunt, or, say .7 amp. Knowing the ampere-turns, we can now determine the number of turns and from this the length of wire. As the voltage is to be 125 and .7 amp. is to flow in the shunt, its resistance will be 180 ohms. We now have the length of the shunt wire and its resistance, and from a wire table the nearest gage may be selected, which will usually involve some slight change in the current selected.

As the field remains at approximately the same strength, the armature winding must be changed so as to develop only half the original voltage. This may be done by short-circuiting every other commutator bar on its neighbor, disconnecting the ends of the armature conductors and reconnecting, so that the coils in each pair of adjacent slots will be in parallel. Some care will be necessary in doing this, as the operation must be continued in the same order all the way around. If it is desired to compound the machine, the series winding may be determined roughly by running the machine. first on open circuit, then with full load, and noting the drop. The ratio between this drop and the normal voltage, multiplied by the shunt ampere turns, will give the additional ampere-turns required; and this divided by the full-load armature current will give the number of series turns. If the machine is to be over-compounded, add the extra volts to the drop above found and proceed as before. The above is a somewhat rough method, but it is accurate enough for any ordinary practical case. By changing the speed of the machine the voltage, if not exact, may be brought to the desired value. The above method may be used to change a 500-volt railway motor to a 250-volt shunt dynamo or motor.

Our Leading Articles.

The subjects of the leading articles in this, our annual Electric Light Convention or souvenir number, have naturally been selected with especial reference to the department of central station engineering. In making the selection, however, the interests of those connected with the average American central station have been more particularly kept in view. The installations in great centers of population form but a very small percentage of the 2700 or more central stations in this country, and many of the problems there encountered are of such a special character as to have little more than an academic interest for the average central station man.

Among the live topics of the present day are the employment of gas engines and storage batteries in central stations, and the reconstruction of old arc light plants. Each of these will be found treated elsewhere in this issue, and the first two with reference to plants of a size that form the great majority in this country. The article by Prof. Flather describes a gas engine station of moderate capacity, but one in which all of the engineering details have been worked out in a proper manner. As natural gas is found over a large region in the Central States, this article should give food for reflection to those in charge of electric lighting stations situated therein, while others may find it to their advantage to investigate the claims made as to the intrinsic economy of the gas producer and engine over the steam boiler and engine. The electric light station described by Mr. Sage is a type of many hundreds of small stations scattered throughout the country, which, from their nondescript character and small income, would seem to offer little encouragement toward such an innovation as a storage battery would likely be considered in such a quarter. It is, however, most frequently in just such stations as these, where the load line conditions are peculiarly unfavorable, that the storage battery may turn a losing venture into a financial success.

The article by Mr. Herrick on switchboard reconstruction will particularly appeal to the central station man who has begun to realize that an old-time switchboard is nowadays apt to result in doubt being cast upon one's progressiveness. Mr. Herrick shows that any electrician of mechanical skill can reconstruct or replace an old board, and at an expense that is far from appalling to even a close board of directors. Prof. Shepardson, in his article on the 220-volt system, discusses the subject from the dollars and cents point of view, and shows that it cannot be taken for granted that this system has always the advantage over the alternating current system in the case of small towns, as claimed by some of its supporters. Indeed, the two are often so nearly balanced that when a decision is to be made between them, the part of wisdom is to engage a competent engineer to give final judgment.

In no branch of central station engineering has there been a greater change in recent years than in arc lighting, and this is strikingly exemplified in the article on the new Brooklyn arc light plant. Circuits of 6000 volts and units of 250 lights are a great advance, and coupled with this is the driving of centrally located plants by motors supplied with power generated in a station located miles away. There is little doubt but that in the near future the arc plants in all large cities will be similar to the one here described. The article by Mr. Francis Jehl on underground distribution will be found of much interest in showing that on the Continent the cheap and simple method of laying underground on sand in a ditch is now almost universally employed and with excellent results. This practice has commenced to be adopted in this country, and the facts adduced by Mr. Jehl should result in removing any remaining doubts concerning its practicability.

The steam plant is considered in two able articles—one by Mr. Snow on mechanical draft, and another by Prof. Aldrich (now serving as a volunteer Engineer officer in the navy) on the steam engine. These articles bring forward the two most important points of the day in steam practice, and the first mentioned is of particular importance with reference to electrical generating plants. That under all circumstances where the boiler plant is of any size there is economy in mechanical draft is, we believe, no longer denied. In electrical generating plants, however, it presents, owing to the character of the load line, a precious advantage in permitting the rate of combustion to be varied according to the demands of the moment. With mechanical stokers, economizers and induced draft, the steam generating department will be on a par with the other parts of a power plant instead, as in the past, the wofully inefficient and neglected part. Prof. Aldrich agrees with the views expressed by Prof. Durand in these columns a few months ago concerning the advantages of superheated steam, and also holds that to be most beneficial the steam should be initially heated and to a high temperature above that corresponding to saturation. We doubt, however, if most engineers of to-day will agree with the statement that if the steam jacket is to be placed on but one cylinder of a multiple-expansion engine, it should be on the low-pressure cylinder, for in this situation it acts during half of the stroke as a super-heating chamber for the vapor entering the condenser. The benefit to be derived from steam jacketing has always been elusive, and at any rate, now that reheaters are being applied, the steam jacket might be well left off all cylinders.

DESIGNS FOR SMALL MOTORS—V.

ONE-HALF H.P MOTOR, WITH DRUM ARMATURE.

BY CECIL P. POOLE.

For this size of motor three types of field magnet are described, the single-coil Jenny, like those previously described, a bi-polar, one-piece magnet, of the so-called iron-clad type, and a similar form with four poles (Kapp type). The armature core and shaft are the same in each case, excepting the number of slots in the four-pole machine. The machine is a ½-h.p. motor, to operate on a 110-volt constant potential circuit, at a speed of 2000 r.p.m. The single-coil magnet, Figs. 1 and 2, has a round core of commercial wrought iron 2½ ins. in diameter and 11 ins. long over all. The ends are turned tapering, as indicated by the dotted lines, to insure intimate contact with the yokes; the taper is from the full diameter to 1¾ ins. and begins with 2½ins. from each end. The pole-pieces are of cast iron. The arms which support the journal yokes are cast solid with the pole-pieces, and their horizontal thickness tapers from ½ in. at the pole-piece to ¼ in. where the yoke is bolted in place.

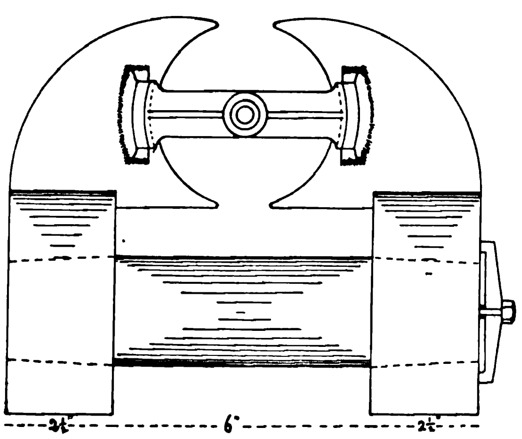

FIG. 1.—SIDE ELEVATION OF SINGLE-COIL FIELD MAGNET.

In fitting the magnet frame together, the best procedure is to bore the tapered holes in the lower part of each pole-piece and turn the ends at the magnet core to the same taper but just a trifle large; then dress each tapered end of the core down very gradually with a fine file (the core being run on a lathe) until the pole-piece can be pushed on by hand far enough to bring the end of the core within 3-64 in. of the surface of the cast iron. The pole-pieces and ends of the core should be punch-marked so as to insure finally mounting each pole-piece on the end which was fitted to it. After dressing down the ends of the core as above described, drill and tap in each end a hole for a ¼-in. machine screw, the purpose of which will be made apparent by a glance at the right hand end of the complete magnet, in Fig. 1, where C is a four-armed claw or spider, with a hole through the centre where the arms intersect. The arms are 3-16 in. thick, measured at right angles to the bolt, and taper from 3-16 to ⅜ in. thick, measured parallel with it. One of these claws or spiders is used at each end of the core, though the drawing shows it at one end only.

After drawing one pole-piece home solid by means of the spider and bolt, slip the other on the other end of the core loosely and clamp the pole-pieces lightly between two iron plates with planed surfaces, applied between the journal arms, so as to keep the four horns of the pole-pieces in alignment; then force the second pole-piece home and clamp the horns hard between the iron plates. The bottom surfaces of the pole-pieces are then to be trued up on a shaper or planer and the iron clamping plates removed from the horns.

The next operation is boring the armature chamber and the seats for the ends of the journal yokes. The bore of the armature chamber is 4 3-16 ins.; the seats for the journal yokes are machined to a 4⅝-in. circle for ¾ in. from the outer ends. These operations must be completed before the original position of the frame on the lathe or boring machine is altered. This completes the machine work on the magnet, with the exception of the holes through the ends of the supporting arms and holes in the bottom surfaces of the pole-pieces for bolting to the base.

The journal yoke must be made of brass or some similar composition. The bar is 3-16 inch thick and 1 inch wide, except near the ends where it flares to correspond with the width of the supporting arms. At each end is a right-angle lug, ⅛ inch thick after machining; these lugs fit the machined seats in the ends of the iron arms, and the yokes should be fitted to these arms before the frame is taken apart to put on the magnet coil. The journal box is 1½ ins. long over all, 3-16 in. of its length projecting on the inside of the yoke bar, and 1⅛ ins. on the outside. As shown by the plan view of the yoke in Fig. 3, there are stiffening webs starting flush near the ends of the yoke and attaining a height of ¾ in. where they join the box; these ribs are ⅛ in. thick. The box is 1 in. in outside diameter and bored out 9-16 in.; the bore is bushed to ⅜ in.

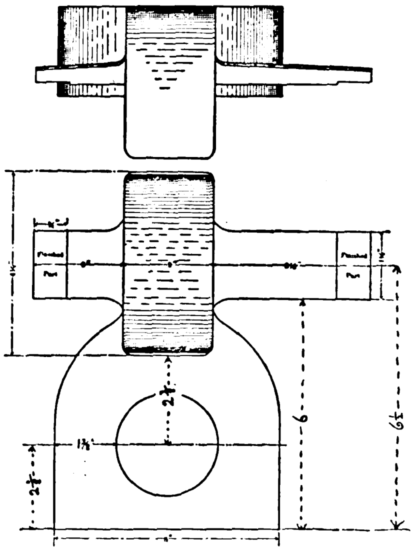

FIG. 2.—ARMATURE DISK FOR FOUR-POLE MACHINE.

No particular form of oiling device is specified as any amateur of sufficient ability to build such a motor will be fully competent to decide this detail for himself. The journal yokes are held in place by ¼-in. cap screws passing through the ends of the supporting arms and tapping into the lugs on the yokes.

The field coil contains thirty-five layers of No. 26 double-cotton-covered magnet wire. After the magnet is fitted as above described, it is taken apart and two circular fiber heads, 4½ ins. in diameter and ⅛ in. thick, are put on the core with a driving fit, care being taken that the distance from outside to outside of the heads corresponds with the space between the perpendicular faces of the pole-pieces when the frame is assembled; this measurement should be taken prior to dismantling the frame. A groove must be cut on the outer face of one head, from the centre to the outer edge, in order to form a channel for leading out the starting ends of the coil when the frame is re-assembled, at which time two disks of oil paper with one of mica between them, must be threaded on the core outside of this head to insulate the leading-out wire from the pole-piece. Before winding the coil insulate the core with a strip of muslin just wide enough to go between the heads and long enough to wrap around the core three times; this should be heavily shellacked before it goes on. If the coil is carefully wound it will be 210 turns in length along the core; the number of turns in this direction is not particularly essential, but as many should be put on as possible without jamming the insulation, in order to reduce the heat loss. The depth of the winding must be 35 layers.

After winding the coil and securing the ends, put one pole-piece on solid and slip the other on loosely. When it begins to bind, bolt the journal yokes to the lugs on the pole-piece first put on, and insert the bolts through the lugs of the one that is loose. Then tighten up the spider bolt at the end of the core and force it into place, the bolts through the lugs serving as guides to keep the pole-piece from twisting on the core. These bolts should be set up little by little with the spider bolt so as to keep the bolt heads within 1-16 in. of the surface of the lugs. As an additional precaution the frame may be set on a true surface and tried at intervals to see if it gets out of alignment; if it does, tap the horn of the loose pole-piece until the bottom surface agrees with the guide. The magnet frame must be provided with a non-magnetic base, preferably composition metal, but allowably of wood.

Figs. 4, 5 and 6 show the shaft and armature core (the latter in cross section), an armature disk, and the shell and head. The disks are of charcoal iron, 4 ins. outside diameter with a 1 in. hole in the centre and an ⅛ in. key-seat, annealed after punching and key-seating; there are eighteen slots ⅜ in. wide and ⅜ in. deep. The shell and one head are cast in one piece (of brass) and consist of a barrel 1 in. outside diameter (when finished), and 2 ins. long, with a head, S, at one end, 3⅛ ins. in diameter and tapered in thickness from ¼ in. near the centre to 1-16 in. at the periphery; at the opposite end of the barrel is a cross-bar, ⅛ in. thick, cast with the barrel, and of the shape shown, being ⅜ in. wide where it joins the barrel and ¾ in. at the center. A ½-in. hole is drilled in the center of this cross-bar and another in the center of the head, S, at the other end of the barrel; the shell is mounted on a mandrel, the barrel is turned down to fit the hole in the armature disks, and both sides of the head are faced off smooth. A ⅛ in. key-seat 3-16 in. deep is cut in the barrel so as to come in the center of one end of the cross-bar, as shown; a ⅛ in. x ¼ in. feather, or parallel key is laid in the key-seat and the disks are threaded on the barrel and compressed against the head by the collar, H, drawn down by two bolts (not shown) passing through the collar and inside the barrel, and tapping into the head at the other end. This collar, H, is of brass, 3⅛ ins. in diameter and tapering from 3-16 to 1-16 in. in thickness when finished. The opening in the center should fit the outline of the cross-bar on the end of the barrel at least closely enough to prevent the collar from shifting under stress of centrifugal force; the collar must be finished up smooth on both sides. A disk of insulation should be put on next to the brass head before the iron disks are put on, and another insulating disk should go between the last iron disk and the clamping collar, H.

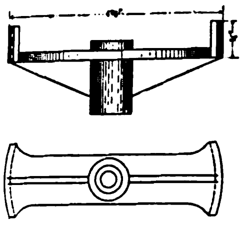

FIG. 3.—JOURNAL YOKE.

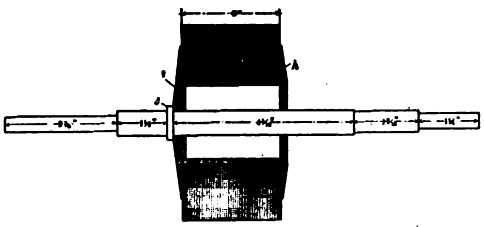

FIG. 4.—ARMATURE CORE AND SHAFT.

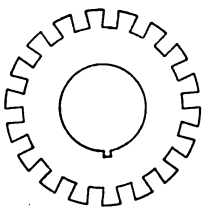

FIG. 5.—ARMATURE DISK FOR BIPOLAR MACHINE.

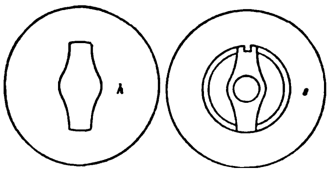

FIG. 6.—ARMATURE SHELL.

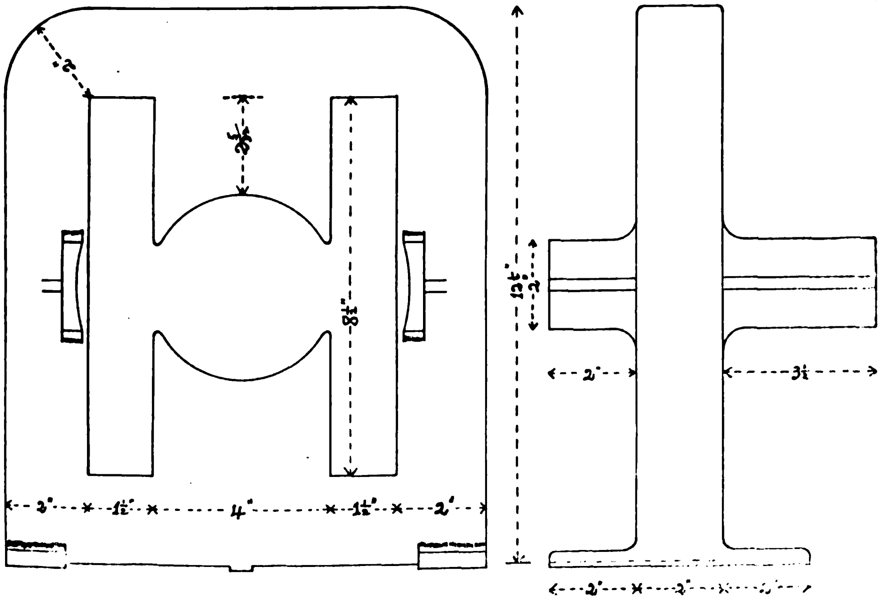

FIG. 7.—END AND PLAN VIEW, SINGLE-COIL MAGNET.

If the slots are cut in the core with a milling machine, the disks must all come off the barrel to have the burrs removed and also be reannealed; the key-seat will insure their returning in the original angular position. It is much better to have disks with the slots punched before the first annealing. The shaft is 10¾ ins. long over all; ½ in. in diameter in the largest part, 7-16 in. where the commutator goes, and ⅝ in. in the journals. A 1-16 in. x ⅛ in. collar, C, is shown back of the armature, the purpose of which is merely to "locate" the armature shell; it is not absolutely necessary, however, and may be left off if desired. The easiest way to provide for it is to make the shaft of ⅝ in. stock, leaving the original metal to form the collar when turning the shell to the proper diameter. The armature shell may be keyed to the shaft or pinned obliquely through the thick part of the head; it must be positively secured by some such means.

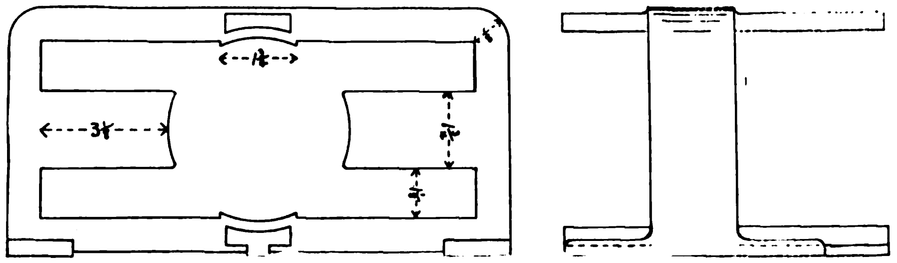

FIG. 8.—FOUR-POLE IRON-CLAD MAGNET.

The commutator shell must be bored to fit the 7-16 in. portion of the shaft, and must not exceed 1¼ ins. along the shaft. The lugs where the wires are attached to the segments may project toward the armature ⅛ in. or so. There must be eighteen segments, and a diameter of 2 ins. is recommended. The quadrant carrying the brush-holders should be fitted to the inner end of the journal box, and carbon brushes (one on each side) not smaller than ¼ in. x ½ in. on the contact surface should be used. If the machine be used as a dynamo (it will maintain about ten 110-volt lamps) metal brushes of the same surface should be used to reduce the resistance of the brush contact. The armature winding is divided into eighteen coils, each having thirty-two turns of No. 20 double-cotton-covered wire, eight turns wide and four turns deep in the slot. The slots must be insulated with troughs of muslin and mica or, preferably, flexible micanite, 0.03 in. thick. The troughs are easily made by cutting the material into strips 2½ ins. long by 1⅛ ins. wide, and slitting the ends so as to permit the projecting portion of the trough to be folded back flat against the core. Before putting in the troughs a disk of heavy drilling, 3¼ ins. in diameter, should be secured to each end of the core by means of varnish, and the outer faces varnished and allowed to nearly dry. Then put in the troughs and put on two more muslin disks, carnishing the whole, and bake until thoroughly dry. Instead of winding each coil in diametrically opposite slots, take slots lacking one of being precisely opposite.

A good plan is to make a sketch of an armature disk and number the slots from left to right successively around the periphery. Then wind the coils as follows, the coil numbers indicating the order in which the coils are put on, not the order in which they are connected to the commutator:

Coil Number.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
Starting in Slot Number.	1	10	13	4	7	16	2	11	15	6	14	5	18	9	3	12	8	17
Ending in Slot Number.	9	18	3	12	15	6	10	1	5	14	1	13	8	17	11	2	16	7

Each pair of coils must be covered with muslin where they cross the heads before the next pair is put on, and before coil No. 8 is wound on top of coil No. 1 in slot No. 1, the bottom coil must be insulated by a strip of micanite laid in the slot; this is true of every bottom coil.

After the winding is on, and before connecting up to the commutator the band wires should be put on. Use No. 19 B. W.

G. soft tinned-iron wire, known by hardware dealers as "white stove-pipe wire," for the bands, and put them on under as heavy pressure as possible without endangering the armature shaft. Two bands of eight turns each, ½ in. from each end of the core, will suffice. A strip of mica, between two strips of fuller-board, must go under each band, and the bands should be soldered at intervals, not all the way around. Four tin clips located equidistantly, with a dab of solder at each, will give ample security.

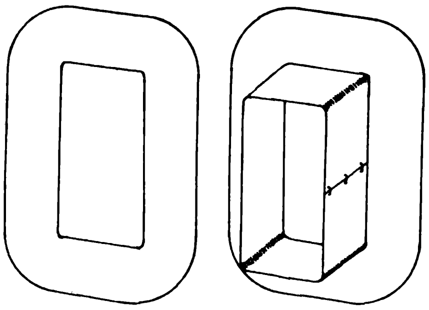

FIG. 9.—MAGNET-COIL BOBBIN.

If cast steel be available, one of the iron-clad types of magnet, shown by Figs. 7 and 8, is somewhat preferable because of the small amount of machine work required. Of these two the four-polar type is considered preferable by the writer, being much lighter in weight and having an "open-head" armature winding. Each of the iron-clad magnets is a single casting; the essential dimensions are shown in the sketches with the exception of the bore of the armature chamber, which is, of course, the same as for the single-coil maget—4 3-16 ins. As the two magnets require the same treatment, varying only in dimensions, the following remarks apply to both:

It will be noticed that the feet of the machine project ⅛ in. below the body and that there is a transverse rib under the center of similar depth. These are to give the machine a floor bearing which may be trued up on a shaper or planer without finishing the whole bottom of the machine. The first operation on the casting is chipping off the numerous fins and lumps with which steel castings are invariably afflicted. An emery wheel may be used for this purpose around the outside of the frame, but in the corners of the coil-spaces a cape chisel and lots of muscular exertion will be required.

Next, the bearing surfaces are trued up, and ½ in. holes drilled in the feet; then the magnet is mounted for boring out the armature chamber and the seats for the journal yokes, all of which must be done with one mounting. This finishes the magnet frame, unless it is desired to put a terminal block on the machine instead of on the base, and do away with the latter. In this event, four ¼-in. holes are to be drilled in the top surface of the frame and tapped for machine screws to hold the block, which may be 2 by 6 ins. and 1½ ins. thick. The journal yoke and journal are the same as shown in Fig. 3, except that for the bi-polar magnet the yoke is 7½ ins. long instead of 4⅝ ins.

The field coils for the bi-polar machine consist of No. 25 double-cotton-covered wire, wound 45 layers deep, and each coil is 80 turns long. The coils are to be wound in fibre bobbins as shown by Fig. 9. The heads of the bobbin must be 2⅛ ins. apart, and the body must be ⅛ in. wider and longer than the magnet core, actual measurement. Before winding the coil, the bobbin must be mounted on a wooden core of proper size to fit the opening through the center and having flanges or heads at each end to "back up" the heads of the bobbin; one of these heads is put on permanently and the other is secured by two screws so as to be removable. A spindle of 1-in. iron goes through the center of the wooden core upon which to mount it in the lathe for winding.

When a coil is completed, bend the wire back upon itself near the end, tie a linen thread in the loop formed and secure the end of the coil by passing the thread several times around the coil and tying its ends together. Then varnish the outside heavily and bake the coil at a low temperature—100 to 125 deg. F.—until the varnish is hard.

The coils for the four-poular machine are 35 layers deep and 110 long, of No. 25 wire. The heads of the winding bobbin are 3 ins. apart. The instructions for winding the coils for the bi-polar iron-clad machine apply to these also. In connecting the coils on the machine, however, there is a difference. On the bi-polar machine the final end of one coil must be connected to the beginning of the other; on the quadri-polar the reverse is true. Fig. 10 shows diagrammatically the manner of connecting the field coils of the quadri-polar machine. It will be noticed that the exciting current passes around the cores in opposite directions.

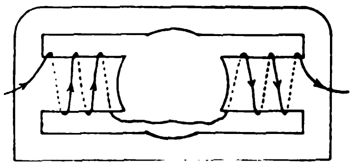

FIG. 10.—BIPOLAR IRON-CLAD MAGNET.

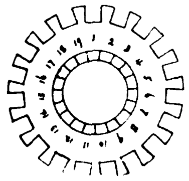

FIG. 11.—ARMATURE DIAGRAM.

The connection for the bi-polar machine is exactly the reverse of that shown.

The armature core of the four-pole machine has 19 slots 3-10 in. wide and ⅜ in. deep, instead of 18 slots ⅜x⅜. There are 19 coils, each having 28 turns of No. 20 wire, 7 turns wide and 4 turns deep. These may be wound directly on the core, but it will probably be easier for an amateur to wind them in a little frame, tie them at intervals with thread, and put them on the core complete. The winding frame will be exactly like the one for the field coils except in size. The "channel" formed between the heads must be 9-32 in. wide and ¼ in. deep. The body of the frame, which determines the length and width of the coil, is 2¼ ins. one way and 2¾ ins. the other. The coils are put on and connected up as indicated by the following table:

Number of coil.	In slots No.	Beginning end goes to segment number.	Final end goes to segment No.
1	1 and 6	1	11
2	2 " 7	2	12
3	3 " 8	3	13
4	4 " 9	4	14
5	5 " 10	5	15
6	11 " 16	11	2
7	12 " 17	12	3
8	13 " 18	13	4
9	13 " 19	14	5
10	15 " 1	15	6
11	16 " 2	16	7
12	17 " 3	17	8
13	18 " 4	18	9
14	19 " 5	19	10
15	6 " 11	6	16
16	7 " 12	7	17
17	8 " 13	8	18
18	9 " 14	9	19
19	10 " 15	10	1

The numbers of the coils indicate the sequence in which they are put on the core, and this order should be observed in order to secure maximum symmetry of the wires across the heads of the core. The numbers of the slots and segments refer to the diagram shown by Fig. 11. Each figure applies to the slot and segment between which it is located.

The brush quadrant for this machine is also different from that of the other two; instead of bearing upon the commutator at diametrically opposite points the brushes must be 90 deg. apart—corresponding with the relative angular positions of magnet poles of different signs. In the bi-polar iron-clad the "north" and "south" poles are, of course, opposite each other; in the four-pole machine the poles directly opposite are of the same sign—if one horizontal pole is "north" the other must also be "north," and the other two, without coils, will be "south."

◆

ELECTRICAL APPARATUS FOR AMUSEMENT—V.

SPIRIT CHIROGRAPHY.

BY NEVIL MONROE HOPKINS.

During the early periods of civilization those possessed with the faculty of inscribing their thoughts and expressions on parchment were classified among the highly educated. Waiving the modern and liberal meaning of the term, we will have introduced to us, associated with the following experiment, a highly educated spirit, whose manifestations are apparent in a very "marked" degree, although the etherial constitution of the phantom hand prevents an impression of its image on the optic nerve. The necessary simple requirements for the use of this unseen hand consist of a coarse quill pen, flagon of India ink, a school slate and light wooden easel, together with the little swinging cabinet illustrated in Fig. 1. The spirit never protests at a close examination of the pen, ink and paper upon which its writing is dependent, and allows of a close, unobstructed observation of the slate, easel and cabinet, which serve merely to mount the "parchment" and provide a place for the pen and ink, respectively.

Before describing the secret of the spirit hand, the effect of the experiment will be given. Having satisfied the skeptical by freely presenting the writing material for scrutiny, the paper selected is immediately mounted on the slate in full view of the onlookers, by means of small gummed wafers, and the whole placed carefully on the little supporting easel. Attention is called to the little cabinet which is seen swinging from a pair of cords or colored ribbons, which may be swung around in any position in order to show up its construction. The cabinet is sharply rapped inside and out, with the magician's wand. demonstrating wooden construction, and proving the absence of wires, strings and other delicate and complicated contrivances.

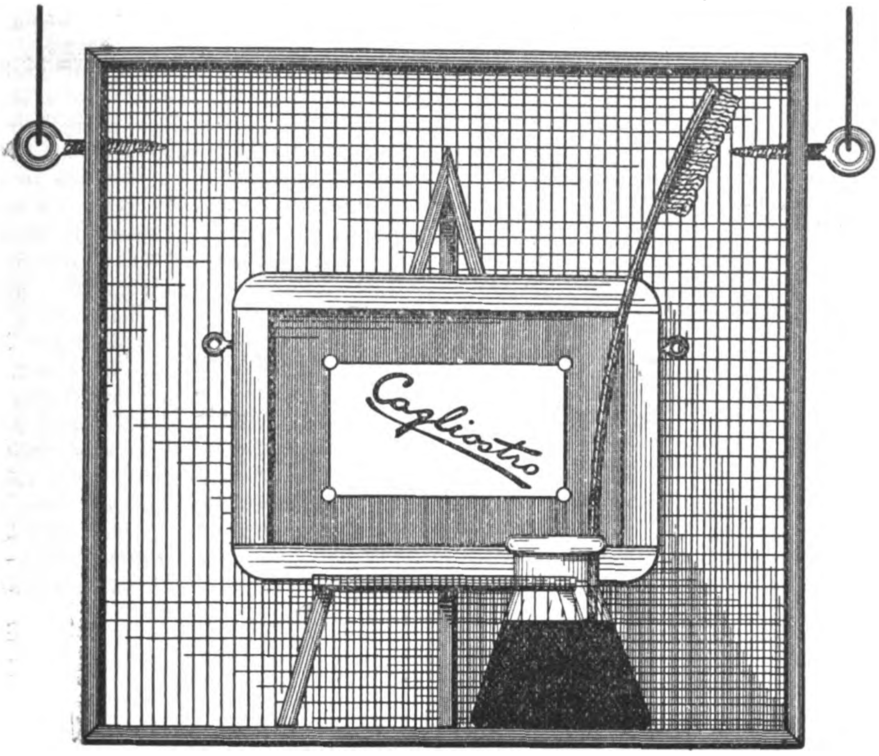

FIG I.—ELECTRIC SLATE AND CABINET.

The easel, slate, ink and pen are now placed inside, and the cabinet is covered with a silk handkerchief or colored scarf Sounds are heard within, and the cabinet is seen to tremble as if a material living thing had entered. When the moving ceases and no more sounds are emitted, the covering is removed, displaying an inscription plainly written across the paper, and the pen, which was previously in the ink, removed from the bottle and lying on the bottom of the cabinet. The paper can be taken from the slate at once and be passed around for inspection, where the writing will be immediately identified as executed with the India ink. Almost any inscription or answers to queries may be produced in connecion with this cabinet if the performer is quick and exercises some little skill and ingenuity. A small bell placed inside may be made ring by the spirit when the writing is complete, or rappings can take place inside in response to questions.

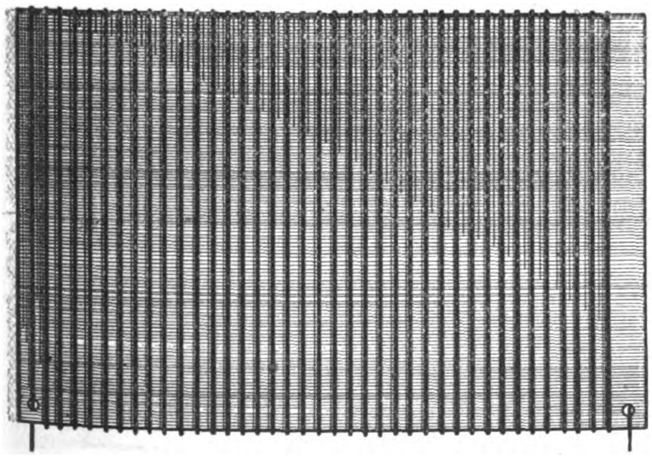

FIG. 2.—HEATING COIL OF ELECTRIC SLATE.

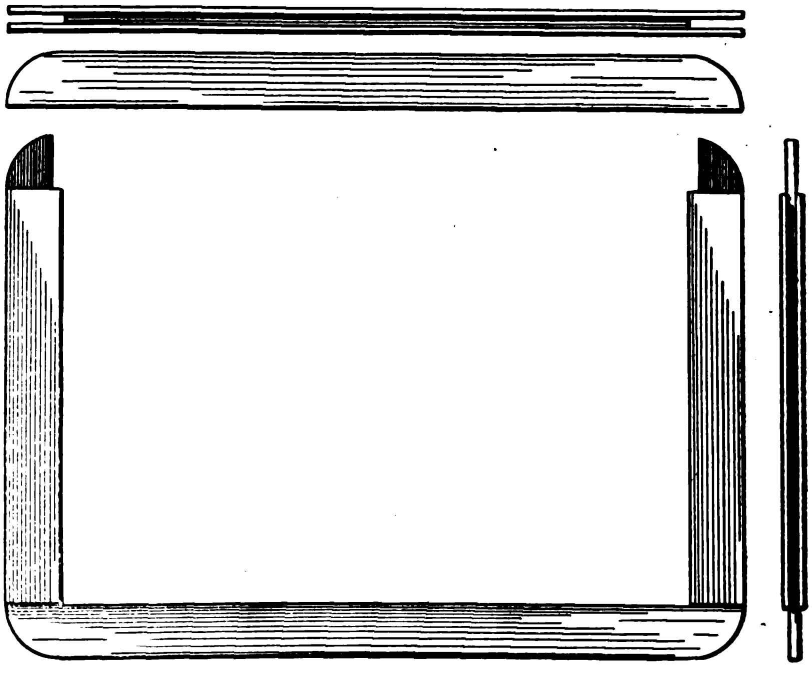

FIG. 3.—FRAME OF ELECTRIC SLATE.

The explanation of these manifestations is as follows: The paper, which may be closely examined, is previously written on with diluted sulphuric acid and allowed to dry thoroughly. Many sheets of paper may be prepared in this way, being secretly marked by pin pricks in order that the performer may know one inscription from the other. By subjecting these sheets of paper to heat the inscription appears in the blackest and most vivid characters, bearing the closest resemblance to dried India ink. The slate and easel, together with the cabinet and the supporting "ribbons," provide the heat through the "medium" of electricity. The pen is drawn from the ink, and the rappings and bell ringings are accomplished by black silk threads.

Different kinds of linen writing paper should be written on with pure acid of varying strengths, until the most perfect results are reached. Linen paper with a slightly rough surface, and a suspicion of yellow in its whiteness, will usually give the best results, it being very difficult to discover any traces of writing when the acid has dried. The acid used should be the purest, the cheaper grades of sulphuric having a yellow tinge. To make the writing fluid, add about fifty drops of the concentrated acid to one ounce of filtered water, and test the writing done with this after drying by holding over a bunsen flame or alcohol lamp, if the electric slate is not made. The blackest characters will appear in a few seconds and be of permanent character.

Let us now take up the construction of the "electric slate" and easel. Fig. 2 represents the slate removed from the frame, being wound with the heating wire. This slate is designed for direct connection with a 110-volt electric lighting service, and will heat up nicely if the directions are carefully carried out. Before winding the slate a small hole is drilled in each of the upper corners, as shown in the figure, to facilitate the putting on and the securing of the wire. An ordinary school slate measures seven by eleven inches, not taking into account the wooden frame. The frame can be taken apart without breaking the corner mortices by applying a strong pressure alternately at two diagonally opposite corners. In this manner the glue used in joining the frame is weakened and parted without injuring the frame.

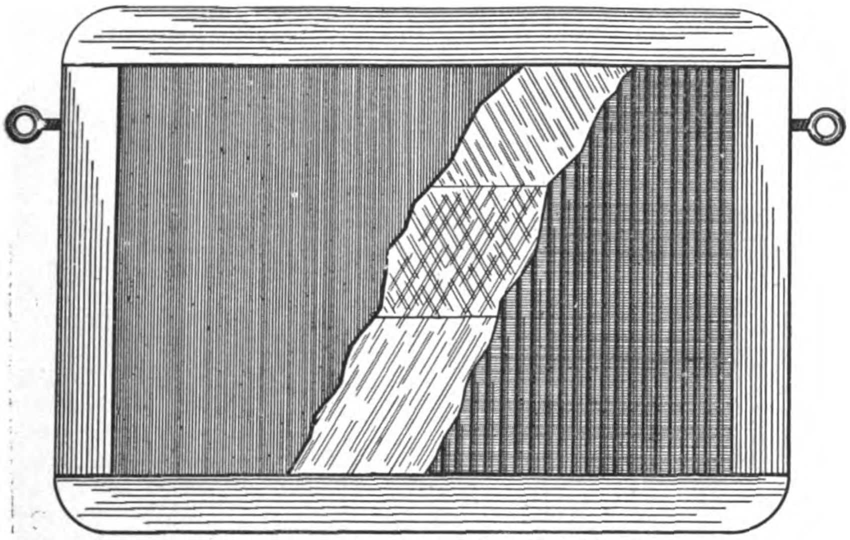

FIG. 4.—CONSTRUCTION OF ELECTRIC SLATE.

The slate is wound with 55 feet of No. 27 tinned iron wire, the different convolutions being put on with a space between of a trifle less than one-quarter inch. If this winding is neatly done the 55 feet of wire will just go on. As the two covers for this slate and winding are made from thin Russia iron, the wire winding must be covered with sheets of mica. Plates of mica are carefully laid on each side of the slate and sheets of mica are bent around the edges just before the iron plates, accurately cut to the proper size, are laid on and temporarily attached by binding with twine.

Great care must be exercised to prevent the ends of this winding from coming in contact with the Russia iron sides, and to prevent this the following precaution is suggested: Where the holes are drilled, insulated copper wire can conveniently be made to join the iron by cutting off a small length of the insulation and wrapping the copper wire about the iron. As copper conducts electricity about seven times as readily as iron, the copper wire will not get very hot, and consequently its insulation will not be injured. The copper wire should be about No. 20, being larger than the iron winding, which gives it an additional factor against heating.

Figure 3 shows the frame of the slate partly taken apart, illustrating the usual construction of the frames. As the slate with its winding, together with its iron sides and mica, is thicker than the width of the groove in the framing, it will be found necessary to widen the groove all around. This can be accomplished by taking the frame to pieces, and after clamping in a vise, by running over it with an adjustable plow or groove cutting plane. Almost any carpenter is ready to do this if the reader does not possess such a plow.

The slate, with its winding, mica covering and iron sides, is illustrated in Fig. 4, with the mica and Russia iron partly cut away. The screw eyes serve as one pair of terminals for the winding, allowing of the suspension of the slate direct to the lighting wires should the performer wish to vary the trick. A four-ampere fuse is sufficient to place in the circuit of this slate and the lighting wires, fusing out quickly without damage to anything should the iron covers of the slate accidentally come in contact with the wire on the slate. As a matter of precaution, even with the most carefully made "electric slate," the writer strongly recommends careful fuse protection. The ends of the winding of the slate can be conveniently brought out through the crack formed at the juncture of the pieces of framing and secured secretly to the screw eyes.

As the slate is primarily designed to stand on an easel, it must have a second set of terminals for the winding near the bottom, where the framing rests on the shelf of the easel. By referring to Fig. 5 the idea will be made clear. By means of a very small gouge plane or chisel a groove is run around the outside of the frame, designed to accommodate a copper wire in order to make contact with a copper stud at the bottom of the frame. This is done on each side as illustrated, the groove being filled with putty after the wire is in place. The little easel is not quite as innocent as it appears, having a wire concealed in each leg and a pair of contact studs on its little shelf. The floor of the cabinet is equipped with little brass or copper plates, for contact with the studs under the feet of the easel, which lead to the large supporting screw eyes of the cabinet.

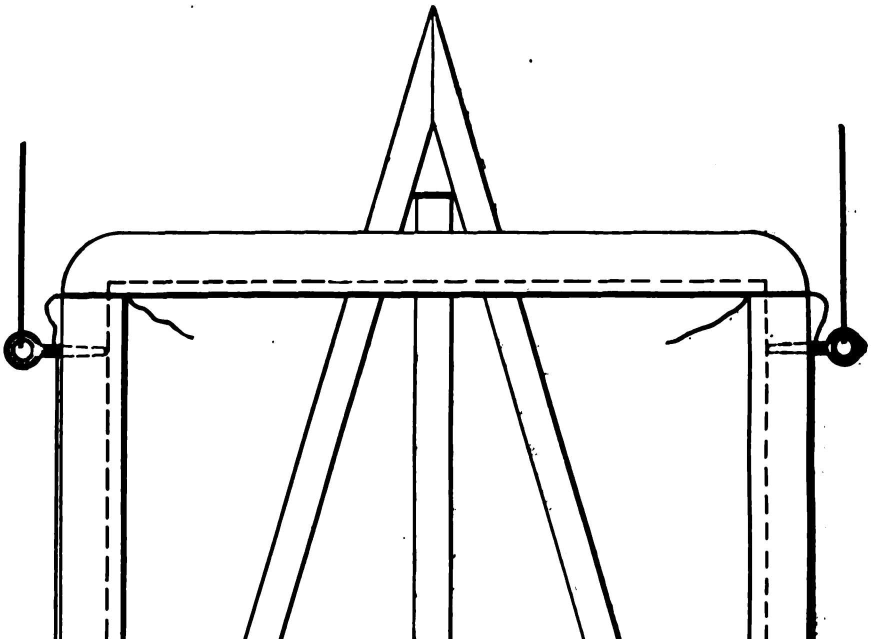

FIG. 5.—ELECTRIC CONNECTIONS OF SLATE AND CABINET.

The ribbons, which are innocent in appearance, possess their own trickery in the form of copper conductors, No. 14 copper wire being sufficient to carry the current economically. This wire had better be of the double cotton covered type, which may be tinted the same shade as the supporting ribbon, and effectually hidden from view if a little care is taken to stitch the wire to the ribbon with silk thread. The Russia iron sides of the slate may be given a slate colored covering of mineral paint to resemble so closely the real thing that detection is very improbable. The slate as described here requires about thirty seconds to get "piping hot" and accomplish the "spirit work." Numerous trials should of course be undergone before exhibiting the trick to an outsider, as the performer would find it awkward to remove the covering scarf with a flourish and find the spirit had not completed the writing. Of course, the ribbons with the secret wires must run to innocent looking hooks above, and the circuit must be equipped with a switch readily reached by an assistant behind "the scenes." The writer wishes to impress, in closing, the importance of neat and, above all, careful work in the matter of insulation and fuse protection, as a voltaic arc within the cabinet would make things too uncomfortable for any well behaved and properly brought up spirit to associate with.

◆

Central Station Working.

METER TESTING.

BY R. H. STERLING.

In the first portion of this paper, on the testing of meters, two methods of testing were given: one where the meters were run in comparison with a standard meter of the same capacity, and the other by the use of the stop watch. A timing watch that can be purchased for $6 will answer as well as a more expensive article.

While the method of taking the revolutions with a stop watch in calibrating meters may require less current, it is nevertheless a tedious operation with a large number of meters to be tested, but is very accurate and reliable and may be used for calibrating the standard meters, or an occasional meter brought in to ascertain if a customer's complaint is just.

The speed of the meter is directly proportional to the load, and by taking the number of revolutions of the small "telltale" seen revolving on the top of the meter, in a number of seconds equaling the constant for that meter, the number of revolutions noted will correspond to the number of amperes passing through it. The following are the constants for the various Shallenberger meters:

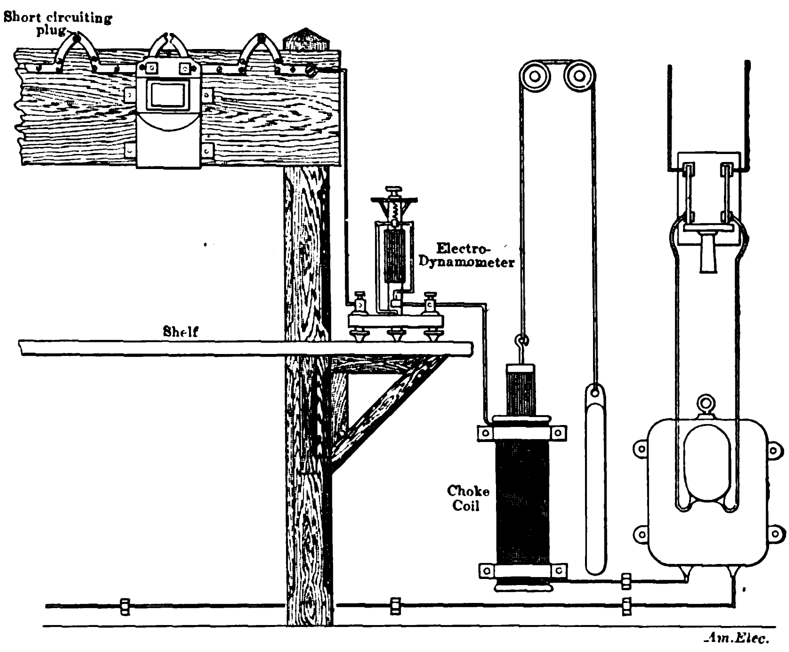
5 Ampere	22.5	80 Ampere	252.1
10 "	33.8	120 "	386
20 "	63.3	160 "	506
40 "	126.6	200 "	623

For example, take a 10-amp. meter, the constant for this being 33.8; if the "telltale" makes three revolutions in 33.8 seconds, 10 amps. are flowing through it; if five revolutions in the same time, 5 amps. are passing through it, and so on. It is, of course, essential that the case should be on the meter at the time of making the test, otherwise the currents of air would cause inaccuracy. A case with a square of glass inserted in the top, so as to observe the index, is necessary for this test.

A positive means must be employed to determine the exact amount of current passing through the meter. This is the first and most essential requisite in meter testing, and calls for a reliable alternating current ampere meter placed in series with the meter being tested. A Siemens electro dynamometer is the best form of instrument in use. It is correct for either direct or alternating current, but is not a portable instrument, and should only be used in the testing room. They are capable of quite a wide range of load, and will be found far better than a switchboard instrument in meter work. It will pay a station to own a reliable instrument of this kind, for all the switchboard ammeters can be checked up by it as well. Careful instructions should be had from the maker for using it, as it is not a direct-reading instrument.

Another useful appliance that is almost indispensable in a testing room is some means to graduate the amount of current to send through the meters. A bank of lamps is frequently used, but fine gradations cannot be had with these, and besides, the current used is wasteful. A reaction or choking coil will be found most serviceable, and the current it consumes is negligible. One to control current from 5 to 40 amps. can be easily made as follows:

A brass tube, 3 ins. inside diameter and 2 ft. long, is split on one side its whole length with a narrow cold chisel or saw to prevent its heating from eddy currents; fiber or lead wood head are placed at each end, and the spool thus formed is wound with four layers of No. 4 B. & S. magnet wire. A core is now required of soft iron wire. Common bare iron wire of about No. 12 gage is cut up into lengths of 2 ft.; enough to make a solid core is formed around a long brass rod with an eye at the end; two fiber or wooden heads threaded on the rod to keep the iron wires in place, the wires being further held in place by wrappings of tape or twine. The core should slide up and down easily inside of the brass tube, and should be counterpoised with a cord and weight. This coil is to be placed in series with the meters and convenient to the standard ampere meter. For controlling heavier currents a somewhat larger coil will be required.



TESTING RACK FOR METERS.

A convenient rack to carry the meters while being tested is very important. It should be a rigid frame, high enough to allow the dials to come on a level with the eyes, and rows of stiff ¼ in. brass studs projecting out about 3 ins. from strips of brass which are screwed to the rack. The object of these studs is to support the meter in a perpendicular position, and at the same time make connection with it to the current—for the studs are placed the same distance apart as are the binding posts of the meter into which they slip, and are fastened by the set screws. The first and last strips in the row are connected to the circuit, and the series of meters completes the circuit.

The accompanying sketch illustrates a convenient arrangement for a testing rack with connections of dynamometer, choke coil and transformer. The details are also shown for the brass strips and studs to support meters on the rack.

These pieces are best cast in brass, and the studs of ¼-in. round brass rod and 3 ins. long, screwed into them. Where they meet at the top a narow space is left and a conical hole drilled in the center, into which is fitted a conical brass plug. This is for completing the circuit should not the full complement of meters be tested at once. A short circuiting switch should also be provided for the dynamometer, for it should not be left in circuit continuously.

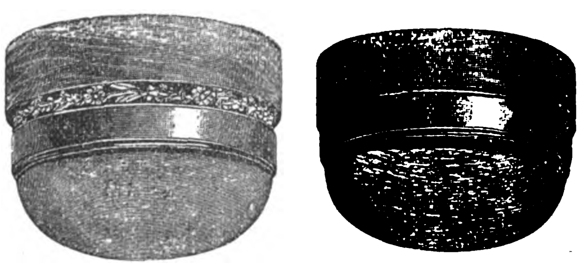
The fact was mentioned previously in

this article that meter cases were not dust or moisture proof; the great importance in this matter seems to be hardly realized by the manufacturers. If they could see a meter brought in with a family of cockroaches enjoying the gear wheels as a merry-go-round, they might deem it necessary to provide some means to exclude such elements; as it is, the station manager has to rely on his own ingenuity in the best manner at hand. The first thing that would naturally suggest itself would be putty—that good old stand-by, but a sticky and unpleasant thing to handle—but if taken in the right manner is no trouble and is very effective. The writer has for some time employed a large tin force gun, something on the order of a battery syringe. The putty must be somewhat softer than it usually comes to force out easily, and the opening at the end made short and not more than ¼ in. in diameter. The putty is placed in the instrument by removing the top and withdrawing the piston.

Now, before the case is placed on the meter a thin even streak of putty is laid on the edge of the back plate by drawing the instrument quickly along while forcing in the piston at the same time. The case can now be placed on and screwed down, and with a cloth any of the putty that may be squeezed out between the edges wiped off. With the later type of meter, which has a cast iron cover over the binding posts, a line of putty should be laid in the crevice between the wooden block and the back plate, for insects can crawl from there down behind the block into the meter. A meter thus treated can defy dust, moisture and all other of its enemies; and with reliable jewels may be safely left to guard the company's revenue for long periods of time without being overhauled. In a large number of meters examined, sealed in this manner and in use for three years, I have yet to find one that needed cleaning, and a far lower percentage of worn jewels discovered, proving that dust and grit have a tendency to shorten their life.

A book should be kept giving a history of each meter under its respective number; the date it was cleaned and tested, and per cent of error; the date installed with consumer's name, and the state of dial when taken from the testing rack. This last is important, for a meter-man frequently forgets to take the reading when he installs the meter, so that when the monthly reading takes place there would be no first reading to make the subtraction with.

Of course, it is important to seal a meter with the lead seal, which in some measure prevents tampering with the instrument, but, unfortunately, the public is becoming educated up to the different means to "beat the meter," and the only safe guard is careful inspection for jumpers on meter loops and small punctures in the tin case, in which is inserted a fine wire to retard the movements. The meter-men should be instructed to be on the lookout for such appliances. The clerk who has charge of the meter books is in the best position to watch for these thefts, for he soon becomes familiar with the average monthly consumption of each consumer, and upon his discovering a sudden falling off in a bill with no good reason, and the standing of the consumer would warrant it, a watch should be kept. When a person undertakes to steal current, he is not discreet and starts in to cut his bill in two the first month. I can recall one instance, a saloon keeper, who paid $10 to a discharged electric light employee for the knowledge of using a jumper. He got so reckless that he never turned his lights off, night or day, and his bill was less than half the usual amount. An observing meterman discovered this and looked for the trouble and found it. Now that different States are enacting laws to protect companies from the theft of current, this practice will be somewhat abated.



FIGS. 1 AND 2.—CEILING FIXTURES.

There is one more subject before closing that is worthy of discussion, and that is, the complaints of consumers regarding their meter bills. These complaints are more prevalent during winter when bills are naturally higher. The man whose self and family were away for an entire month and whose bill was as large as ever, is sometimes a difficult question to deal with. If he will admit he left a servant in the house, that explains it, for the average "hired girl" is a timid thing, and is apt to turn on a full blaze of light to scare away burglars. The cellar light with switch at the head of the stairs is a source of big bills in residences, for it is hard to remember to turn it off on coming up stairs when the light itself is not in view. It is best to listen to all complaints patiently, even to the most angry customer. "A soft answer turneth away wrath"—let him have his say, but stoutly maintain your meter is correct, for it is a sign of weakness to too quickly give in and offer to have the meter tested and is often a poor policy, since you well know nothing can change a meter to make it run faster than it should, being, on the contrary, only liable to change in the customer's favor. When he says he knows to a cent what his bill should be, for he has kept track, etc., there is where you have him, nine times out of ten, for give him paper and pencil and ask him to kindly put down the number of hours he has burned each lamp for the month. On footing up the lamp hours, you will discover he has over-reached, or come very near the amount of the bill. This is a trying time for both, for he cannot go back on his figures. Do not crow over him, for then he will become hot, but smooth him over and you have a friend in him evermore.

NAVAL MARINE ELECTRIC LIGHTING.

BY E. W. COUNTISS.

APPARATUS AND CIRCUIT FITTINGS.

In the preceding article the design and running of circuits was considered, and some of the more special fixtures described. To return to the drilling, we must take into consideration the structural work of the ship. Where a number of feeders and mains are carried along on the same deck, each wire having a hole, and every hole being from ¾ in. to 1⅝ ins. in diameter, it will be seen that considerable metal is to be taken out of the beams, weakening them to a very appreciable extent. To remedy this as far as possible, the plan of allowing the web between holes of the same circuit to be of the same thickness as the diameter of the hole, has been instituted, and the circuits spread apart some distance from each other, the further the better.

In securing the backing in place, holes are never drilled in the deck plate, and wood-screws run into the deck plank above it. Should this be done, as soon as the deck leaks, the water will find its way to that hole, and a dirty, rusty streak will show across the molding, even if nothing more serious occurs. This is the reason the government specifies machine screws for this purpose; and all screws must be brass, no iron ones being allowed, except in the water bottoms, where chemical action would be set up between two different metals by the salt water.

The point to be secured is the greatest amount of illumination with the least number of lamps, thereby reducing the number of parts, and also the weight of the installation. Some idea of the weight of one of these plants may be had from the statement that the 300-light plant on the U. S. S. "Raleigh" weighed 18 tons of 2240 lbs. exclusive of foundations, steam, exhaust and drain pipes, and sundry other fittings, while the plant of the U. S. S. "Texas," with 583 lights, weighed about 40 tons. It will be seen that by the time a plant is completed, there is quite a weight added to the ship, in spite of the fact that every article and appliance is reduced to a minimum weight. The fewer the parts the less complex it is, and the less care it takes to keep in order.

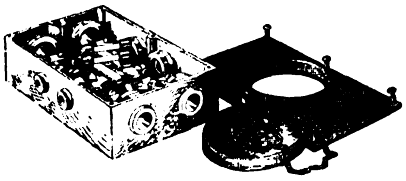


FIG. 3.—BRANCH JUNCTION BOX.

Proceeding to place the fixtures and other wiring appliances, we will start in the cabin. Over the table is placed a ceiling fixture like that of Fig. 1 or Fig. 2. If the table extends both ways equally from the center when drawn out for state occasions, one light would be placed over the center and another at or near each end. If the center of the table happens to be in the center between two beams, little trouble is experienced in locating the fixtures, but if the center should be on the bottom of a beam, the method is to build out on both sides of the beam with a shapely block and secure the fixture to it; and the other fixtures in the same way.

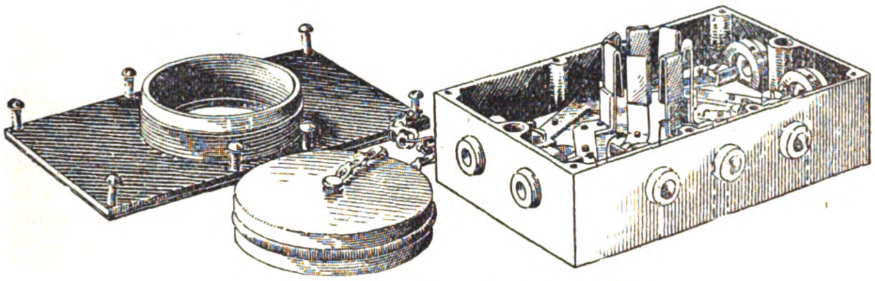

FIG. 4.—WATER-TIGHT ATTACHING PLUG.

The sideboard next is in order, and in the center of the crown piece is usually a single light bracket, or possibly a double ram's-horn bracket. If no conveniences are available for this purpose, and none can be made to suit, then a ceiling fixture like those in Figs. 1 or 2 is installed on the deck in front of it, using the same style fixtures throughout. Over the transom is placed one, two or three one-light brackets, so that a person sitting or lying down may have light for reading.

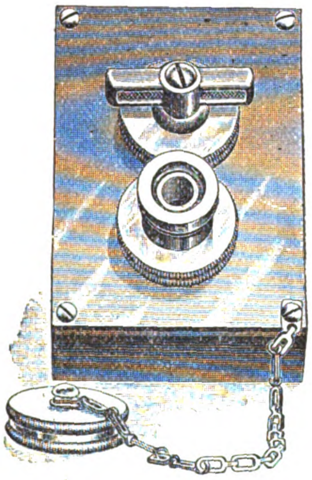

FIG. 5.—WATER TIGHT SWITCH AND RECEPTACLE.

Provision must also be made for the portable desk light, as well as for the ventilating fan. So over the table on a branch circuit are cut in two ordinary keyless receptacles. These have no switches, as the desk light has a key socket and the fan a starting switch. Into this receptacle is screwed a non-water tight attaching plug made of hard rubber, to which is attached the double-conductor silk portable wire at one end, with the fan or light at the other. Fifteen feet is the length allowed for this cord. In the stateroom are located two more of the same style of receptacles for the same uses as in the cabin. The bath room has a ceiling fixture to correspond with the rest of the suite. In the office is installed duplicates of the stateroom fittings.

The ward room is fitted in the same manner, the number of the lights varying according to the size of the space to be lighted. The ward-room staterooms are each provided with non-water tight attaching plugs and receptacles for fan and desk light.

Solder joints are prohibited, and a junction box (Fig. 3) is inserted in the mains, either single or double, as occasion requires, and specifications permit. Where the wires enter the ends of these boxes the spaces are filled up with a soft rubber coned gasket and stuffing nut, the wire and gasket both being treated to a liberal coat of P. & B. paint or its equivalent, after the braid has been removed from the end of the wire and the strands well soldered together. The branch wires enter and leave the sides in the same manner, and with the same precautions taken. All lights are taken from the mains in the same manner, each one having a double-pole fuse protection.

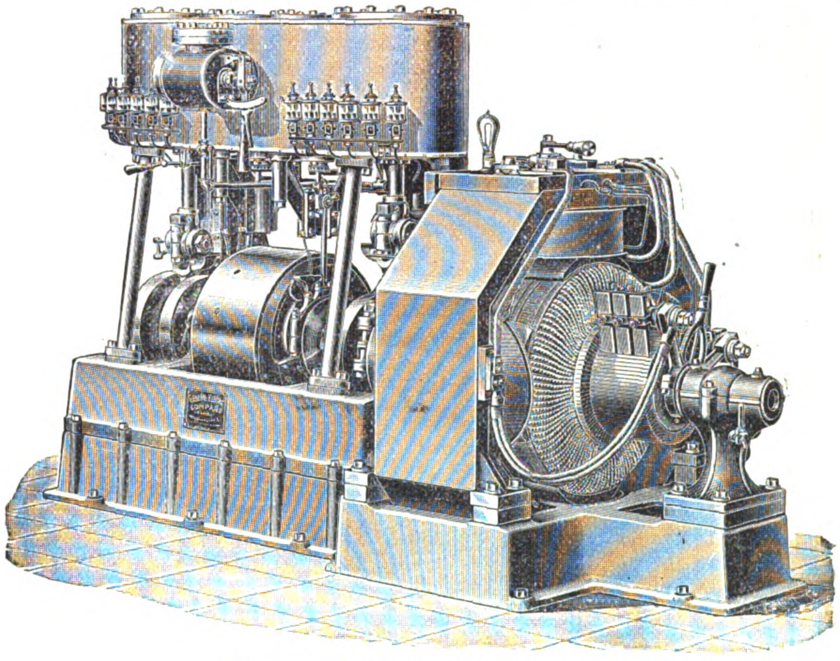

FIG. 7.—NAVAL TYPE GENERATING SET.

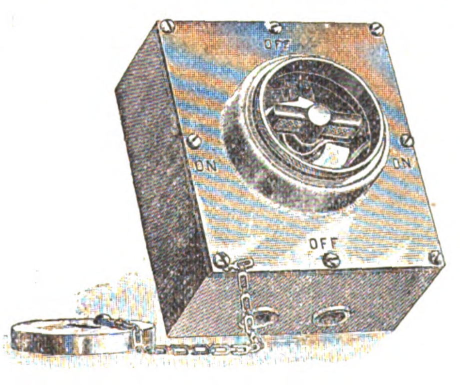

FIG. 6.—WATER-TIGHT SWITCH.

To prevent any accidents through lights going out at inopportune times, such places as on the bridge and magazines are provided with double outlets. Each side light and the masthead and towing lights are provided with two sockets and two lamps, which are attached to lengths of heavy portable wire, with a water-tight-at- places as on the bridge and magazines are taching plug (Fig. 4). Where the water-tight receptacles (Fig. 5) are drawn off from the mains, each one has its own junction box; so that in case one fuse or one lamp fails, the other is still in working order.

The same arrangement is carried out in lighting the magazines and shell rooms. except that the magazine lanterns are placed in light boxes fitted with heavy glass bull's-eye lenses, instead of the light being in the magazine. These lanterns are still further supplied with a candlestick, so that in case the plant is totally disabled during battle, the men in the magazines may still be able to serve out ammunition. The water-tight combination switch and receptacles are placed inside the light boxes so that the lids may be closed down over them to prevent accidents to persons passing by.

In some instances large narrow spaces take the place of these light boxes, being built between the magazines, as in the "Texas," which had two of these, each of which lighted up five magazines. A sub-main was taken off the principal main by means of a feeder box, with a switch (Fig. 6) to control the lights. In front of each bull's-eye, two steam-tight globe fixtures were installed, each having its own junction box. This was the electrical outfit. In addition, a magazine candle lantern was hung permanently behind them.

The mast-head light must have a circuit

running up the mast, with a switch at or near the deck, and two water-tight receptacles near the light, which plug into the receptacles by means of water tight plugs and heavy cords.

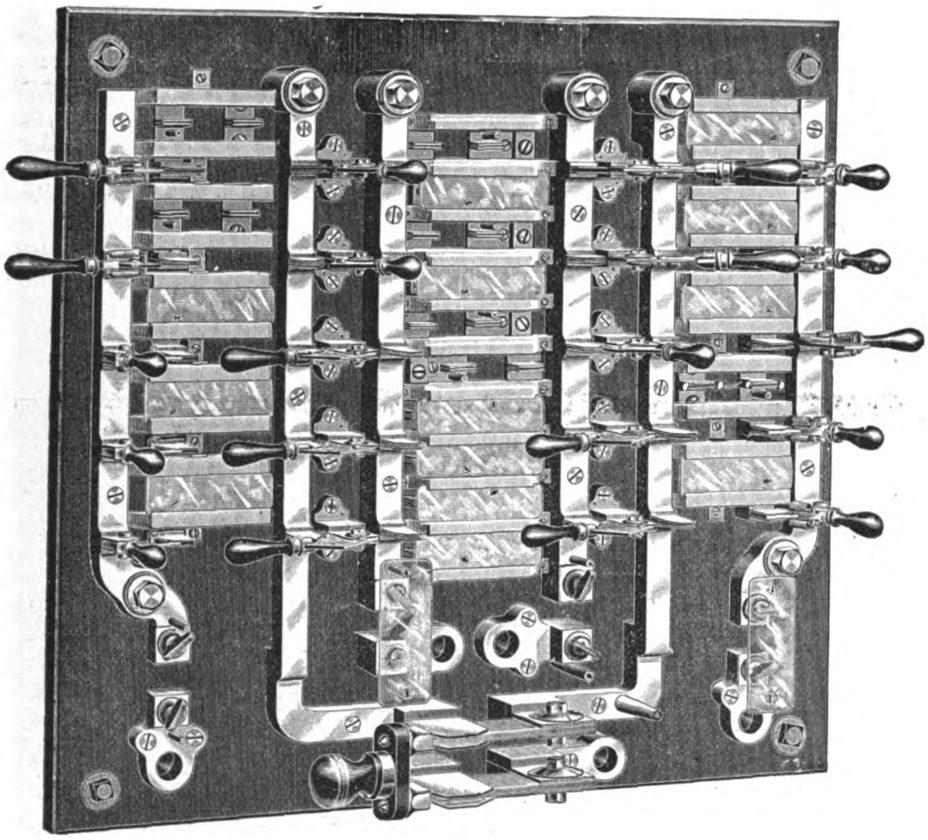

FIG. 8.—STANDARD SWITCHBOARD—2 GENERATORS.

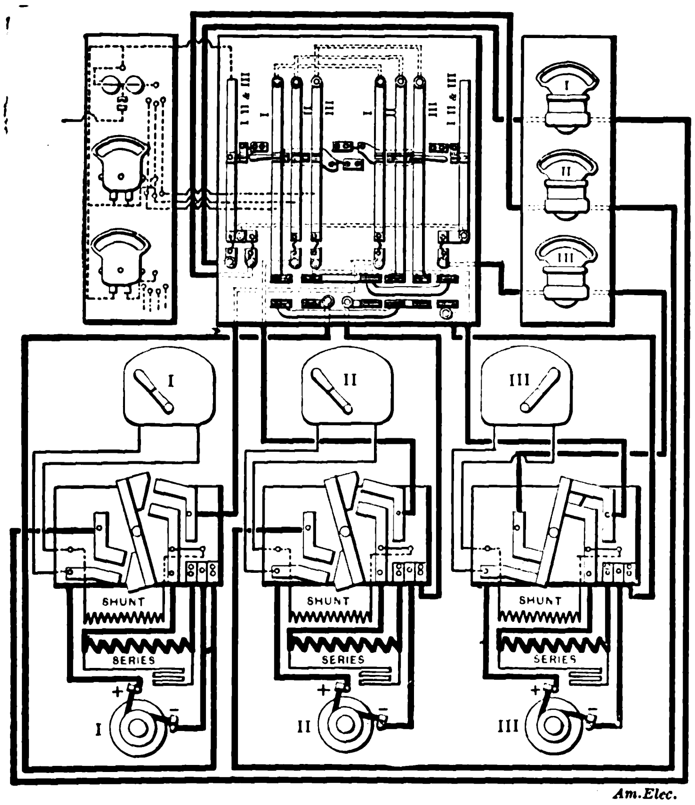

FIG. 9.—CONNECTIONS OF STANDARD SWITCHBOARD—3 GENERATORS.

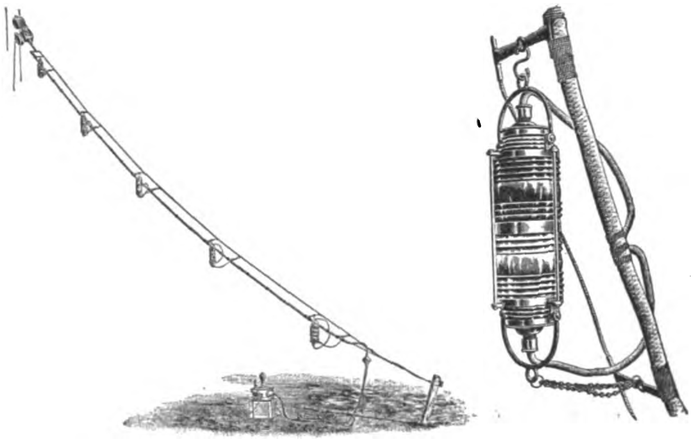

FIG. 10.—ARDOIS SIGNAL HOIST.

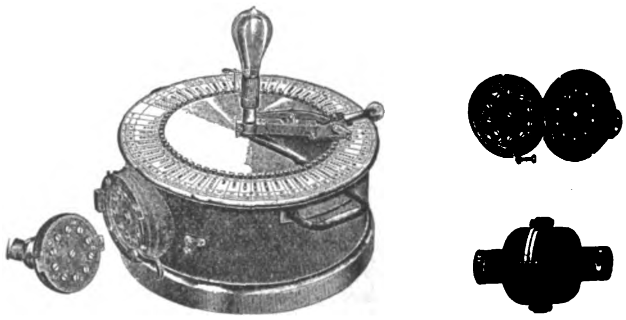

FIG. 11.—ARDOIS KEYBOARD AND COUPLING.

The truck-lights are double lanterns fixed to the top of the mast by a stationary cap, into which the lantern proper screws. The upper or red half is separated by a diaphragm from the lower or white half. Each half has a 32-c.p. lamp, to which current is fed by means of portable wire through pulsating switches located on the bridge. Either half can be caused to burn at will, according to the signal to be transmitted.

The engines and dynamos (Fig. 7) are direct-connected, bolted to a common bed plate, and rigidly secured to the foundations. Each engine is fitted with thrust collars, oil guards and pipes, and so built that the different parts may be easily reached for examination and repair. All nuts have suitable locking devices to prevent them from working loose.

The engines are of the inverted vertical type working with a steam pressure of 100 lbs. per square inch if compound, or 80 lbs. if simple, with a vacuum of 25 ins. they must also be able to work with a variation of 20 lbs. above and below these figures. A variation of not more than 2 per cent in speed is allowed by specification between full load and 20 per cent of full load, when the steam pressure is constant; and the extreme allowance in revolutions is 5 per cent when the variations of steam and load are within the limits, and between full load and no load.

The generators are of the multipolar direct-current compound type, so designed that the magnetic field is inappreciable at a distance of 15 ft. The field frame is divided horizontally through the center of the shaft so that the upper half may be quickly removed. The normal voltage is 80, and the compounding must be such that at the regular speed of the engine the characteristic curve shall show not over 1½ volts from 80 volts from full load to no load. They must be capable of operating in parallel. The armature must be thoroughly ventilated, well balanced and run true, precautions being taken to prevent oil running along the shaft to the windings.

The dynamo must also stand an overload

of 33 per cent for a continuous run of two hours. Both engine and dynamo must be capable of standing this strain for this period without injury to either, mechanically or electrically. The insulation resistance of generators must be one megohm, pressure not being over 1000 volts.

The switchboard, as shown in Fig. 8 is for two dynamos, and the wiring diagram of Fig. 9 is for three dynamos. They are so designed that one or more dynamos may be run singly or together, each circuit being fed at will from either dynamo, or both; or, if three are installed, from all three. It is one of the most compact boards ever used. The center panel shown is placed between two instrument boards, one on each side. The one to the right has on it the ammeters and the one on the left the voltmeters and ground detector.

The three panels are of dark slate, free from minerals, and set in a heavy hard wood frame, the whole being supported by a rigid iron framework or heavy brackets, with sufficient space behind to allow of inspection and repairs.

The Ardois signal hoist (Fig. 10) is composed of four double lanterns, similar in general construction to the truck lights. Each half of each lantern has a wire leading to the keyboard. A general return wire forming the heart of the cable is also connected to each half lantern. The keyboard shows the combination of the lanterns, of which combinations there are 30, each having its own key. Either half of the lantern may be made to burn at will, but both halves of the same lantern never does when the set is in complete order.

For signaling, the Boughton telephotos sytem has also recently been tried experimentally. This consists in the use of four double lanterns similar in general construction to the Ardois light. The lower portion of the lanterns is surrounded by a red lens inclosing four lamps; and the upper portion by a white lens inclosing three lamps, the lesser number being used above in order to equalize the intensity of the red and white rays. Four of these lanterns are placed on wire cables as shown in Fig. 10, each half of these lanterns has a wire leading to a keyboard, a general return wire forming the heart of the cable. By means of the keyboard, combinations of the lanterns may be made by which signals are transmitted. Either half of the lantern may be made to burn at will, and both halves are never illuminated at the same time.

The binnacles, engine, telegraph and rudder telegraphs are also lighted electrically, of which more will be said later on.

The searchlights (Fig. 12) are of the horizontal carbon type of lamps, with both hand and automatic feed. The positive leg of the light has an adjustable resistance inserted in it, so that the current can be varied at will. The standard sizes are 18 ins., 24 ins. and 30 ins. for the projectors, the size given being the diameter of the reflecting mirror at the back of the arc. The turntable upon which the drum is mounted is connected for turning freely in either direction, by means of gearing, and by throwing out the clutches it can be moved about freely by hand. The drum itself is mounted and swung on trunnions, and is controlled in the same way as the turntable, with similar gearing and clutches.

In Fig. 12 the various parts are lettered as follows: A, hand star for slow vertical movement; B, wheel for nut clutch, used for connecting or disconnecting the drum from base mechanism; C, wheel for slow horizontal movement; D, hand star nut for fastening turntable to center pin; E, wooden handles to move the drum by hand; F, clutch for preventing hand star A from moving when electrical control is used; G, controller switch; H, controller handle; K, focusing screw; L, tube in which crank handled socket wrench is inserted to move the carbon carriers by hand; M, door used when carbons are to be adjusted or changed; N, doors used for the changing of the carbons or the cleaningof front door and mirror; O and F, peep-sight holes; R, sliding case, to be opened

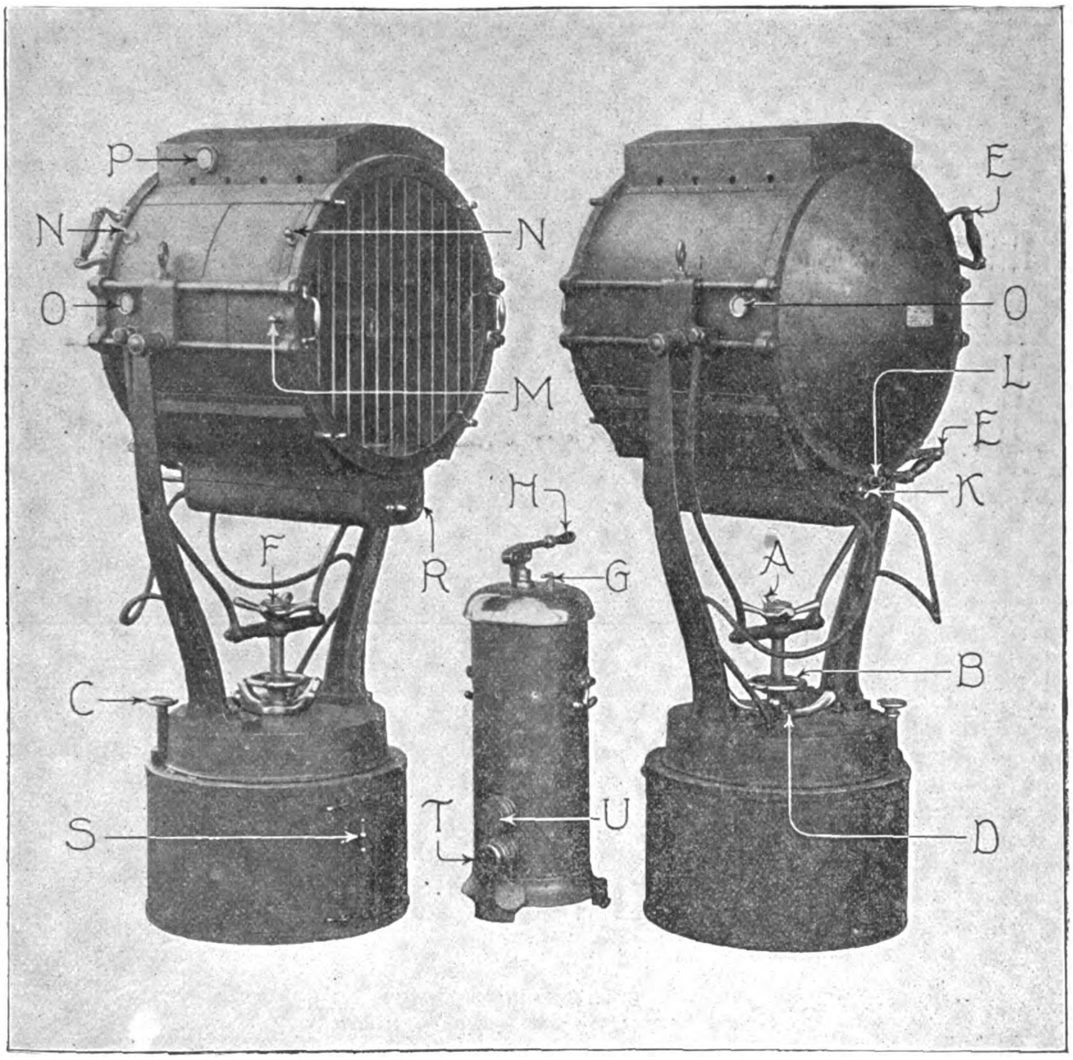

FIG. 12.—SEARCHLIGHT, RECEPTACLE AND CONTROLLER.

when lamp mechanism is to be inspected; S, lamp main switch; T, contact box for controller cable; U, controller fuse.

The electrically controlled projector has a cable connecting it to the controller, which can be placed at a distance and the operator may direct the beam of light where needed. Two shunt motors are contained in the base of the projector, one for training and the other for elevating and depressing. The connecting cables between the projector and controller is so arranged that by depressing the handle on the controller the beam of light is depressed; by raising it, the beam is elevated; turning to the right or left, the beam follows the handle.

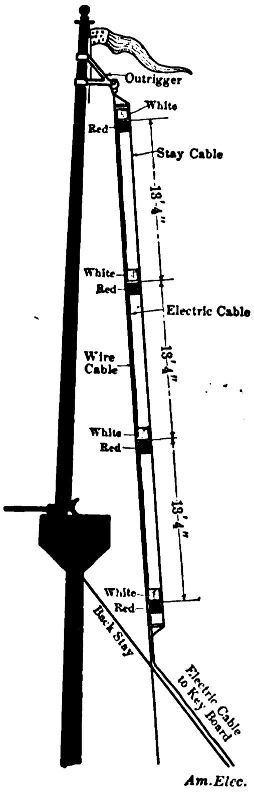

FIG. 13.—TELEPHOTOS SIGNAL HOIST.

If the handle is both pulled up and carried to the right, the beam follows the handle, which is capable of transmitting a double motion to the lamp. The speed of the motors is governed by the distance the handle is moved, and their motion can be checked instantly by releasing the handle of the controller, which immediately flies back to zero.

FIG. 15.—DESK FIXTURE.

These lights will burn six hours with one trimming, and an 18-in. light will render plainly discernible a light colored object 10 ft. x 20 ft. at a distance of 2¼ miles; the 24-in. light at a distance of 3 miles, and the 30-in. light at a distance of 3½ miles.

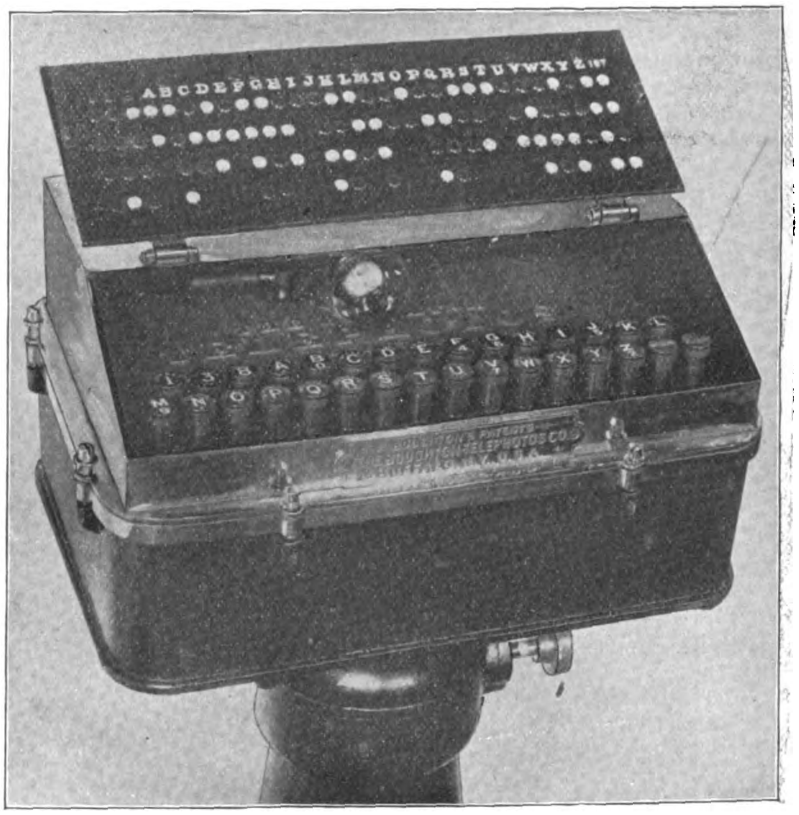

FIG. 14.—TELEPHOTOS SIGNAL KEY BOARD.

The 18-in. light is most economical and gives the best results at from 30 to 35 amps.; the 24-in. at from 50 to 60 amps., and the 30-in. at from 75 to 90 amps., with voltage at 35, 55 and 75 respectively. An 18-in. light recently installed, during a test burned for 6½ hours at 35 volts and 35 amps., without a flicker, so positive and close was the feeding mechanism as controlled by the automatic feed gearing.

Another very important appliance is the electric whistle operator and controller, shown in Fig. 17, which can be applied to any ordinary steam whistle by removing the bell and whistle valve, securing the magnets and valves to the top of the whistle pipe, and screwing the bell on top of the magnets. The utility of this valve control is such as to commend itself the first time a heavy fog settles down about a ship. By means of proper connections between the clock-work control (Fig. 18), in the case, which is installed in the chart house, a blast of 8 seconds' duration is made once each minute, without any attention other than to turn the handle of the switch to the extreme left (Fig. 20), when the spring catch will hold it, until released by hand.

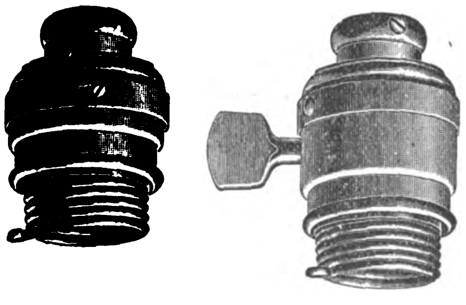

FIG. 16.—LAMP SOCKETS.

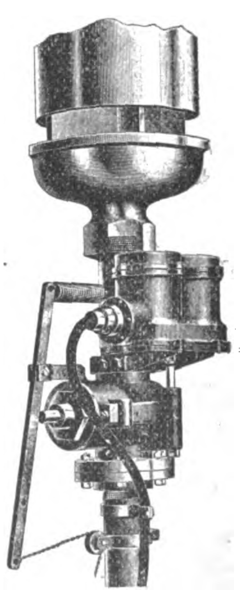

FIG. 17.—ELECTRIC WHISTLE.

When the area of the bridge is such as to make it necessary, several of the whistle valves may be installed, and the whistle operated from any one of them. When the lever (Fig. 20) is turned in such a position that it stands at right angles to the base upon which it is mounted, the current flows through the switch contacts to the valve magnets, which opens the valves, allowing the steam to escape and blow the whistle. On the lid of the clock case is a telegraph key, which, by being depressed, will also blow the whistle.

Current is taken from one of the continual service circuits, by means of a junction box, with a double pole water-tight switch in the circuit.

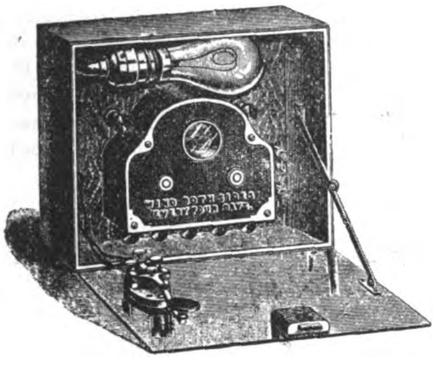

FIG. 18.—ELECTRIC WHISTLE OPERATING CASE.

Single conductor No. 14 B. & S. wire is run between the mains and the clock case to the terminals marked + and —, Fig. 19. A triple conductor wire is run between the operating switch (Fig. 20) to the clock case and connected to terminals 3, 4 and 5. A double conductor is run between the whistle and terminals 6 and 7 on the clock case. This completes the wiring. The fuses are 2 amps.

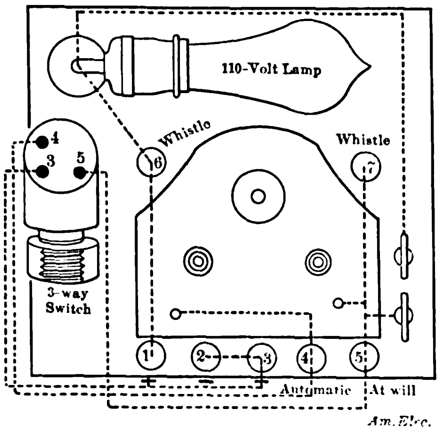

FIG. 19—DIAGRAM OF WHISTLE CIRCUITS.

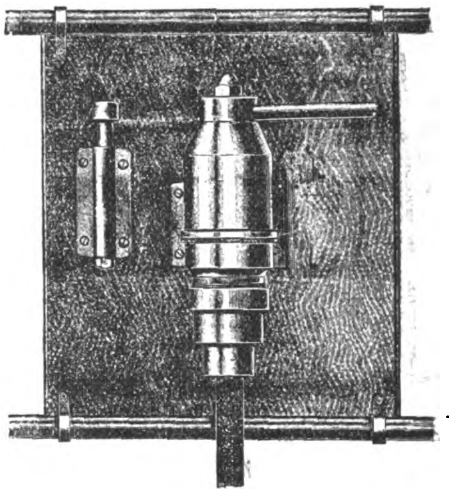

FIG. 20.—OPERATING SWITCH FOR WHISTLE.

◆

INTERIOR WIRING.

BY CHARLES E. KNOX.

CONTROL OF LIGHTS.

So far we have made no particular reference to the control of the lights. This must necessarily be considered now, as it enters very materially in laying out the branch circuit wiring.

In these *fin de siècle* days things formerly considered luxuries are now accepted as ordinary necessities. In the early days of interior wiring local switches for controlling the lights were rarely used. Sometimes a switch was placed at the distributing center for controlling all the lights fed from that point, but even this was infrequently done. Sockets with keys were generally used, and the lamps turned off individually by these keys.

FIGS. 2 AND 3.—TWO AND THREE CIRCUIT ARRANGEMENTS.

Now, however, it is considered almost essential (except perhaps in office buildings and stores) that all ceiling lights be controlled by a local switch placed at a convenient point for turning the lights on or off. In many cases the side bracket lights are also thus controlled. The greater convenience of controlling the lights by a switch, instead of by means of the key at the lamp, is unquestioned.

Aside from the matter of convenience, however, there is another point in favor of the increased use of local switches, and that is the cost of operation. In certain ways the comforts of our time have undoubtedly made us lazy. A door at the entrance to a public building nowadays, which has no automatic closing device, is very liable to be left open. People expect that it shall be closed without the effort required to close it.

So it is with lighting. If, after a person is through using the lights in order to turn them off he has to put himself to any great inconvenience, he is very apt to "forget" it (unless he has to pay for the lighting himself), and allows them to remain burning, while if the lights are controlled by a local switch placed conveniently near the point of exit from the room he is much more likely to turn them off. In fact, to the average person there is more or less fascination in a push button or rotating snap switch, and he more than likely takes some pleasure in turning the lights off by these means.

In many cases, therefore, the reduction in the amount of current consumed, due to using local switches, will, in a few years, overbalance the cost of installing these switches. Of course, where it is essential to keep the first cost or the cost of the wiring installation down, they have to be omitted.

In office buildings switches are not so necessary, as the brackets and desk lights are more used than chandeliers, and are therefore more easily turned on or off. Beside, after the tenants leave their room the cleaners come in, and when they go out they are required to turn off all the lights.

In private houses, hotels and in similar places, the chandeliers certainly should have switches, and it is becoming very common now to use them for controlling the side lights also. Where the side lights are placed more than seven feet from the floor this is almost essential. It is frequently required that the ceiling lights and side lights should have separate switches.

In case of large chandeliers or large groups of ceiling lights it is generally wise to use one or more switches for the ceiling lights in order to obtain different combinations of control. Of course, this is almost necessary where there are more than twelve lights to be controlled by a local switch, for the only alternatives are either to run the supply to the switch, thence returning to the distributing center, and there subdividing into smaller circuits in order not to have more than 6 amps. fed through one fuse (fire underwriters' requirement); or else to use fixture fuses.

Where more than one local switch is neither desirable nor necessary for controlling a certain group of lights, the switch may control as many lights as its capacity will allow, and a wire (of sufficient size, not to exceed the required loss) may be run to the switch and then return to the distributing center, where the circuit will subdivide into circuits not carrying over six amperes, these circuits being run to the lamps. (See Fig. 1.)

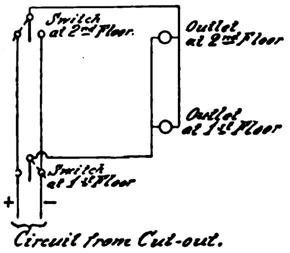

FIG. 4.—HALL OUTLETS CONTROLLED FROM TWO POINTS.

Where more than one switch is used to control a number of lights forming a chandelier the arrangement should be such as to get the greatest possible number of combinations of control; for example, it would be unwise to control a twelve-light chandelier in two groups of six each, for then we could have only two combinations —either half or all; whereas, if it were controlled in two groups, one of four and the other of eight lights, we could get three combinations—one-third, two-thirds, or all the lights.

If the lights are single-light outlets placed in rows or in the form of a square, etc., they are generally wired alternately, giving two combinations. Of course, more combinations can be obtained, but as this greatly complicates the wiring, it is not generally desirable. When it is done, however, care should be taken to have the outlets, occupying similar relative positions, wired on the same circuits, or controlled by the same switch. For instance, the outlets on the end of a row or at the corners of a square should be controlled together; otherwise the result would be unsymmetrical when one group of the lights was turned on. Figs. 2 and 3 show such groups controlled in two or three combinations respectively.

As to the location of switches in bed rooms, parlors, etc., they are best located near the doorway at a point most convenient when entering the room. In large rooms they are sometimes grouped together and placed in a box which is built in the wall back of a panel in the wainscoting. Where the switches control lights in public places, as in the halls or lavatories of a hotel, their location is largely a matter of taste. Some people want them placed so that nobody can "fool" with them, and therefore are placed in the cut-out cabinet or else in the switch lockers; while others want them to be more accessible and located in plain view near the outlets which they control.

For controlling a large number of lights from a point not near the distributing center, an automatic switch is sometimes used, which is controlled by a push-button circuit. Any number of push buttons at various locations may be used to control the switch, the switch itself being located at the distributing center. This switch, of course, performs the same function as a knife switch, but is operated by two electromagnets (or pairs of electromagnets) acting in opposite directions; these electromagnets are controlled by push-button circuits (of small wires), which are run to the desired points of control, the circuits being controlled by the push buttons. There may be any number of points of control without increasing the cost to any great extent, as the control wires are never over No. 14 B. & S. wire.

The advantages of these switches are that they save copper, as it would otherwise be necessary to run the main through which the lights were fed to the point of control and then back to the distributing center; they are also more convenient to operate than a knife switch. Their disadvantage is that they are likely to get out of order.

Automatic door-switches are sometimes used for controlling single lights in closets where the light is only required to be turned on when the door is open. These switches are single pole, and are nothing more than a push-button switch placed in the door casing in such a way as to be operated by the pressure of the door against the push button when the door is closed, and being so connected that when the button is pushed in the circuit is open. When the door is open the push button is forced out by a spring and the circuit is closed, thereby turning on the light. Their sole advantage is that they are automatic; their disadvantages are that they also are likely to get out of order. If the door is not closed the light, of course, is left burning; their position is such as to require cutting the door framing and casing; for this reason it is difficult to get more than one conduit to the switch, which makes it necessary to put this light on the end of the circuit.

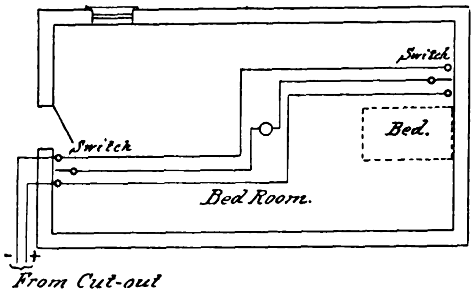

FIG. 5.—CEILING OUTLET CONTROLLED FROM TWO POINTS.

In a private house it is often desirable to have a portion of the hall lights so arranged that they may be turned on (or off) from the lower hall or entrance, and to turn them off (or on) from the upper hall or from one of the bedrooms. Switches for this purpose are specially designed, called "three-point" switches. The connections for such a circuit are shown in Fig. 4. These switches only break one "leg" of the circuit, and are therefore single-pole switches, and as the rules of the National Board of Fire Underwriters require double-pole switches for currents exceeding three amperes their use is limited to controlling a few number of lights only. They are also frequently used in rooms where it is desired to turn on the lights at one point and turn them off at another, as for instance in a bed room, as shown in Fig. 5. In this case the lights may be turned on in entering the room and turned off just before retiring. As will be seen from the diagram, the lights may be turned on or off from either point.

◆

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

THE EXPRESS SYSTEM.

In the last article the main features of the Express system were discussed, but only those parts considered in detail which related to the apparatus and circuits enabling the subscriber to signal the central office. In Fig. 1 is shown a simplified diagram of the Express system. At the bottom and top of this figure are shown the subscribers' lines, leading in each case from the subscriber's telephone apparatus to the drop and jack at the central office. This part of the apparatus is the same as that shown in the last article, but in this figure the details of the local circuit at the subscribers' stations have been omitted for the sake of clearness.

The jacks and drops belonging to these lines are, as has already been stated, stationed at the "B" boards of the exchange. The subscriber's indicator battery is represented at S I B and the indicator at I I. Leading from the section of the "B" board shown at the top of the figure is a trunk line leading to a plug on the second section on the "A" boards. It will be noticed that this trunk line terminates in a plug at each end, and is termed the "A" trunk. An intermediate jack and plug are shown in the circuit on this "A" trunk, but these at present need not be considered. Suffice it to say that the plug at the "B" board is connected by a metallic circuit to the plug at the second section of the "A" board. Leading from a certain jack on the second section of the "A" board is a trunk line extending to a plug on another section of the "B" boards. This is termed a "B" trunk. Only one "A" trunk and one "B" trunk is shown for simplicity, but it must be remembered that a number of "A" trunks lead from each of the "B" boards to the "A" boards, and that from the "A" boards a number of "B" trunks lead back to each of the "B" boards.

When a subscriber, as for instance the one shown at the top of the figure, removes his receiver from its hook, his indicator, I, is displaced automatically, and the operator at the particular "B" board at which this indicator is located extends the circuit of his line to one of the "A" boards over an "A" trunk. This he does by inserting the plug of an "A" trunk into the jack of the calling subscriber. The operator at the "A" board having learned the desire of the calling subscriber, extends the circuit to that subscriber's line by the means of the "B" trunk still further on to the particular "B" board at which the jack of the called subscriber is placed. This the "A" operator does by inserting the plug of the "A" trunk used into the jack of a "B" trunk at her board. The "B" operator at whose board the calling subscriber's jack is placed then completes the connection between the two subscribers by inserting the plug of the "B" trunk used into the jack of the calling subscriber's line. The two subscribers' lines are thus shown connected in Fig. 1 by the process and over the circuits just described.

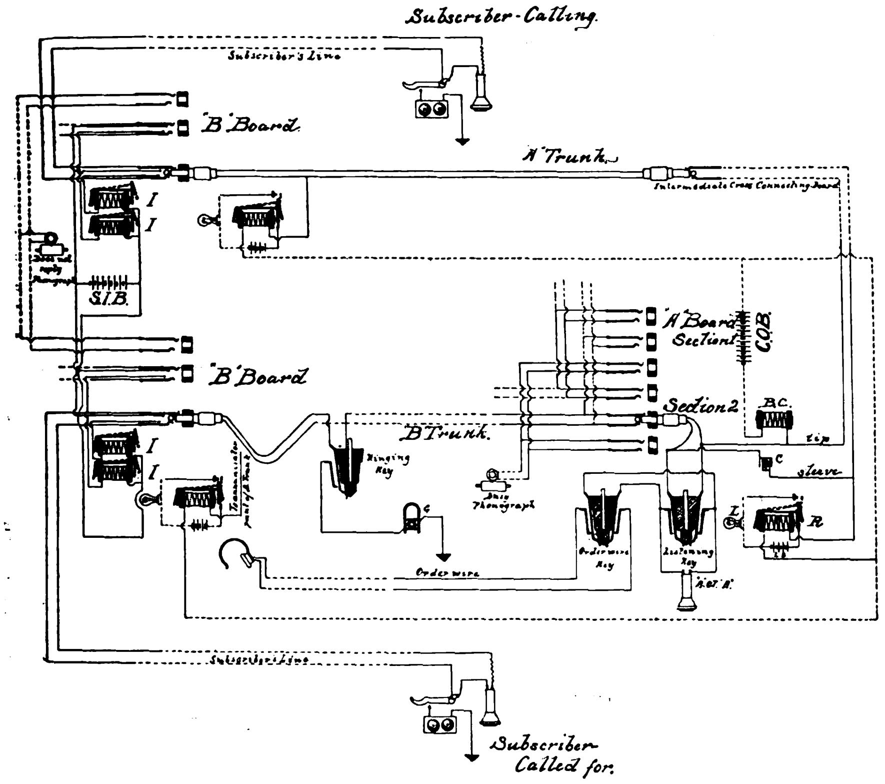

FIG. I.—SIMPLIFIED DIAGRAM OF EXPRESS SYSTEM.

In order to facilitate matters it is evidently necessary that a most complete and elaborate set of signals must be provided between operators. The first in this series of signaling operations is to notify the "A" operator that her attention is desired on a certain "A" trunk. This must always occur just after the "B" operator has inserted one of the "A" trunk plugs into the jack of the calling subscriber's line. It will be noticed in Fig. 1 that the relay, R, operating signal lamp, L, is bridged across the tip and sleeve strands of the "A" trunk circuit, and this bridge may be traced from the tip strand through the balance coil, B C, thence through the clearing out indicator battery, C O B, to the battery wire, thence through the coil of the relay at the "A" board, and thence to the sleeve strand of the "A" trunk. Remembering that the calling subscriber at the top of the figure has removed his receiver from its hook, then the insertion of the plug of the "A" trunk will restore the line drop, I, and at the same time will close the circuit from the clearing out indicator battery, C O B, and the relay, R, through the subscriber's line and telephone instrument. This will operate the relay and cause it to close the circuit of the signal lamp, L, thus calling the attention of the "A" operator to the fact that an unanswered call is upon the trunk line to which that lamp belongs.

The apparatus of the "A" operator is shown more clearly in Fig. 2. The sleeve and tip strands of the "A" trunk are shown at the extreme left of this figure. When the armature of the relay, R, is attracted as described above, the circuit from the local battery and white lamp is completed at the point, b, of the relay. It will be noticed that this local circuit extends through two of the springs, e and f, normally close on the listening key of the "A" operator, and also through a pair of contacts, l and c, held closed by the weight of the plug of the "A" trunk in its socket. The white lamp will therefore remain lighted until one of the following three things happens: Until the operator listens in, which causes the local circuit to break at the listening key; or until she removes the plug of that trunk line from its socket, which would break the local circuit at the point c; or until the calling subscriber hangs up his receiver, which would cause the relay to let go of its armature and thus break the circuit at point b. The white lamp remains lighted therefore as long as the call on its "A" trunk is unattended to.

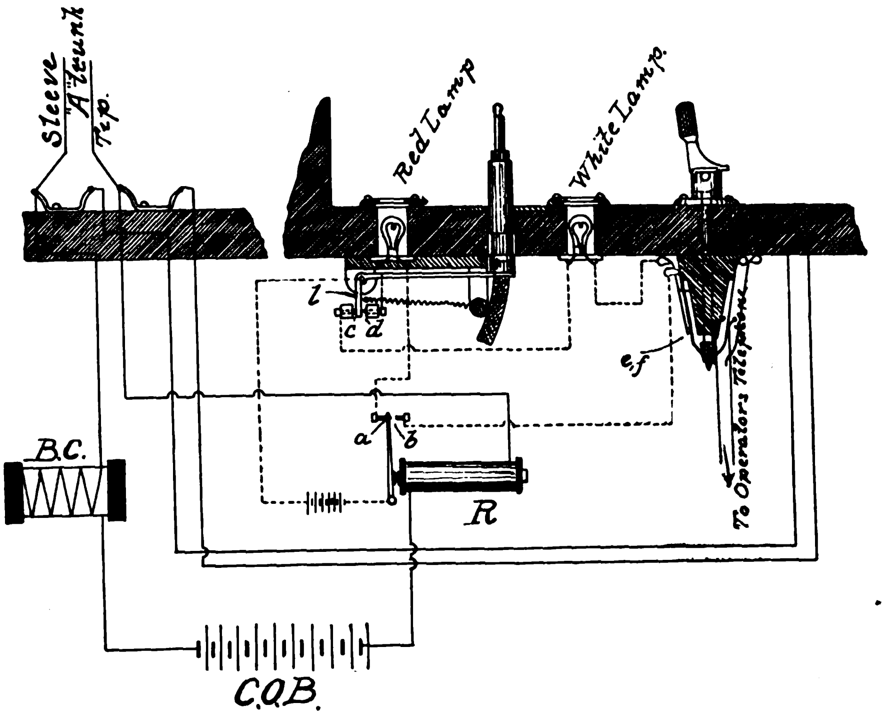

FIG. 2.—TABLE OF "A" BOARD.

The first act of the "A" operator on seeing this light is to throw her lever corresponding to that light into its horizontal position, thus connecting her telephone to the terminals of the "A" trunk in the usual manner. This enables the "A" operator to communicate with the calling subscriber in the ordinary manner. It should be noted that these keys on the "A" operator's boards are the only means afforded to any operators for communicating with subscribers. The operation of this key breaks the circuit of the white lamp at the points, e, f. As soon as the listening key is thrown again into its normal position the white lamp is again lighted, thus calling the operator's attention to the plug to be used in making the connection.

This precaution is a wise one, for before making the next move in the connection, the "A" operator must communicate with the "B" operator at whose board the called-for subscriber's line terminates. The "A" operator does this by depressing her order wire key, shown in Fig. 1, but omitted from Fig. 2, which act connects the "A" operator's telephone directly with the telephone set of the outgoing "B" operator. The "A" operator then tells the "B" operator the number of the line with which connection is desired, and the "B" operator in return tells the "A" operator the number of the trunk line she is to use in making the connection.

Herein lies one of the greatest defects of the system. That is, the necessary waiting by the "A" operator for the reply of the "B" operator. This is a loss of time on the part of the "A" operator, for it often occurs that the "B" operator may have several other connections under way which she could not well leave in order to reply to the "A" operator by designating the number of "B" trunk to be used.

It will be noticed that the trunk jacks of the "B" trunks are in reality arranged on the plan of the multiple board. This is for the purpose of placing within the reach of every "A" operator a jack belonging to every "B" trunk line. No test system, however, is required on these jacks, as an "A" operator always first learns from an outgoing "B" operator which "B" trunk to use, and of course a "B" operator would never designate any trunk which was already in use or "busy," as it is termed.

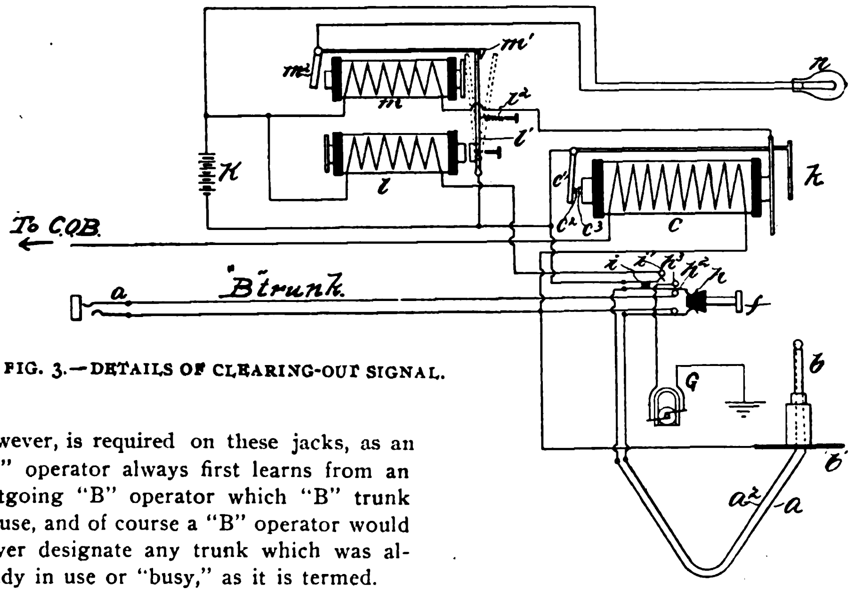

FIG. 3.—DETAILS OF CLEARING-OUT SIGNAL.

It would seem that a "busy" test, or preferably a visual "busy" signal for the multiple jacks on the "A" boards could be used with advantage. This would enable the "A" operator to at once select an idle "B" trunk and at the same time inform the proper "B" operator of the connection to be made and the trunk line plug to use in making it. For instance, the "A" operator could simply say: "1504 on 10," meaning by the first number the number of the subscriber called for, and by the second number the trunk line to be used.

We have now carried the connection, or extended the circuit of the calling subscriber's line, as far as the trunk line plug at the outgoing "B" board. The outgoing "B" operator then completes the connection by inserting this plug into the jack of the called subscriber. The "B" operator then depresses her ringing key, shown in a simplified form in Fig. 1, which sends calling current from the generator, G, over the sleeve strand of the plug cord, thence to line and to ground through the polarized call-bell at the subscriber's station.

The next feature to consider is that of the automatic clearing-out signals. As the connection between the two subscribers is made by three operators, it is evident that three distinct clearing-out signals should be given, one at each of the boards of the operators who help establish the connection. Turning again to Fig. 2, it will be seen that the raising of the "A" trunk plug from its socket changed the circuit of the local battery from the white lamp to the red lamp, by moving the selecting lever, l, from the point, c, to the point, d. Remembering now that as long as the calling subscriber's receiver is off its hook, the circuit from the clearing indicator battery is closed through the relay, R, at the "A" board, thus attracting its armature, V^1. As soon, therefore, as the calling subscriber finishes his conversation, he hangs up his receiver and thereby breaks the circuit through the relay at the "A" board, thus closing the circuit through the red lamp. This lamp will therefore be lighted as a notification to the "A" operator that disconnection on that trunk is desired. The replacing of the plug in its socket opens the circuit of the red lamp at the point, d, thus extinguishing the lamp.

The apparatus at the "A" board is very ingenious and deserves special attention. It should be noticed that should an operator by mistake remove one of the "A" plugs, and replace it in its socket before the subscriber connected had hung up his receiver, the white lamp would be relighted, thus calling the attention of the operator to the error. The clearing-out signal is given to the incoming "B" operator in much the same way as that on the "A" board, the clearing indicator, or relay, on the "A" trunk of the "B" board being wired in multiple with the relay on the "A" board.

The clearing-out signal on the outgoing "B" board is accomplished by much more complicated means, and will be explained by reference to Fig. 3. In this figure the ringing key, f, is shown in more detail than in Fig. 1. a^1 represents the "B" trunk line jack on the "A" board. In the normal position of the key the two strands of the "B" trunk are connected to the tip and sleeve of the corresponding plug on the outgoing "B" board. When, however, the key is depressed, the sleeve strand of the cord is connected with the calling generator, the other terminal of which is grounded. When the operator depresses this ringing key, a secondary pair of contacts, i, i^1, are closed, thus actuating the lower magnet, l, of the compound relay, and causing it to attract its armature, l^1. When the operator allows the key, f, to rise the armature, l, falls back but is caught by the hook, m^1, of the upper coil, m, of the relay. The hook, m^1, and the tip of the armature are platinum pointed, and their contact causes the signal lamp, n, to be lighted. This lamp remains burning until the called subscriber takes his telephone off the hook, which act closes the circuit through the combined clearing-out relay and signal, c, in exactly the same manner as the relays on the incoming "A" trunk line were operated. The operation of this relay therefore closes a circuit at the points c2, c3, through the upper magnet, m, causing it to raise the hook, m^1, and allow the armature, l^1, to drop back. This extinguishes the lamp, n, and shows the operator that the subscriber has responded. The armature, c^1, of the relay, c, remains attracted until the called subscriber hangs up his receiver, which de-energizes the magnet, c, and allows the signal carried by the armature to resume its normal position. This is the clearing-out signal for the outgoing "B" operator, and she accordingly pulls out the plug.

To review the action of the indicators at the outgoing "B" board, the releasing of the key for transmitting a calling signal to the subscriber lights the lamp, n, and shows the operator that this part of her work has been attended to. The response of the subscriber is indicated by the going out of the lamp, and by the raising of the signal, k. The clearing-out signal is given by the lowering of the signal, k.

We have now traced through the operation of all of the signals between the subscribers and the operators, and between the operators themselves, which were necessary to establish a connection between two subscribers; and also the subsequent signals between the subscribers and the operators, indicating that a disconnection is desired. The striking feature of all this elaborate system of signaling is that each signal is automatically given without the volition of the operator or subscriber, inasmuch as it is brought about by some action necessary in the actual connection or disconnection.

In order to reduce the work of the operators to the last degree, two phonographs are placed in connection with the exchange, one of which is constantly and politely repeating the sentence, "Busy. Please call again," while the other repeats with equal regularity, "Subscriber called for does not reply." Each of these phonographs speaks to a transmitter arranged in connection with an induction coil and battery in the ordinary manner. The terminals of the secondary of the induction coil of the "busy" phonograph terminate in a jack on each section of the "A" boards. In like manner the "does not reply" phonograph is connected with a jack on each section of the "B" boards. When, therefore, an "A" operator learns that a line called for is busy, she inserts the plug of the "A" trunk to which the calling subscriber is connected into the phonograph jack, and the familiar but disappointing message, "Busy. Please call again," is automatically conveyed to the calling subscriber.

In a similar manner the outgoing "B" operator may inform the calling subscriber that the subscriber called for does not respond. The use of the phonograph for this purpose may seem at first thought to be carrying the labor-saving idea to an extreme, but it enables an operator to attend to another subscriber while she is telling the first subscriber that his line is busy or that his party does not respond. It moreover insures that the wrath of the calling party will produce no evil effects on the nerves of the operator, which at busy times is no unimportant consideration.

The writer is indebted to an able article by Mr. George P. Low, in the "Electrical Journal" for much information concerning this very interesting exchange system.

◆

LESSONS IN PRACTICAL ELECTRICITY

REGULATING ALTERNATING CURRENT LINE VOLTAGE BY MEANS OF SYNCHRONOUS MOTORS OR ROTARY TRANSFORMERS.

When alternating current transmission of power in large quantities was first brought forward, it was thought that the drop due to line inductance would prove a serious obstacle. As has been explained in previous lessons, a circuit carrying an alternating current becomes a generator of e.m.f. through the cutting of lines of force in and out of the loop forming the circuit as the current rises and falls in value. The e.m.f. thus set up is a counter e.m.f., which reduces the line e.m.f., or gives rise to a drop similar to the drop due to resistance, though, unlike the latter, involving no direct loss of energy. Such drop, however, interferes with regulation, and also increases the C^2R loss on account of the additional current required to transmit a given amount of energy, such additional current being required to compensate for the e.m.f. neutralized by the counter e.m.f.

Steinmitz has shown, however, that the inductive drop may be counteracted by having in circuit a synchronous motor or, what amounts to the same thing, a rotary transformer, the field of which is given a high excitation, or, as usually expressed, is over-excited.

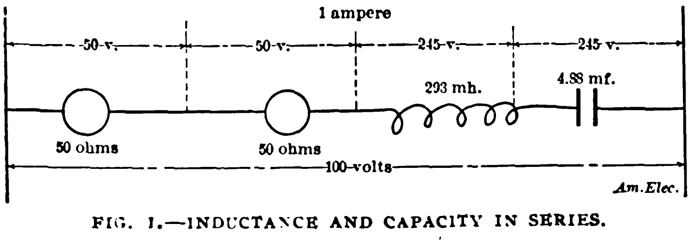

FIG. 1.—INDUCTANCE AND CAPACITY IN SERIES.

Such a motor or transformer placed across, for example, constant potential mains, has in its circuits three e.m.fs.—the impressed e.m.f. of the line, the counter e.m.f. of the armature, and the e.m.f. due to the inductance of the armature. The phase relation between the impressed e.m.f and the current evidently depends on the respective values and phase delations of these three e.m.fs.

Now, the synchronous motor, or the rotary transformer, has its field excited by continuous current, and as the speed of the armature is fixed by the frequency, it will thus be seen that as the strength of the field is changed in value, the counter e.m.f. will also be changed proportionately. Furthermore, such machines may be designed with values of armature inductance and strength of field, that the relation between the several e.m.fs. will be such that the current flowing will lead the impressed e.m.f. In other words, such a motor may be made for the purpose in question to act as the equivalent of a condenser.

Referring to Fig. 2, suppose that with a given current flowing in such a motor, O R is the drop in the armature due to resistance, and L R the drop due to inductance, this latter, of course, being at right angles to the ohmic drop. Then O L will be the resultant, or the total drop in the armature due to the alternating current passing. Suppose, now, that O C represents the counter component of the e.m.f. which overcomes e.m.f. Since the impressed e.m.f. must be the resultant of the counter e.m.f. and the armature inductive e.m.f., its value will be represented by the line O E, the diagonal of a parallelogram, whose sides are O L and O C. In the triangle L O R, the angle L O R is the angle of lag between the armature e.m.f. and the current: this follows, for the reason that, first, as explained previously, an inductance in a circuit causes the current to lag behind the e.m.f.; and, second, that the current flowing in a circuit must be in phase with the ohmic resistance. Consequently the angle R O E is a leading angle, and signifies that the current leads the impressed e.m.f. O E.

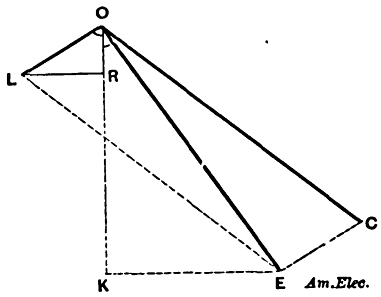

FIG. 2.—DIAGRAM OF E.M.FS.

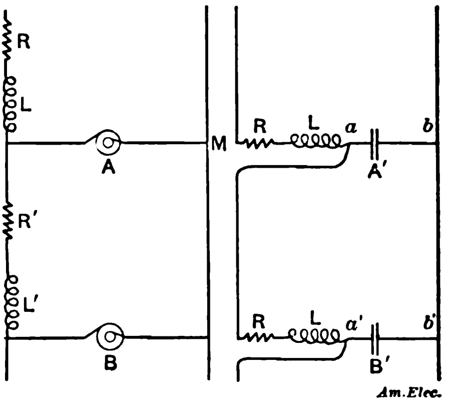
If the line O R is prolonged to K, and a horizontal line drawn from K to E, then the two lines will represent the components of the impressed e.m.f., the vertical component being in phase with the current and the horizontal component at right angles to the current. This latter, or K E, would be the same as that derived from a condenser were it in circuit, the motor thus being equivalent, so far as neutralizing inductance is concerned, to a condenser that would set up an e.m.f. having the value of K E.

In the example illustrated in Fig. 2, part of this condenser e.m.f. would be neutralized by the inductive e.m.f., L R, of the armature, the remaining portion neutralizing, partially or entirely, the inductive drop of the line; or, if of sufficient value, neutralizing both inductive and ohmic drop, or even raising the voltage of the line beyond the motor above the voltage at the terminals of the generator, if there is added to the line inductance additional inductance in the shape of choke coils.



FIGS. 3 AND 4.—MOTOR AND CONDENSER CIRCUITS.

The manner in which a voltage may be raised by an inductance and condenser in parallel is shown in Fig. 1. In this case the line voltage is 100, but the current passing in the circuit between the mains will, as shown, give rise to a voltage of 245 volts between the terminals of the inductance, and 245 volts between the terminals of the condenser. Since, however, the inductive voltage is in the opposite direction to the capacity voltage, the two will neutralize each other, so that the circuit will act as if it possessed neither inductance nor capacity. If, now, a line were to lead away from the terminals, for example, of the capacity, we would have a voltage of 245, or 145 volts more than that of the main circuit.

Referring now to Fig. 3, suppose A and B are synchronous motors or rotary transformers on a constant-potential line. Furthermore, suppose that R represents the resistance of the line from the generator to the motor A, and R' the resistance of the line from the point N to the motor B, L and L' being the corresponding values of the line inductance. Bearing in mind what has gone before, it will be seen that the case is similar to that of the right hand side of Fig. 4, where A' and B' are condensers, and the similarity of this latter figure to Fig. 1 will also be noted.

If the condenser value of the motor A is such as to neutralize the drop due to both L and R, then the voltage at a b will be precisely the same as the generator voltage. Similarly, if the capacity e.m.f. value of B is such as to neutralize the drop of L′ and R′, the voltage of a′ b′ will also be equal to the generator voltage.

In case it is merely desired to neutralize the inductive drop, the motor is designed to give rise to a capacity e.m.f. equal to the inductive e.m.f. of the line. If, on the other hand, it is also desired to neutralize the ohmic drop, or to over-compound—that is, to have at any given point of the line an e.m.f. higher than the generator e.m.f.—it is necessary to introduce into the line an inductance, the field excitation of the motor, of course, being made such as to produce a capacity effect sufficient to neutralize this inductance, as well as the line inductance.

To resume, by means of a properly designed synchronous motor or rotary transformer placed in circuit on a transmission line, the inductive drop of the line may be neutralized; or, by introducing an inductance or choke coil in series with the line, both the inductive and the ohmic drops may be neutralized; or, by introducing a still larger inductance in the line, the voltage at and beyond the motor may be made higher in value than the voltage at the generator.

Letters on Practical Subjects

Arc Dynamo Air Blasts.

To the Editor American Electrician:

I was interested in the letter in a recent issue from Mr. R. H. Sterling, describing his method of repairing the air blasts of T. H. arc dynamos.

His method is all right so far as it goes, but the writer believes that prevention is better than cure, and to do away with this troublesome device is far better than repairing it. I have made blowers and wings of many materials, with the idea of getting more weight in them, and thus obtaining more air pressure, most of which, while giving a 10-pound pressure, would either batter or break or crumble. The best results have been achieved by the use of an aluminum-nickel alloy. The only objection that I had against this is that the blower had to be opened once in three weeks to file off the projecting edge of the wing, which became spread out like a soft hammer; otherwise, these wings gave splendid service, and there was no flashing on 55 lights.

Not satisfied, however, the writer determined to dispense with the blowers altogether. My present arrangement consists of an air pump and reservoir, adapted to stand a working pressure of 100 pounds; a reducing valve, regulated to reduce to 10 pounds and to hold it steady; and a pair of insulated nozzles for each machine having openings of 1-64-in., the nozzles being connected to the fixed piping by heavy ¾ or ½-in. hose; a high and low pressure gauge, with dirt strainer, and the necessary valves, complete the outfit.

With this arrangement a 50-light 2000-c.p. machine will carry 60 lights, with absolutely no flashing, and do so right along.

The interior parts of the air blast are removed and the oil cup done away with, thus preventing the machine from being smeared with oil, as is usually the case. The commutator is oiled by hand, the same as other dynamos, by a stick having leather facings, which are oiled from a small dish of castor oil. The gain in cleanliness is surprising. I expect soon to overcome the last objection named, the oiling of the commutator.

Any company operating five or more 50-light dynamos of the make named should, in the writer's opinion, install a pneumatic outfit as described, and compress air during the day when boilers are underworked and often blowing off. If there is an incandescent day circuit, so much the better, as then the air compressor can be motor-driven, or it may be belted to the main engine. It is well to avoid, however, the small steam direct-acting compressors, as they consume an enormous amount of steam.

The feeling of security and reliability accompanying this device is of immense value, and I shall be glad to furnish any further information desired.

Induction Coils.

To the Editor of American Electrician:

The advantage of increasing the length of the core of the usual form of induction coil does not seem to be generally known. The core should be at least 40 per cent. longer than the secondary winding, which greatly decreases the magnetic reluctance. I was able to increase the length of spark of a certain coil from 1½ to 3 ins. by thus increasing the length of core. As the vital part of all induction coils is the insulation, if paraffine is used, care should be taken not to overheat the material, since overheating impairs its insulating qualities.

Wilmington, Del.

Resistances of Telephone Induction Coil.

To the Editor of American Electrician:

There is evidently some mistake in the answer to a query about a telephone induction coil given in your May issue.* The resistance of the primary would be about 60 ohms, using No. 36 wire, 150 turns on a 9/16 core, and the amperage of the primary circuit would become excessively low. With a primary winding of 60 ohms, a transmitter resistance of 10 ohms, and a battery resistance (two cells Leclanche) of 1 ohm, the total resistance would be 71 ohms, giving a current of only 0.04 amps. But the resistance of the primary is increased, as the current is not a steady one, but an undulatory one, on account of its inductance.

The right size of wire should be No. 20 or 21, with about 180 turns in two layers, and about ½ ohm resistance.

As to the right resistance of the secondary, opinions differ. Some manufacturers advertise coils with 750 and 1000 ohms resistance, but they do not give such good results as 500 and 250 ohms coils, on account of the enormous impedance. I found that on most lines, especially when bridging bells are used, coils with a resistance of 50 to 75 ohms gave better results than those with high resistance secondaries. They will give the best satisfaction on lines having a resistance less than 2000 ohms.

Inductive resistances, i. e., series bells, are very bad in a telephone circuit. If bridging bells cannot be used on account of a long line and unequal distribution of instruments, series bells will give good results if shunted with condensers of sufficient capacity to balance the inductance of the bells. But the cost of condensers renders their use in telephoning prohibitive.

Henry P. J. Van Deth.

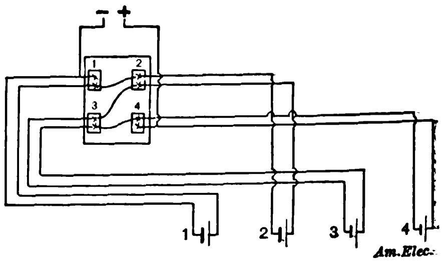
Telephone Connections.

To the Editor of American Electrician:

We use four cells of gravity battery on our exchange transmitter, and some annoyance has been caused to the operator when a cell was disconnected to be cleaned. The following arrangement was therefore installed:

Four single-pole W. U. style fuse blocks of the American Electric Fuse Co. were wired as shown in drawing. By placing a strip of brass in a fuse block, the corresponding cell is cut out by short circuiting. The cell can then be removed without breaking the current, and when replaced it is merely necessary to remove the brass strip, which throws it into circuit.



TELEPHONE CONNECTIONS.

Karl B. Davis.

Middletown, Ind.

Efficiency of Electric Heating Apparatus.

To the Editor of American Electrician:

In a recent issue of an electrical journal the statement was made that all electric heating devices have the same efficiency, and that a certain amount of electrical energy expended on a heater, no matter what its form or construction, would produce a certain definite amount of heat.

This is so obvious from the consideration of natural laws that it cannot very well be contradicted. Nevertheless, I have been confronted with the curves of efficiency obtained in a practical test of two electric heaters in raising the temperature of a small room, and it is found that for a given number of watts the temperature obtained in a given time was much greater in the case of one heater than the other; also, that the maximum temperature possible for a given number of watts was greater with one than with the other heater. From their construction the radiation might have been more rapid in one than in the other, but the test lasted two hours and the maximum temperature above referred to was measured at the end of the time.

Will you kindly enlighten one who has not given heating problems any particular study as to how to account for this apparent contradiction? In the less efficient heater where does the extra heat go?

L. T. RICE.

An Electric Alarm Attachment for Clocks.

To the Editor of American Electrician:

The following illustrations show how an electric alarm may be attached to any clock at trifling cost, and with materials which the average electrician usually has at hand. Fig. 1 shows the common type of dial for setting a mechanical alarm, which in this case will be used with a slight addition. After removing the pendulum, hands and face, pull or take off the alarm dial, which is only held on by friction; make a fibre cam, the duplicate of *F*, but a little larger in diameter, so it will not make contact anywhere, as shown in Fig. 2. In Fig. 2 the fibre is cut away so that the alarm will ring about a half hour, but it can be made to ring any length of time desired by filing the fibre more or less. Drill a hole in the fibre a little small, so it will fit snugly on the dial shaft, and set it so the point of the cam will come directly under the hour of XII. The reason for this is that in this type of alarm the hour set to ring stands directly under the hour hand of the clock; if it does not, this rule will not hold good.

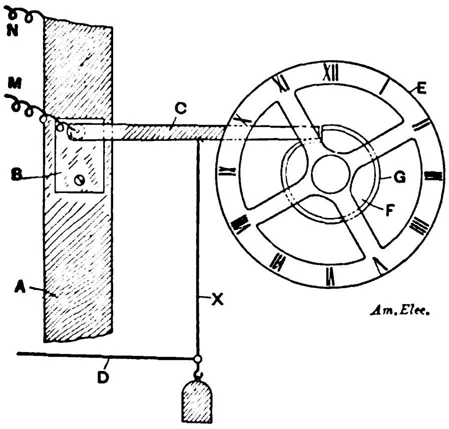

FIG. 1.

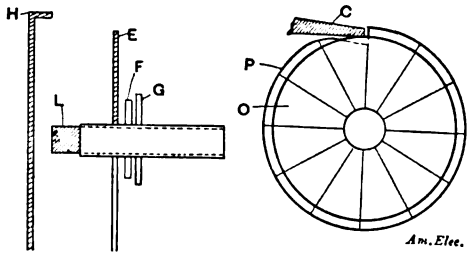
Fig. 3 is a side view of alarm dial, the letters referring to the same parts as in Fig. 1, excepting *L*, which marks the hour hand shaft. The small lever *C* must be removed and insulated from the works by riveting *C* to a small piece of fibre, *B*; utilize the screw which fastened *C* and *A* to screw the fibre *B* to *A*; drill a hole in *A* under the rivet to prevent grounding on *A*; suspend a small weight from *C*, so as to insure good contact; or weight *C* on its contact end by a bunch of solder. The wire may also be adjusted so that the mechanical alarm will ring at the same time. *D* is a guide to keep *X* from grounding; *H* is a top view of *C*. Now solder a small wire, *M*, to the rivet and run it to a single point switch on the side of the clock, the wire *N* from *A* running to one side of the bell. Connect the parts as shown in Fig. 4, and we are ready to test. Make sure that *C* is not grounded to any part of the clock; be careful that *C* makes contact to *F* directly under the hour XII of both dials; for example, if we desire the alarm to ring at 6 o'clock, as in Fig. 4, set the hour 6 of the alarm dial directly under the hour hand of the clock.



FIGS. 2 AND 3.

For clocks which have no alarm dials, make one, as in Fig. 2, *O* being a thin brass or copper washer about 1½ ins. in diameter and *P* a fibre washer ⅛ of an inch thick. Rivet *O* and *P* together, paste a piece of white paper on the front of *P* and lay off the hours on it in good black ink; drill a hole through the centre of *O* and *P* so that they will fit snugly on the hour hand shaft, directly under the hour hand; then file away *P* to adjust the length of time of contact. Cut a hole in the face of the clock 2 ins. in diameter so as to allow room for setting, and otherwise follow directions previously given.

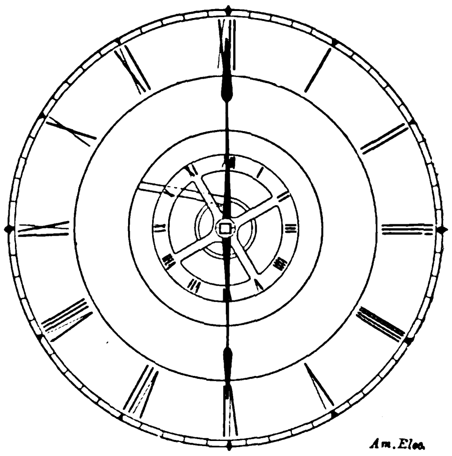


FIG. 4.

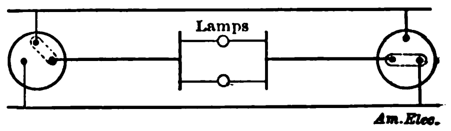
WALLACE BELMONT.

Omaha, Neb.

Three-way Switch.

To the Editor of American Electrician:

The sketch herewith shows a three-way switch which I have found very satisfactory, and which is different from the others which I have noticed in the last few issues of your paper, and requires less wire. I also enclose a very convenient arrangement of the Ohm's law formula, which does away with the memorizing of all three formulas. The method of using is as follows: If you wish to find the E. M. F. place your finger over the letter *E* and you have left *C*×*R* which gives the desired E. M. F.; if you wish to find the *C* or *R* place your finger over these respective letters, and the letters remaining indicate the desired formula. Thus the one formula only need be memorized.



3-WAY SWITCH.

The formula is as follows:

$$\frac{E}{C \times R}$$

Covering the *E* makes it $\frac{\quad}{C \times R}$.

" " C " " $\frac{E}{\times R}$.

" " R " " $\frac{E}{C \times}$.

Mansfield, O. **ALBERT S. WILSON.**

Testing-Set Batteries.

To the Editor of American Electrician:

So many inquiries have reached me regarding the construction of a suitable battery for use with the Wheatstone Bridge testing set, described in this journal, that it will be in order to devote a letter to the battery question. At the time of writing the articles in question, the entire matter on batteries was, on account of the great length of the descriptive matter, omitted entirely, hence the seeming incompleteness of the articles at that point.

For any bridge that is to be used constantly, or for considerable periods of time, I would under no circumstances whatever recommend the use of small cells that can be placed in the lid of a box as described. Even when the instrument is to be used in the same place occasionally, I would by all means set up a few cells of any good open circuit battery, and let the little cells in the box severely alone.

It is only when the box is to be used "on the road," so to speak, that the small battery in the lid is desirable. If I was inspecting the insulation of isolated lighting systems, or testing the insulation of house wirings, then the portable battery is not only desirable, but necessary. But for general use it is very unsatisfactory.

The battery described in a recent letter, made of silver plate, over which silver chloride has been fused, is known and described in the text books as the "De la Rue" cell, and it is the strongest cell commercially known at present. So many complaints of unsuccessful attempts to make up this cell have been sent to me that I am led to advise the use of some other, unless the silver chloride cells be purchased complete. They are on the market.

For occasional testing, plain cells of zinc and carbon, with the blotting paper wet with common sal-ammoniac solution, will work very well, and form a very cheap and efficient battery, provided their use is not steady enough to cause polarization. Some cells which will run quite steadily without polarizing are made of two thin carbon plates, 1 x ⅜ in., with finely pulverized black oxide of manganese placed between them, then the double plate is wrapped in blotting paper and treated exactly as described for the elements in the original description of the instrument.

Animal Horse Power.

To the Editor of American Electrician:

In your issue for April there is a question in regard to the number of horse-power required in an engine or electric motor to take the place of 14 horses. By long experience in the New England States with tread-mill horse-power, it is found that it cannot be replaced and do satisfactory service, unless the number of horse-power furnished in the engine is at least twice as great as the number of animals employed on the tread-mill. The reason for this is found in the fact that horses are not often worked continuously in the tread-mill. In many parts of New England the animals are driven almost up to a trot, and the railway horse-power, as it is called, is set at a very high angle, usually much higher than manufacturers intend. At this rate of speed horses can work for a short time only and then are compelled to rest.

In sawing wood, this rest is made use of to bring up a new supply of sticks and perhaps to take away that which has been sawed. In these short spurts horses sometimes do more than double the amount of work represented by a horse-power. It would, therefore, be impracticable in furnishing machinery to satisfy the demands of those who have used horses for motive power, which would do not less continuously than the horses can do at a spurt.

In the question referred to, the animal horse-power supplied should be 28, and with the 6 reserve which you properly added, the total would be 34 or 35. This would enable the work to be rushed and would probably give satisfaction.

It must not be supposed that horses can work at this rate for any length of time. The horses used in threshing, after the season is over, are notoriously in bad condition, and those sawing wood in the spring are equally thin and pretty well "played out" when wood sawing is over.

R. G. COTTRELL

Boston, Mass.

ELECTRICA CATECHIS

214. How can one calculate the force with which a magnet attracts another magnet or a piece of iron?

The force between the two equals the area of the common surface multiplied by the square of the number of lines of force per sq. c.m. divided by 25.14, or multiplied by 0.04. For example, suppose two pieces of iron 1 c.m. square and of any convenient length are bent into half circles and that the current is sent through a coil of wire wound about one or both pieces so as to magnetize the iron to a saturation of 5000 lines per sq. c.m.; the force at each joint between the two parts of the ring will be

$$0.04 \times 1 \times 5000 \times 5000 = 0.04 \times 25{,}000{,}000 = 1{,}000{,}000 \text{ dynes;}$$

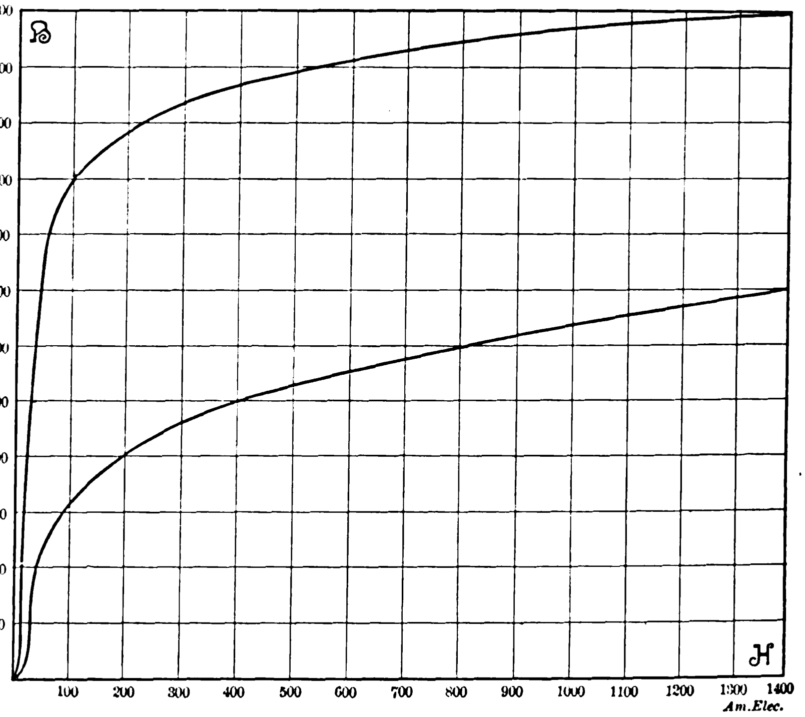
the total force will be the sum of that at the two joints, or double that at one, hence the total pull is 2,000,000 dynes. Since 981 dynes equal the weight of one gramme, the total pull between the two pieces is

$$2{,}000{,}000 \div 981 = 2024 \text{ grammes,}$$

or about 4.4 pounds.

215. How can this rule be modified for English measures?

Four hundred fifty-three and six-tenths grammes equal one pound. Hence if the dimensions and saturation are given in centimeters, the pull (in pounds) at each pole equals the area multiplied by the square of the number of lines per sq. c.m. divided by 25.14 times 981 times 453.6; or divided by 11,183,000. If English measures are used throughout, the rûle becomes: The pull (in pounds) equals the total area of contact (in square inches) multiplied by the square of the number of lines of force per sq. in. divided by 11,183,000 times 6.45 or divided by 72,134,000.



216. Give an example of calculating the pull of a magnet.

Suppose the magnet is made of iron 1½ x 1¼ ins., bent into U-shape and magnetized to a saturation of 40,000 lines per sq. in. The area of the iron is 1.875 sq. ins. at each end. The pull at each end is

$$\frac{40{,}000 \times 40{,}000 \times 1.875}{72{,}134{,}000} = 41.6 \text{ pounds.}$$

The total pull for both ends will then be twice this, or 83.2 pounds.

217. Is the above rule for the pull of a magnet rigorously correct?

It supposes that the magnetism is uniformly strong over the whole end of the magnet. If the contact between the magnet end and the piece it is lifting is equally good over the whole surface, the magnetism will usually be equally distributed and the rule in its simple form holds true. If the magnetism is stronger in some places, then the rule becomes more complicated.

218. How strongly can iron be magnetized?

There is no definite limit. Cast iron is well saturated at 40,000 lines per sq. in., or 6200 per sq. c.m. Wrought iron is well saturated at 100,000 lines per sq. in., or 15,500 lines per sq. c.m.

219. What is meant by iron being saturated?

When iron is subjected to a magnetizing force such as a current through a coil of wire surrounding the iron, the magnetization of the iron increases very rapidly at first as the current increases from zero. After the current has reached a certain value, any increase has less and less effect. This is illustrated in Fig. 1, in which horizontal distances represent magnetizing force and vertical distances represent the resulting magnetization of the iron. The turning point in each curve is called the point of saturation, being at about 100,000 for wrought iron and 40,000 for cast iron. These values vary with the quality and treatment of the iron.

QUERIES AND ANSWERS

Note.—Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied.

What is the liquid used in polarity indicators? E. B. M.

Iodide of potassium dissolved in glycerine is used for this purpose.

How many pounds of wire are required for the armature of the motor described on p. 280 of July, 1897, number? R. B. C.

Not quite two pounds.

What metal or substance will act as a positive insulator of magnetism? D. W. S.

None. An object may be screened from magnetic influence by means of an iron envelope.

What voltage and current is necessary to charge a storage battery? D. W. S.

About 2½ volts per cell, and 8 to 10 amperes per square foot of positive surface, including both sides of the plates.

In the article in the May number on "A Universal Motor and Dynamo" the working drawing gives the diameter of the d.c. motor field as 2⅛ in., and the text as 2½-in. Which is correct? T. E. O.

The text is correct.

Can the 50-volt dynamo described in the February, 1897, number, be used to run an arc light, and, if so, what size of carbons should be used? G. L. B.

Yes; use an ordinary constant-potential arc lamp burning 7-16 in. carbons.

What is the capacity of a storage battery of two positive and three negative plates and its discharge rate? L. A. V.

About 80, 70 and 60 amp.-hours for 8, 5 and 3 hours, respectively. The normal discharging rate is about 10 amps.

Does it make any difference on which leg of a circuit an ammeter is placed? H. R.

No, except in a case when it is not desirable to cross wires, when the leg making straight connection may be determined by trial at a switch or fuse.

Where is the voltmeter connected in testing an arc lamp? B. R.

It is customary to connect to the terminals, though it is sometimes desirable to find the e.m.f. across the arc, the difference being the drop in the mechanism.

How can I change a battery induction coil to work on a 110-volt circuit? J. N. P.

Find what battery current is used, and adjust the current from the lighting mains to the same value by means of incandescent lamps in parallel, or other non-inductive resistance.

What is a booster? M. L.

A booster is a dynamo, usually operated by a motor, placed in the circuit of a feeder to boost its voltage above that of the switchboard. All of the feeder current flows through the booster, which acts like an extra cell placed in one of several circuits leading from a battery.

Why does the following brushes of a Wood arc machine vary in distance from the leading brush? J. S.

When the regulator separates the brushes, the segments between them are short-circuited, the voltage of the machine thus being reduced. When the brushes are approached to each other, the converse is the case.

It is necessary to have a line of No. 2 B. & S. wire to carry a certain current a distance of one mile; would a line of 4 No. 8 wires already up carry the current if connected together in pairs? L. A. V.

Since a No. 2 wire has a cross-sectional area of 66,370 circular miles, and a No. 8 wire only 16,510 circular miles, the drop would be double with a pair of the latter.

I have a boat (bluff in form) about 34 ft. long, 7 ft. beam and 18 in. draft, which I wish to fit with electric power to run 10 miles per hour. What h.p. is required, and what should be the dimensions of the screw? J. D.

About 19 h.p. With a screw of 20 ins. diameter and 18.5 pitch, the speed will be 762 r.p.m. The speed is too high and the boat too large for electric power.

I am electrician of a summer hotel and find it convenient to use connectors in the case of mains that are taken down for the winter. I have been informed that connectors should not be used, and shall be glad if you will tell me the reason. J. W. M.

Any unsoldered joint apt to become loose is a source of danger through the heat thereby generated.

Can water be electrolized in sufficient quantity to run an oxy-hydrogen lamp, and what voltage is necessary? E. H. B.

Not economically. Over 3 h.p.-hours will be required to electrolyze one pound of water. As the voltage is only 1.7, this corresponds to a very large current, requiring a large electrode surface, if a single cell is used.

By holding the receiver of a telephone in front of the transmitter and short-circuiting the line, a whistling sound is produced; what is the cause of this? F. L. S.

This may occur from a slight vibration of the transmitter, which will change the resistance of the carbon; the effect of the vibration will be increased by the telephonic action of the receiver on the diaphragm of the transmitter.

We have two direct-connected units of 80 k.w. each, running on the three-wire system. Both machines run from 6 p. m. to midnight; one from midnight to 8 a. m., and the other from 8 a. m. to 6 p. m., in the latter case the polarity of circuits being changed. Could we use wattmeters or recording ammeters in this case? H. C. P.

Yes, with a pole changer. It will be best to put the steady load on one side of the three-wire circuit and use pole changer at switchboard.

What are the relations of the voltages between the conductors of a four-wire, three-phase circuit, and three-wire, two-phase circuit? J. S.

In the first case, if the voltage between the fourth or neutral wire and any of the three main wires is 1000, the voltage between the main wires is 1728. In the second case, if the voltage between the large wire and either of the smaller ones is 1000, the voltage between the latter two is 1410.

Is not the e.m.f. of self-inductance liable to injure a shunt machine if the circuit is suddenly broken? What protection may be used? A. D. L.

In large machines, yes. A pilot lamp affords some protection; copper shields around the field coils have been used; a simple method is to connect the shunt terminals with two carbon plates separated by a thin piece of perforated mica, a small fuse being also placed in the circuit.

How can I make a small electric heater for heating coffee? A. D. H.

Coil iron, steel or German silver wire on an asbestos pad, insulating the convolutions with asbestos thread. Iron and steel wire have about 6 times the resistance of copper wire, and German silver wire about 12 times. The lengths per ohm of copper wire at 170° F. are 80, 63, 50 and 40 ft., respectively, for Nos. 20, 21, 22 and 23 wire. From the above data the length of wire for any given current can be found. As an example, for No. 22 iron wire and 5 amps. on a 110-volt circuit, about 220 ft. of wire will be needed.

I want to use 19 magnets in series with 25 dry batteries. What should be the resistance of the windings? C. M.

For maximum effect, the combined resistance of the magnets should equal the internal resistance of the batteries, plus the resistance of the line. To find the former, if unknown, place the cells in series and short-circuit through an ammeter; the internal resistance of the cells will then be the combined e.m.f. divided by the current. To this add the resistance of the line, and dividing by the number of magnets will give the resistance of each. The size of wire will depend upon the dimensions of the magnet bobbin.

I have a 1-h.p., 10 ampere, arc machine which I wish to change to an incandescent machine. How may this be done? M. M.

Count the turns on the field, which, multiplied by the series amperes, will give the ampere turns, of which take, say, 80 per cent. for an incandescent machine. As a 10-amp., 50-volt machine, the shunt winding may take 1 amp. or less, and its resistance will, therefore, be 50 ohms or more. Select a wire such that with the necessary turns the resistance will be that determined as above, changing the shunt current if the resistance does not come out right on the first calculation.

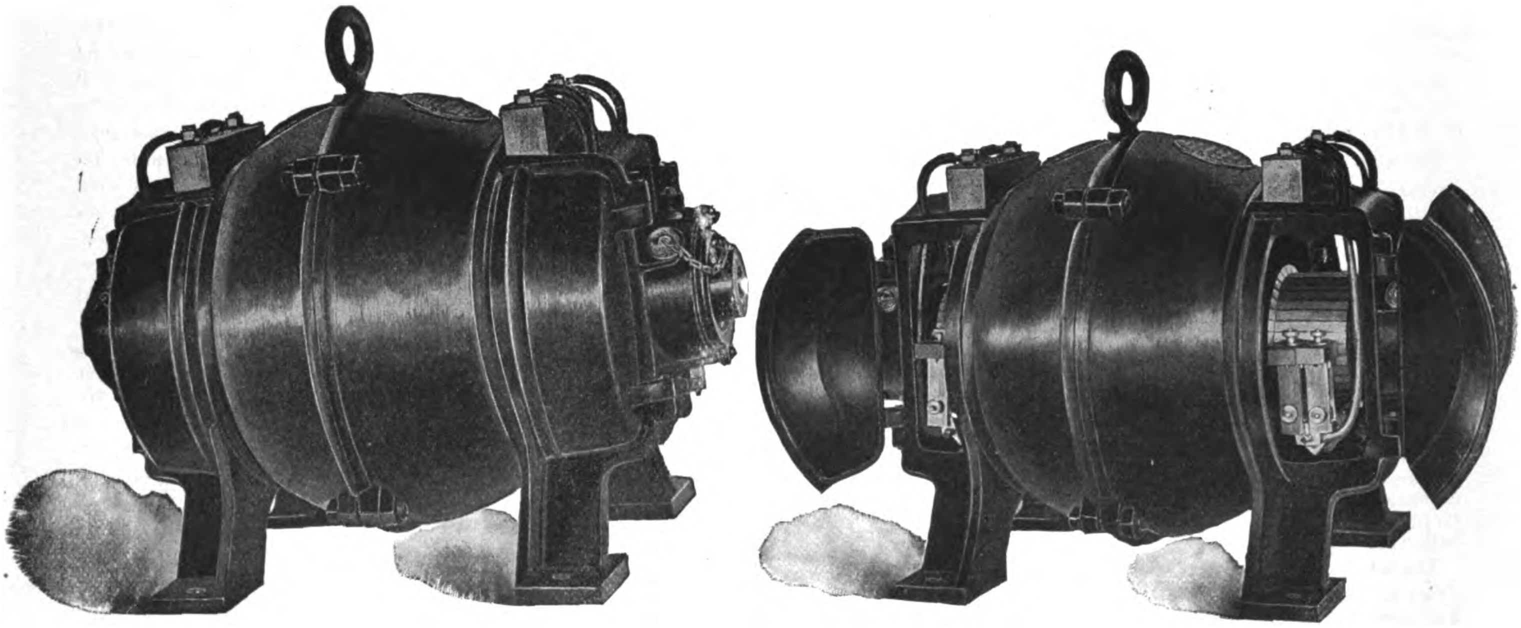
I find an abnormal drop in a line of No. 6 wire feeding a group of lamps in a mill several hundred feet from a transformer. What can be done to lessen this drop, which is probably due to inductance? R. A. L.

Run two circuits of No. 9 wire some distance apart, which will halve the inductive drop, or the No. 6 wire may be retained and another line of No. 9 wire run, in which case it may be well to put a non-inductive resistance in the larger line to bring its resistance up to that of the smaller. The reason for the resistance is that, as the inductive drop is due to the current, this should be reduced in the larger line to get the full benefit of the second line.

NEW APPARATUS AND APPLIANCES.

SPHERICAL BI-POLAR MOTORS.

The accompanying cuts illustrate a new line of bi-polar machines now being placed upon the market which, from their appearance, are called the spherical or round type. The machine shown is a new motor-generator and is represented with open and closed trap door.



SPHERICAL BI-POLAR LUNDELL MOTOR.

The new motor is designed to meet the requirements for the rapid widening field and demand for electric motors suitable for all lines of power used. These motors are particularly adapted for direct connection to exhaust and ventilating fans, blowers for forced draft for steamships, for pumps, automobile vehicles, etc., and range in size from ¼ to 10 h.p., and in speed from 1000 r.p.m. in the larger, to 1500 r.p.m. in the smaller sizes.

The chief characteristics are embodied in the construction of the field magnets, whereby a single energizing coil magnetizes all the pole pieces, a strong protective shell for the windings of both field and armature completing the magnetic circuit. A feature of the design is that the pole pieces are magnetized directly, and the leakage of the magnetic line of force is reduced to a minimum, thereby resulting in considerable economy in ampere turns.

The armature is the ironclad type having slots or curves in its periphery for holding the armature conductors; the core is well laminated, consisting as it does of thin disks of soft annealed sheet iron, the irons having the highest magnetic permeability. The slots are insulated, and there is also a special insulation between conductors embedded in the same slot having a considerable difference of potential.

The field frame is of cast steel and the detachable end brackets shown are of cast iron. When a dust proof or any entirely closed machine is required, the trap doors on the commutator and brackets are solid iron; screened doors are used where there is an absence of dust or flying dirt, or where a high degree of ventilation is required. Carbon brushes are used, and an adjustable tension is provided, the tension spring, however, not carrying any current. The bearings are self-oiling and self-aligning. The commutator bars, which are of hard drawn copper, have such dimensions as to permit the use of carbon brushes of ample capacity, the current density never exceeding 20 amps. per square inch of contact surface.

The new type of Lundell motor above described is made by the Sprague Electric Company, 20 Broad Street, New York.

HELENA, MONT., TRANSMISSION PLANT.

A third water-power electrical transmission plant has recently been installed along the short length of the Missouri River which flows through Montana—that at Helena, situated between the Butte and Great Falls transmission plants. The effective head here is 32 ft., and the minimum continuous power available is 7000 h.p.

In the power house at present there are four pairs of turbines and four generators, but the building is designed for ten generating units. Each unit consists of a pair of 42-in. special new American turbines of 960 h.p. per pair, direct-connected to a Westinghouse 650-k.w. two-phase generator. The current will be generated as two-phase at 500 volts and a frequency of 60, and then stepped up by oil phasing transformers to 11,500 volts, three-phase, for

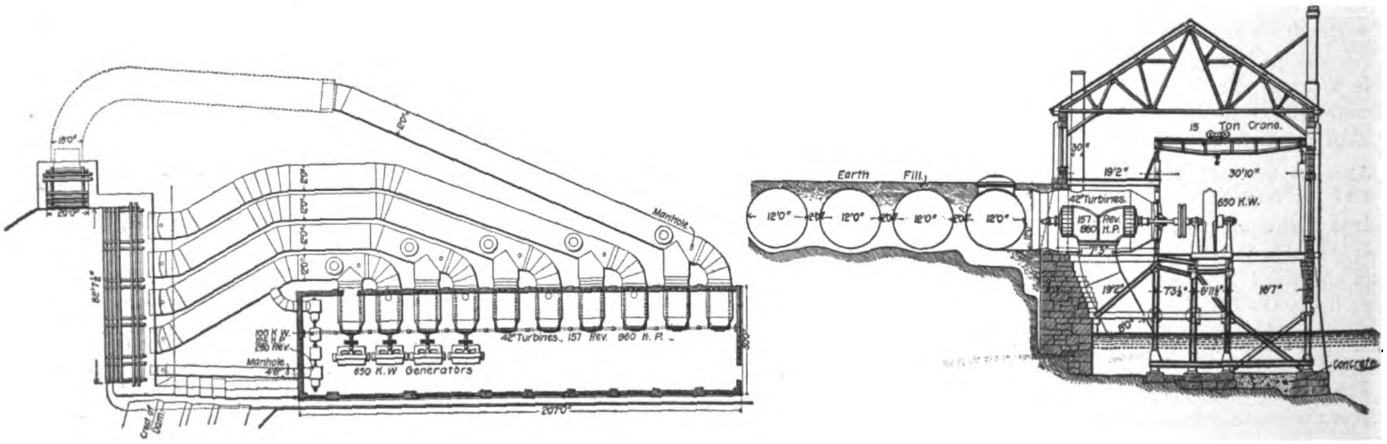


FIG. 1.—PLANT AND CROSS-SECTIONAL VIEW OF HELENA PLANT.

transmission from the power house at Cañon Ferry to Helena, a distance of 18 miles, where the current will be stepped down and transformed to two-phase current for distribution at a voltage of 1000 and 2000.

A plan and cross sectional view of the plant is shown in Fig. 1. Fig. 2 shows four of the turbines in place, and Fig. 3 gives an enlarged view of the first two turbines installed.

The turbines are placed horizontally and on cast iron double quarter-turn draft chests. Each of the draft chests, with wheels, is inclosed in a flume 12 ft. in diameter, 21 ft. 4 ins. long, and made of 5-16-in. tank steel; one end of the flume has a cast iron head and the other end is riveted to a cone connection leading to the steel supply pipe which furnishes water to the wheels.

These large flumes are mounted on bases made of steel I beams firmly bolted together with cross ties. The wheels are supplied with safety steps to prevent end thrust, and the cast iron flume heads have combined follower and stuffing boxes attached. There are also follower boxes supported by columns which carry the other ends of the wheel shaft. The shafting is in two sections, one of which is 6½ ins. in diameter and the other 8 ins. in diameter, the two sections being coupled together by means of a pair of large compression couplings inside the draft shaft. The 8-inch shaft transmits the power of both wheels to the generators through a flexible coupling.

The discharge from the turbines passes through 8-ft. draft tubes which are curved outwardly and are 16 ft. long, being made of ¼-in. tank steel. The speed of each pair of wheels is regulated by means of a Replogle governor. Each unit is guaranteed to develop 960 h.p. under 28 ft. actual working head at a speed of 162 r.p.m. In addition to the four pairs of 42-in. wheels, there are two single 25-in. special new American turbines for driving the exciters. These wheels are encased in horizontal iron flumes and discharge outwardly through a cast iron quarter-turn attached to the flume heads. The steel feed pipe which conducts the water from the dam to the flume is 12 ins. in diameter and about 200 ft. long.

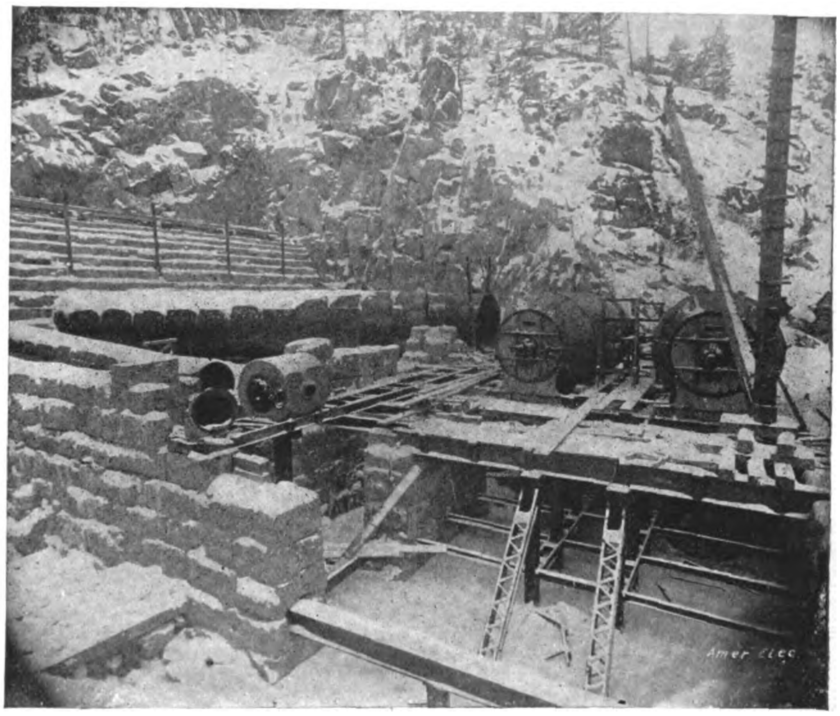

FIG. 2.—SHOWING FLUME AND TURBINES.

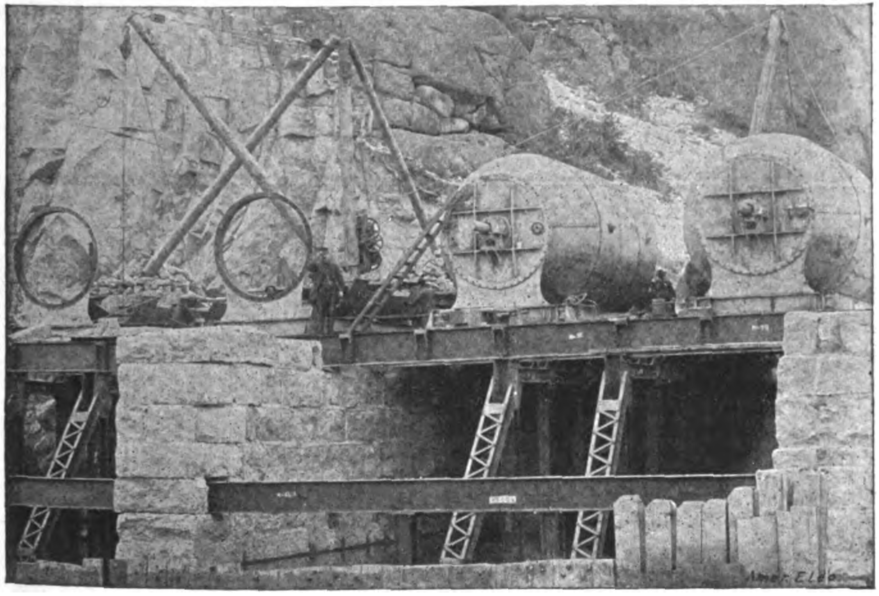

FIG. 3.—TWO OF THE TURBINES.

The new American turbines herein described were made by the Dayton Globe Iron Works Company, Dayton, Ohio

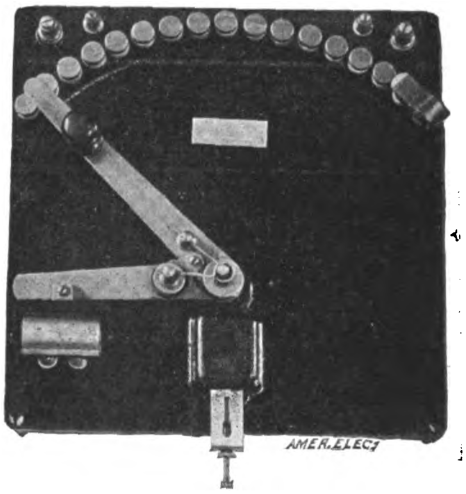
---

AUTOMATIC RHEOSTAT.

We illustrate herewith a recent type of automatic rheostat for motors of about 20 h.p. The rheostat has two levers, an operating lever for manipulating the rheostat and an automatic switch lever; as shown, the arm is in its starting position.

With this rheostat the circuit can only be closed when all the resistance is in circuit with the motor. A magnet connected across the main circuit holds the automatic switch lever closed under normal conditions. If the voltage falls, the holding magnet loses its magnetism and the automatic switch lever rapidly opens the circuit, being actuated by the coiled spring shown at the center of the rheostat.

A solenoid magnet, the core of which is attracted vertically against the action of gravity, furnishes the overload safety device. In case, during the acceleration of the motor or after it is running at full speed, the current exceeds a predetermined maximum amount, the plunger of the overload magnet is drawn up by magnetism and finally delivers a blow which opens a double pole switch in the circuit of the shunt magnet holding the automatic switch lever. The switch lever, being thus released, is caused by the coiled spring to rapidly open the main circuit, the final break occurring upon renewable carbon contacts. It will be observed that in order to again close the circuit, the operator must first insert all the resistance of the rheostat.



AUTOMATIC RHEOSTAT.

The overload magnet has a wide range of adjustment and is both positive and simple in its action, and cannot by any misuse be altered as to its calibration.

The Ward Leonard Company, the manufacturers of the above rheostat, has been for several years past slowly but surely perfecting this type of rheostat. The recent improvements have been in the direction of cheapening the cost of production and in making the instrument "fool proof."

OUTLET AND JUNCTION BOX.

The accompanying illustrations show a new type of outlet and junction boxes, which are so constructed as to have at frequent intervals on the surface thin webs or films which a slight blow of a hammer will knock out, leaving round holes for outlets in as many combinations as are generally required. The method of attaching the box to the conduit is new, a hollow bushel or nipple being used, which is threaded on the exterior and insulated with enamel on the interior; the nipple passes through the hole made in the box at the point desired and is screwed into a coupling at the end of the conduit, thus making a perfect mechanical connection, which may be made water-tight if desired. This type of box can be instantly disconnected from the conduit by unscrewing the nipples from the inside of the box, regardless of the number of conduits that enter it.

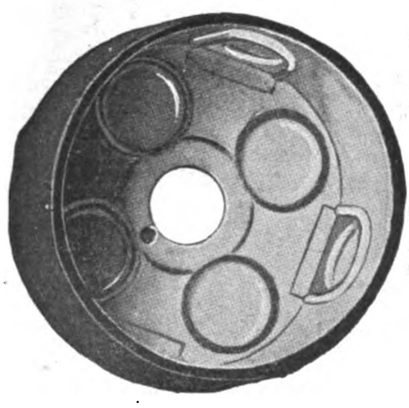


FIG. 1—CEILING OUTLET BOX.

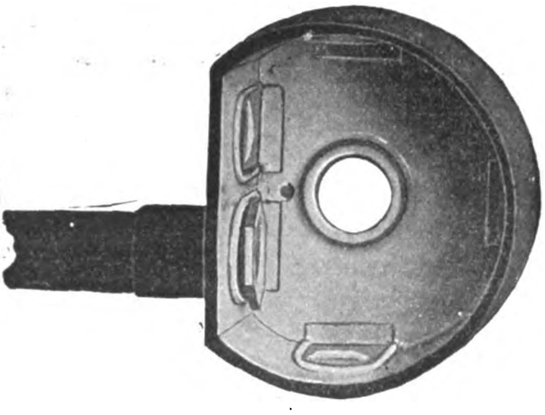

FIG. 2.—WALL BOX.

Fig. 1 shows a ceiling outlet box, which may be used for outlets where the conduits enter from the side or back of the box. The hole shown in the center acts as a support for the fixture, or for the entrance of a gas nipple if used in combination work; for straight electrical work this hole may be also used for a wall outlet.

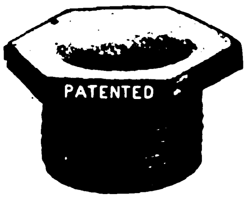

FIG. 3.—NIPPLE.

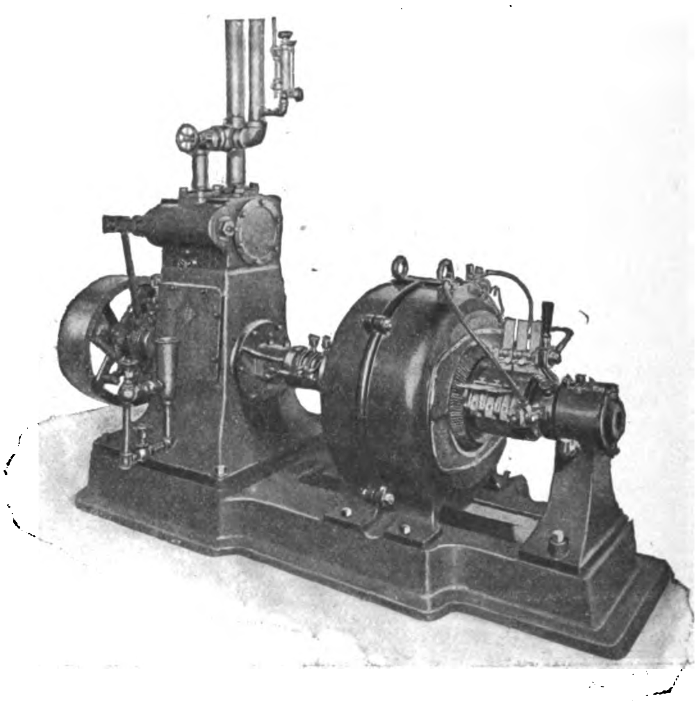
Fig. 2 is designed for a wall box where two conduits enter both on the same side; this box can also be used as a ceiling box when outlets come on the bottom of iron beams.

The nipple used with this fitting is shown in Fig. 3. As will be seen, it is made with a hexagon head, which allows it to be easily screwed into a coupling or on the end of a conduit; the nipple is painted with a special hard dry enamel that adheres firmly and will not chip off. In drawing in, this type of nipple is of special advantage, as it prevents abrasion and enables wires to be drawn in with much ease.

The above described fittings are made by L. A. Chase & Company, 161 Ft. Hill Square, Boston, Mass.

MARINE ELECTRIC LIGHTING.

The accompanying illustration shows an electric generating marine unit, two of which have been installed on the steamer Juniata, formerly the Merchants and Miners' Line, but now in the service of the Navy as a floating machine shop. The set consists of a Case high-speed automatic engine, direct-connected with a Lundell dynamo, and while capable of supplying 250 16-c.p. lamps, it takes up no more room than an ordinary roll-top desk.



MARINE GENERATING SET.

Aside from the compactness and light weight of this outfit—two extremely important qualifications in apparatus for use aboard ship—the Case engine possesses a number of features rendering it especially desirable for marine work. One of these consists of oil retaining devices by means of which the lubrication is not affected in a sea way. Another is the use of thrust bearings, which hold the crank and armature securely, thus taking care of unusual strains upon the bearings arising from the ship's motion.

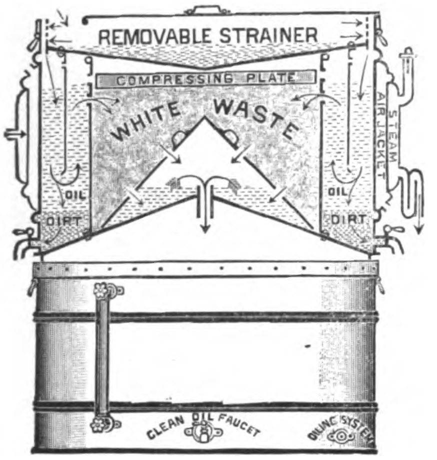
The above outfit is made by the New Britain Machine Company, New Britain, Conn.

OIL FILTER AND PURIFIER.

The main feature of the oil filter shown in the accompanying illustration lies in the initial heating of the oil to be filtered by means of exhaust or live steam, which is admitted into a steam jacket surrounding the upper part of the casing, but separated from the inner surface by an air chamber.

The dirty or waste oil is poured into the strainer shown, which retains all the grosser impurities; the oil then passes very slowly through a large area of fine straining surface; then downward toward the bottom of the straining and refining chamber, the oil being kept away from the filtering material by a deflecting shield. The annular settling and refining chamber is always filled with heated oil, which is almost completely purified before it overflows into the central filtering chamber. In the latter, it gradually filters through a large area of compressed filtering material, passing finally through a muslin cover over a perforated central cone, this cone presenting a large area of filtering surface.

As stated in the opening paragraph, in the refining and settling chamber the oil is heated through the medium of air within a jacket interposed between the steam jacket and the annular filtering space. The heat thus applied thins the oil, makes it bright and clear, all of the entrained water and heavier impurities being quickly separated and precipitated to the bottom of the chamber, whence they are readily drawn through faucets. Any desired temperature, from 140 to 180 degs., may be thus applied to the oil. One of the advantages of this method of heating oil is that the temperature can be very exactly regulated by simply screwing large or small bushings into the outlets of the air jacket, and at no time is the oil exposed to a temperature more than a few degrees above the normal temperature desired. The purified oil accumulates in the bottom tank and is delivered cold at the clean oil faucet.



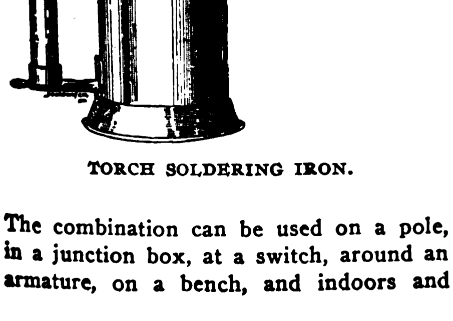
OIL FILTER AND PURIFIER.

The compressing plate shown in the illustration maintains a uniform pressure on the filtering material, thus making it compact and insuring good work. By simply lifting off this plate, the filtering material may be inspected or removed without drawing off any oil or disturbing any part of the apparatus.

The oil filter described, known as the "Famous Oil Filter," is made by the Famous Filter Company, St. Louis, Mo.

SOLDERING IRON.

The accompanying illustration shows a soldering iron which may be very simply attached to the ordinary blow torch. As will be seen, it is only necessary to slide a ring through the blow torch tube and tighten it with a screw. By means of this attachment a connection can be soldered without burning the insulation on the wire. The combination can be used on a pole, in a junction box, at a switch, around an armature, on a bench, and indoors and outdoors without danger of blowing out in the latter case.



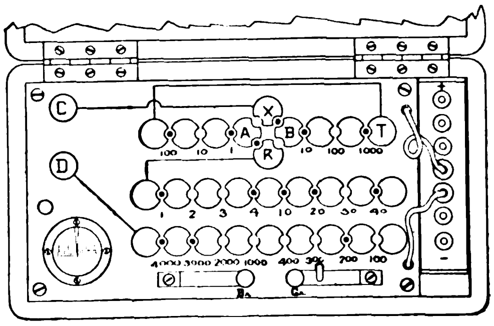
TORCH SOLDERING IRON.

This attachment is made by the Electric Supply Company, 232 King Street, Madison, Wis.

PORTABLE TESTING SET.

The "Jagabi" portable testing set, recently placed on the market, is claimed by the makers to be the simplest, lightest in weight and most compact instrument of its class which has yet been made. It has outside dimensions, 9½ ins. x 5 ins. x 4 ins., and weighs about 7 lbs. The apparatus comprises a highly sensitive D'Arsonval galvanometer, Wheatstone bridge, rheostat, silver chloride battery, and keys for both galvanometer and battery, all mounted in a handsomely finished mahogany case with lock and handle. This combination forms a remarkably convenient piece of apparatus for use in making all classes of resistance measurements that come within its range.

The general scheme of arranging the different parts is shown in Fig. 1. From this it will appear that the rheostat has sixteen coils, ranging from 1 to 4000 ohms, and having a total capacity of 11,110 ohms. The bridge arms are 1, 10 and 100 ohms on one side, and 10, 100 and 1000 ohms on the other side. A unique reversing device enables the same result to be obtained with the bridge as if four pairs of coils were on each side. Six cells of chloride of silver battery are provided, these being sufficient for all ordinary requirements. When specially high resistances are to be measured, an outside battery of greater capacity should be used. An important improvement to be noted in connection with the galvanometer is a small exterior milled head screw, by means of which the zero may be adjusted in case of any small change of tension in the spring. This feature will be much appreciated by those familiar with testing sets already on the market.



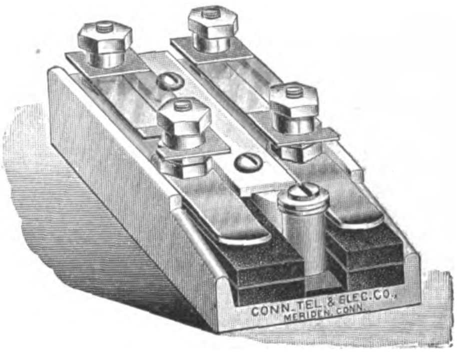
PORTABLE TESTING SET.

The apparatus is so arranged that the rheostat coils may be used by themselves; the galvanometer may be used independently; the galvanometer and battery connected in series may be used without the rheostat and bridge; or, the galvanometer, battery and rheostat may be connected in series. Thus every possible combination is provided, so that, practically speaking, each distinctive part of the set may be used alone, or in connection with the other parts, as desired. By means of traveling plugs, any coil, or group of coils may be isolated or used for a derived circuit. By a simple arrangement of the plugs the set may be used to measure high insulation by the direct deflection method.

The Jagabi portable testing set is manufactured by Elmer G. Willyoung & Company, Philadelphia, for which firm James G. Biddle, 910 Drexel Building, Philadelphia, is sole selling agent.

LIGHTNING AND SNEAK CURRENT ARRESTER

The accompanying illustration shows a device for protecting switchboards or instruments from lightning discharges and sneak currents. The protection is double, consisting of a fuse and a spark gap. The fuse link consists of a piece of mica with metallic terminals, the two latter being connected by a fusible wire of small cross-section, the wire being held firmly in place against the mica by shellac. The spark gap is made up of two pieces of carbon separated by a piece of mica in which several holes are punched.



CONN. TEL. & ELEC. CO.
MERIDEN, CONN.

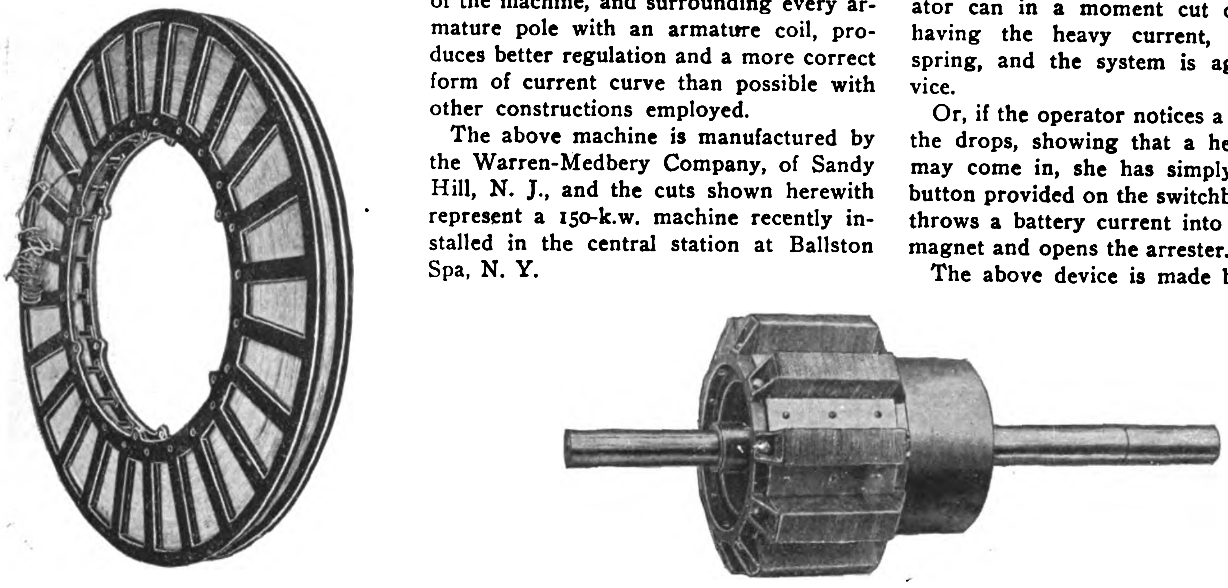
LIGHTNING AND SNEAK CURRENT ARRESTER

The mechanical details of the block are very efficient. The fuse link may be very quickly renewed, not differing in this respect from the ordinary metallic clip link. The spark gap carbons are held in place by two projecting springs, as shown in the cut, and for renewal or examination they are merely slid from under the springs. The Connecticut Telephone and Electric Company, Meriden, Conn., are the manufacturers.

INDUCTOR ALTERNATOR.

In the improved type of inductor alternator shown in the accompanying illustrations, the utmost attention has been given to the perfection of both mechanical and electrical details. The lower half of the frame, including supports for bearings, constitute a single casting, thus insuring great strength, rigidity and proper alignment. The bearing sleeves are made solid and have a large surface, which is lined with anti-friction metal. The bearings are self-oiling and their supports so designed that when it is desired to remove a sleeve, the only operation is the removal of the cap, after which the sleeve may be slipped off endwise of the shaft.

By the removal of two frame bolts the upper half of the frame which carries the upper half of the armature and corresponding armature coils, may be lifted off. The revolving inductor is surrounded at the small end by a field coil, which latter is attached to an annular yoke casting. The armature body is made of soft steel and the armature is built up of very thin sheets of metal, served on both sides with an insulating compound to prevent the formation of eddy currents, and there is a series of internal recesses which admit of a free circulation of air entirely around the armature.



FIGS. 1 AND 2.—ARMATURE AND INDUCTOR.

The armature coils are machine wound and thoroughly saturated with an insulating compound, being retained in shape by a single layer of tape covered with waterproofing compound. The insulation of the coils is mainly obtained from a special insulating trough forming the interior lining of the coil slots in the armature. For 1000 or 2000-volt armatures these troughs are subjected to a break-down test of 6000 volts. After the troughs and coils are in place in the armature, an insulated and perforated cover closes up the coil slot, and the revolving inductor causes a current of air to flow continuously around the coils.

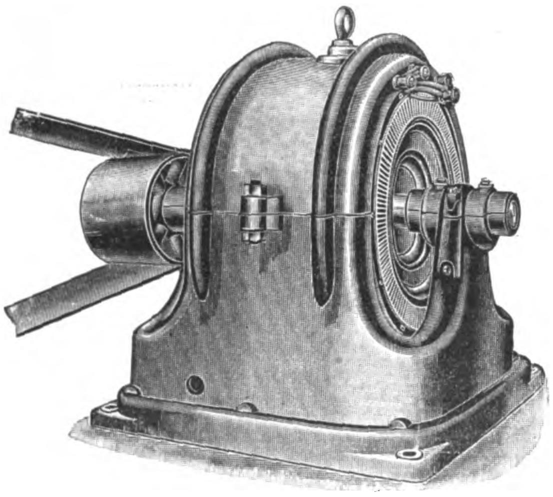


FIG. 3.—INDUCTOR ALTERNATOR.

The field coil case consists of two ring castings spaced by means of rods of insulating material, the sides being lined at numerous places with narrow strips of insulating material. The wire is wound over the insulating rods in such a manner as to leave exposed the outer and inner circumferences of the coil and practically both sides, thus insuring efficient ventilation. It is claimed that the placing of all the armature coils in a single wreath at one end of the machine, and surrounding every armature pole with an armature coil, produces better regulation and a more correct form of current curve than possible with other constructions employed.

The above machine is manufactured by the Warren-Medbery Company, of Sandy Hill, N. J., and the cuts shown herewith represent a 150-k.w. machine recently installed in the central station at Ballston Spa, N. Y.

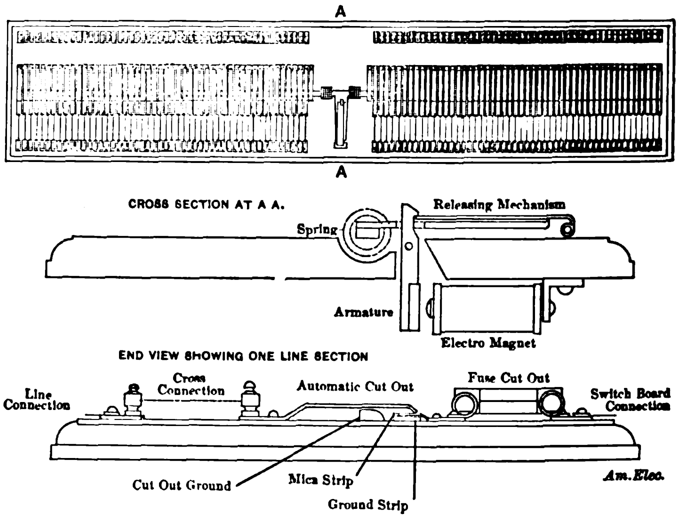
AUTOMATIC LIGHTNING ARRESTER FOR TELEPHONE EXCHANGES.

The accompanying cut shows the details of a new type of lightning arrester, the one illustrated being for 100 lines. Connection to the line is made from the binding posts shown in the lower cut, and from the latter the connection is along the automatic spring, over a ground strip insulated from the spring through a ¼-amp. fuse to the switchboard.

When a heavy current comes on any line, it seeks, of course, a ground through the path of least resistance, and in passing over the tension spring, finds an outlet to the ground strip, which is insulated from the line spring by a thin piece of perforated mica. In following this ground strip it is conducted through the electro-magnet shown in the middle cut, which, being thus magnetized, releases the spring, throwing open all the cut outs on the board through the cut-out ground strip being raised by the action of the springs. All the lines are then grounded, and the switchboard operator can in a moment cut out the line having the heavy current, replace the spring, and the system is again in service.

Or, if the operator notices a fluttering of the drops, showing that a heavy current may come in, she has simply to push a button provided on the switchboard, which throws a battery current into the electro-magnet and opens the arrester.

The above device is made by the Keystone Telephone Company, 565 Old Ave., Pittsburg, Pa.

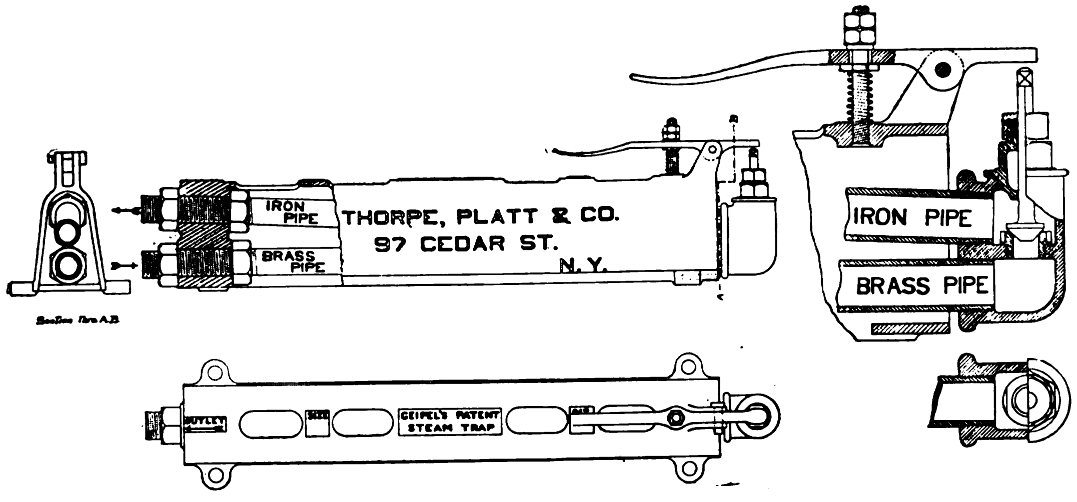


AUTOMATIC LIGHTNING ARRESTER.

AUTOMATIC DRAIN COCK.

The steam trap or automatic drain cock shown herewith utilizes the expansion principle in its working, the motion of expansion being, by the simple arrangement adopted, multiplied many times.

Referring to the illustration, the lower or brass pipe is connected to the steam pipe, the upper or iron pipe forming the discharge. These two pipes form the two sides of an isosceles triangle, the valve seat being at the apex. The valve spindle butts against the lever. When cold, the brass pipe is contracted, the apex is drawn down so that the valve is fully open, and the water is discharged. As soon as steam enters the brass pipe, the latter expands and raises the apex, when the valve is closed. In order that the valve may be set to blow off at any pressure desired, a screw adjustment is provided. In addition to this, when it is desired to "blow through," the valve may be opened by hand by merely pressing the lever. The valve may be readily examined by unscrewing the top; this is a desideratum, as it is a common occurrence for the valves in all steam traps to become choked with sediment or to require attention otherwise; it is claimed that this trap can be taken apart and put together again in five minutes.



STEAM TRAP.

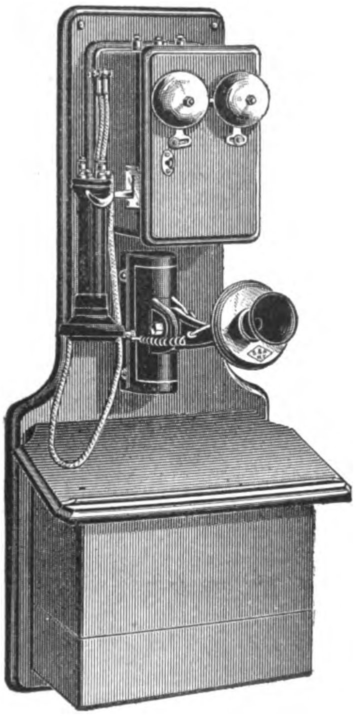


FIG. 1.—LONG DISTANCE WALL TELEPHONE.

The inventor of this trap is Mr. William Geipel, a well known English electrical engineer, and one of the authors of Geipel & Kilgour's "Electrical Engineering Formulae." The American manufacturers are Thorpe, Platt & Company, 97 Cedar Street, New York.

LONG DISTANCE TELEPHONE.

The telephones shown herewith have been especially designed to meet the requirements of both general exchange and long distance work. The transmitter contains a diamond grain carbon, imported by the makers and prepared by them for use after a secret process. A 10,000-ohm generator is used with these sets and two cells of Stanley battery. The switch is of the long lever type, with rubbing contact and German silver springs. All contacts have platinum points, thus obviating any trouble from corrosion. The compound magnets used in the receivers are magnetized with great care, and the lifting power of each magnet carefully tested before assembling. The bobbin is wound with silk wire and tested to a standard of resistances. Fig. 1 shows a wall set and Fig. 2 shows a desk set of the same type of apparatus, which is made by Stanley & Patterson, 32 Frankfort Street, New York.

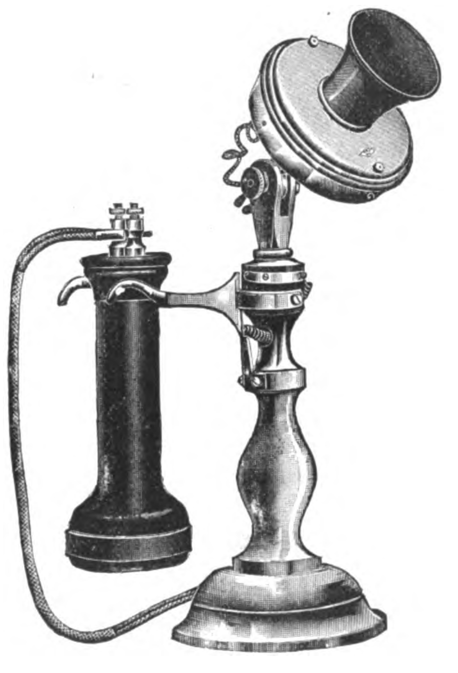

FIG. 2.—LONG DISTANCE DESK TELEPHONE.

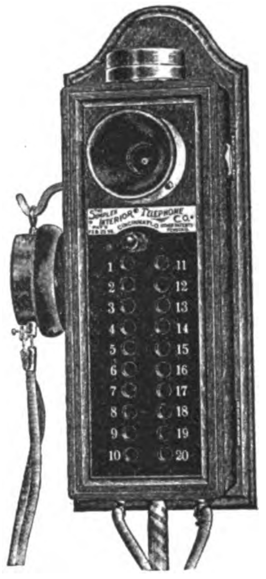
INTERCOMMUNICATING TELEPHONE.

The twenty-station intercommunicating telephone set shown herewith is of a type intended for factories, stores, warehouses, institutions, etc. By its means communication may be had between any two telephones, and any number of pairs may hold conversation at the same time without interference, thus obviating the necessity of a central exchange. But one set of batteries is used. The manufacturers are the Simplex Interior Telephone Company, Cincinnati, Ohio.



SIMPLEX TELEPHONE.

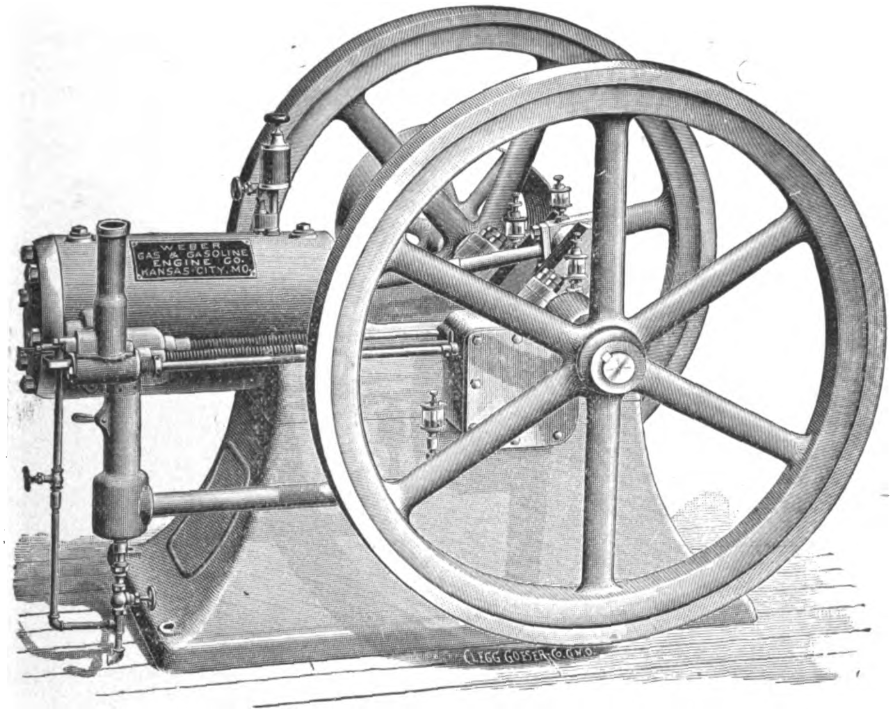
THE WEBER GAS ENGINE.

In the Weber gas engine, shown herewith, the latest mechanical improvements in machinery construction have been introduced. The wearing parts are made interchangeable, and the valve seats are separate castings, so that they may be cheaply renewed when worn. The valves are located so as to render them easy of access for examination or regrinding and, together with the valve chambers, are kept from becoming overheated by water around the seats.

The valve gear is incased in an iron housing, dust and grit proof, and the gears run constantly in oil. The governor regulates so that the engine receives only so much of the charge as is needed to do the work; when on light load, only as many charges are admitted and ignited as are needed to keep up the speed of the engine, which speed can be instantly changed while in motion. This type of engine is fitted with the incandescent tube igniter.

The makers claim that this is the only type of gas engine in which the point of gas ignition may be altered while in operation, which effects not only a saving in fuel, but prevents the engine from starting backward.

The pistons are of unusual length, and instead of being packed with ordinary snap rings, packing rings are employed made up in sections with a German silver spring behind each section, which forces the rings



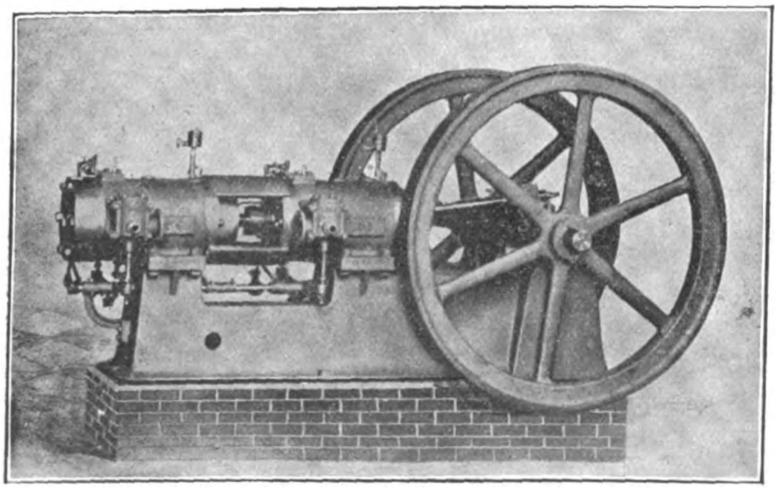
WEBER
GAS & GASOLINE
ENGINE CO.
KANSAS CITY, MO.

WEBER GAS ENGINE.

against the walls of the cylinder at all times, thus taking up the wear, however slight it may be; by this means, it is claimed that the springs can be used until they are worn down to an extreme thinness.

The gas engine described is made by the Weber Gas and Gasoline Engine Company, Kansas City, Mo.

FRONTIER GAS ENGINE.



FRONTIER GAS ENGINE.

In the gas engine shown herewith there are two single-acting cylinders placed tandem, each cylinder operating alternately on the four-cycle principle, which arrangement secures an impulse every revolution instead of every second revolution, as in the usual single-cylinder engine. The impulse is consequently only about one-half as great as in the case of the one-cylinder engine of the same power, and the resulting strains are, of course, reduced in the same proportion.

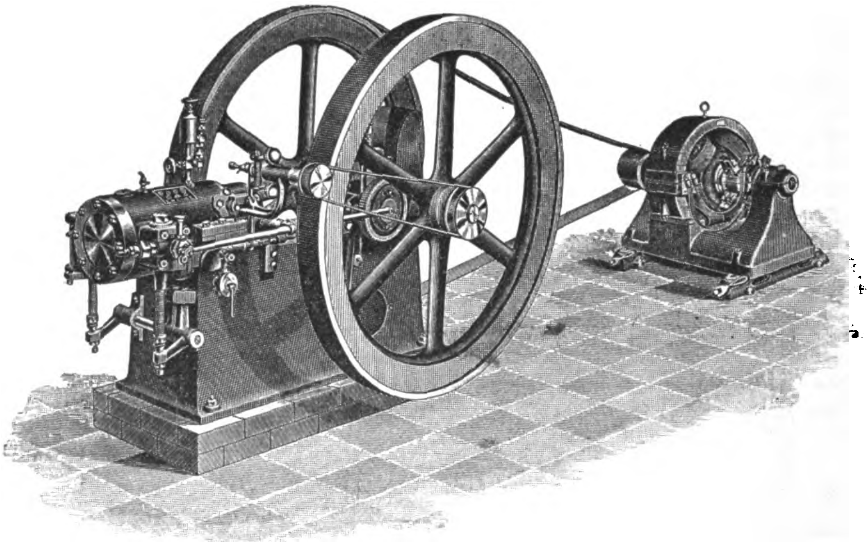
The type of governor used operates the throttle valve and regulates the amount of gas or gasoline required in almost direct ratio to the power used under varying loads. The speed may be readily changed by adjusting the governor, and the point of ignition is varied at will when the engine is running. Electric spark ignition is used exclusively on this type of engine, the igniting device being both simple and accessible. Engines of 25 h.p. and under are quickly and readily started by hand. Above this size pneumatic self-starting appliances are fitted.

A special claim for this type of engine is in the use of but one crank, one connecting rod and one piston rod, thus reducing the principal moving parts to a minimum. The vertical valves have positive motion as well as the gas feed, and while this adds to the number of smaller parts, the advantages are obtained of superior efficiency and economy.

All the valves as well as cylinders and cylinder heads are water-jacketed. The gears are cut from solid blanks and no bevel gears are used. The crank shaft bearings are so designed that the thrust is against the bearing itself and not on the caps. The engine may be readily changed from gas to gasoline, or vice versa.

We understand that a number of these engines, which are made by the Frontier Iron Works, Detroit, Mich., are in operation running electric light plants, and giving very satisfactory results.

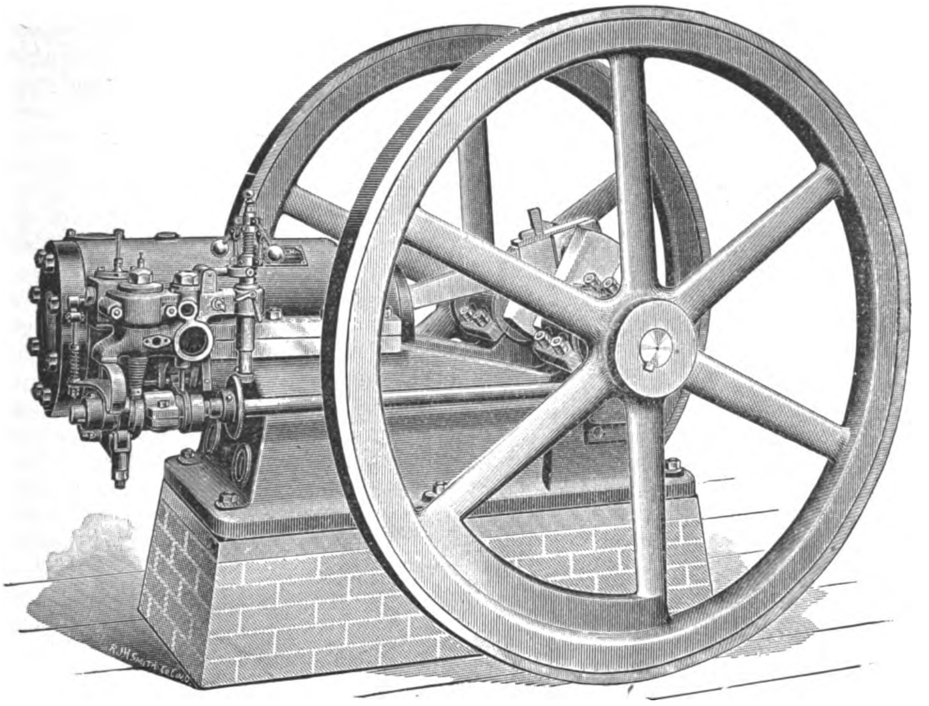
FOOS GAS ENGINE.



FOOS GAS ENGINE.

The manufacturers of the gas engine shown in the accompanying illustration state that in its design simplicity of construction was one of the points kept constantly in view, and the engine has been made to comprise as few parts as possible. The inlet and exhaust valves, as well as the igniter (which is of the electric type) require occasional cleaning, and are therefore so constructed and placed that they may be easily removed and examined. The crank shaft boxes are of phosphor bronze, and designed to insure the least amount of friction obtainable with liberal proportionate bearing surfaces. All the parts of the engine are made to carefully constructed gauges, thus making parts interchangeable. The governor is of the centrifugal type, and the speed of the engine can be increased or reduced, if desired, while it is running. The valves are positive in their operation, and are made of ample size to procure the highest efficiency without putting them to an unduly severe strain. The engine as built at present can be changed in a few moments to use either gas or gasoline.

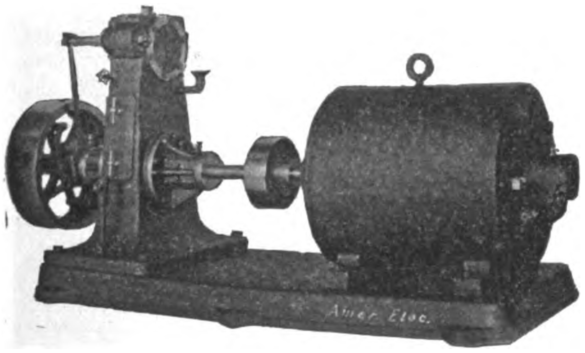
The engine shown in the illustration is specially made for electrical work, and designed to give a perfectly steady light even under partial load; and under a full or nearly full load the makers guarantee a variation not to exceed 2 per cent. The manufacturers are the Foos Gas Engine Company, Springfield, O.



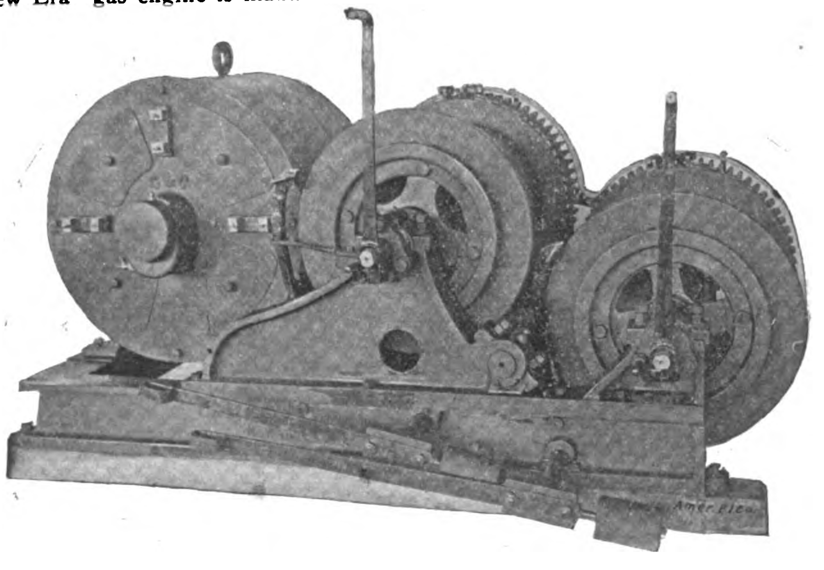
"NEW ERA" GAS ENGINE.

"NEW ERA" GAS ENGINE.

The engine shown in the accompanying illustration uses either gas or gasoline for fuel and is of the single cylinder, self-scavenging type. As will be seen by reference to the cut, the valves, igniter, governor, etc., are all arranged on one side of the engine, and operated by cams or gears on a shaft at right angles to the main shaft. The angle pillow blocks receive the shock of the explosion at the bottom, the wear being thus easily taken up. The shaft which carries the cams is run by spiral gears covered by a shield, the gears running in oil; this overcomes the noise made by the usual type of cog gears, and increases the life indefinitely.



MARINE GENERATING SET.



DOUBLE-DRUM ELECTRIC HOIST.

There is a valveless port in the seat of the cylinder, so placed that it is automatically uncovered by the piston, allowing the burned gas to escape to the exhaust vessel or pipe. The only duty for the regular valve to perform is therefore to provide for the escape of what little is left in the cylinder. This not only extends the life of the exhaust valve, but improves the efficiency of the engine. For igniting the charge, an electric igniter is recommended, though the hot tube may be employed.

The "New Era" gas engine is manufactured by the New Era Gas Engine Company, of Dayton, Ohio.

SOME NEW "C. & C." COMBINATIONS.

We illustrate herewith a new form of marine generating set recently placed upon sale by the C. & C. Electric Company, of New York, which seems to possess a great many good qualifications for the work it has been designed to perform. The set consists of a C. & C. entirely inclosed type, four-pole ironclad dynamo, directly connected to a "Case" vertical automatic engine, both mounted upon one cast iron base. Both the engine and dynamo being entirely enclosed, there is no danger of the apparatus being disabled through a drenching, to which many marine lighting plants are liable in rough weather. These sets are made in capacities of from 2½ to 12 k.w.

Another illustration shows a C. & C. electric hoist, of the double-drum type, in which the C. & C. ironclad motor is employed. The manufacturers are furnishing these hoists in either the single or double-drum type and in capacities from 5 to 50 h.p.

The company showed one of each of the above mentioned combinations in their exhibit at Madison Square Garden during the May exhibition, where they attracted very favorable notice.

SILEX INSULATED CONDUIT.

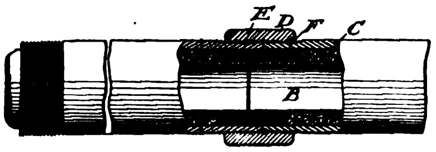
Electrical insulation can be accomplished more or less perfectly by materials which, beyond their similarity as insulators, vary to the widest extent. The qualities necessary to the ideal insulator are incombustibility, non-conduction of heat, non-conduction of shock, unchangeability, flexibility. Every insulator possesses one or more of these qualities; the mineral insulator has been held to come the nearest to the ideal, but hitherto has lacked in flexibility.

The method of insulation applied in the type of conduit shown in the accompanying illustration is claimed by the manufacturers to fulfill the idea requirements. An iron or steel outer tube is separated from an inner tube, B, of metal by finely pulverized, densely packed silex, C. Each section of the conduit has at one end a projecting and, at the other end, a receding insulating device, as shown in the accompanying illustration, at E and F.

The converse ends fit into each other when lengths of conduit are brought together with right and left screw-coupler, D, and thus form a perfect union, insuring continuous insulation and a smooth-bore raceway, free from any possible obstruction.

Silex, in its pure state, is recognized not only as possessing extremely high insulating properties, but also exceptional heat-resisting qualities, fusing only in the oxy-hydrogen flame. As used, the silex is thoroughly waterproofed.

If silex is pulverized and a little put under a microscope, it will be discovered that there are no round particles in it, all being wedge-shaped, sharp, splintery and irregular. The material, therefore, may be packed to nearly the solidity of the rock from which it was ground. It is completely unchangeable, and in being packed it so arches around the inner tube that this tube cannot change its relation to the outer tube though it may be bent to an angle of 90 degrees.

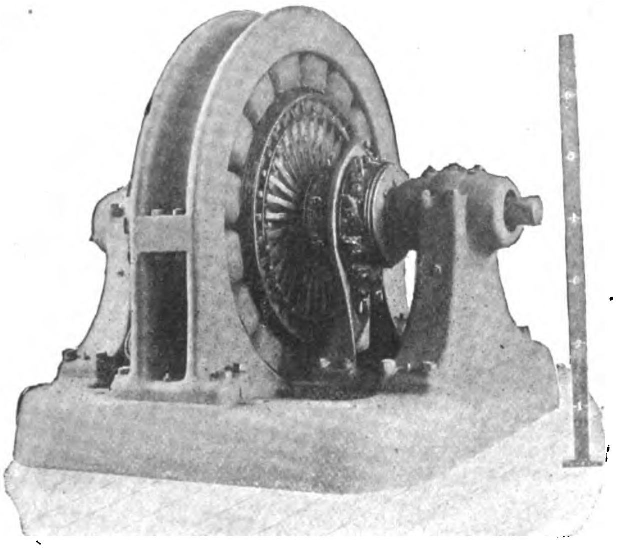


SILEX CONDUIT.

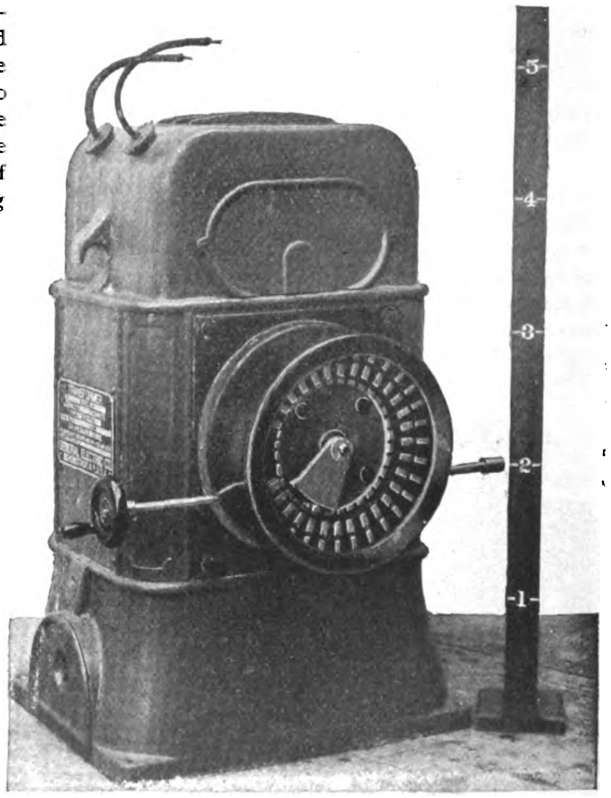
The Silex Insulation Company, 39 Cortlandt street, New York, are the manufacturers, and at their booth at the late Electrical Show, Madison Square Garden, the new conduit, above described, called "Three-eye Conduit," attracted much attention.

BATTERY TELEPHONE GENERATOR.

The machine shown herewith is designed for use in telephone exchanges, and can be operated either by a battery or from an electric lighting circuit, in the former case requiring about .3 amp. at 8 volts.

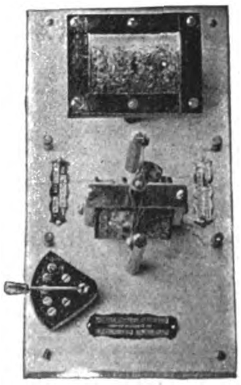


400-K. W. ROTARY CONVERTER.



220-K.W. TRANSFORMER.

Many exchanges do not have access to a lighting circuit or to any other source of power by means of which to operate a separate generator, and therefore have been compelled to use a hand ranger. To such as these a machine like that illustrated will without doubt appeal very forcibly. The manufacturers are the W. F. Warner Co., Muncie, Ind.



BATTERY TELEPHONE GENERATOR.

A LARGE ROTARY CONVERTER.

In the station of the Pennsylvania Heat, Light & Power Company, Philadelphia, Pa., has recently been installed by the General Electric Company the largest 60-cycle rotary converter yet constructed. It is a 16-pole machine, of 400 k.w. capacity, running at 450 r.p.m., and was designed to convert an alternating two-phase current of 60 cycles' frequency and voltage variable between 165 and 220 volts, into continuous current at from 225 to 300 volts. It stands 8 ft. high on a base 8 ft. 4 ins. x 8 ft. 6 ins.

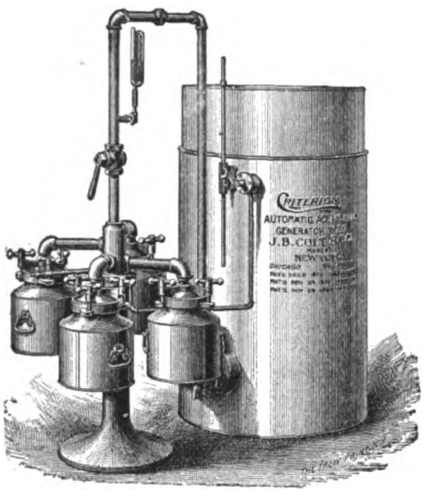
The field frame of this machine is heavily ribbed, divided horizontally and susceptible of movement along the base to allow of inspection of the armature and field coils. The bearings are extra long and of the self-oiling and self-aligning type, that at the commutator end of the shaft being provided with an end play device to keep the armature in constant motion in the direction of the length of the shaft and distribute the wear of the brushes over the commutator surface to avoid the wearing of grooves. The armature is of the iron-clad type.

To facilitate the removal of a brush for examination and replacement without varying the tension under which it runs, a brush-holder of unique design has been devised. To remove the brush the prolonged end of the brush-holder is disengaged from the brush-holder by a slight end motion. Another feature in this machine is the design of the brush-holder studs and the method of attaching them to the yoke. The former, instead of passing through insulating bushings in the yoke—as has been customary in this type of machine—is provided with a lug bored to fit down upon a radial stud held by bolts passing through the insulating bushings. To slide the brush-holder stud off, it is simply necessary to loosen the nuts on the bolts passing through the bushings. By employing this method all labor and expenditure of time usually consumed in removing the insulating bushings and washers from the brush-holder yoke to remove the stud are avoided, and the change can be effected in a very few minutes. Upon the collector rings press numerous leaf brushes, having a long contact on the rings, and a very large current carrying capacity.

To obtain the necessary variation in the continuous current of the rotary converter the General Electric Company has furnished with it two special 60-cycle transformers each of 220-k.w. capacity. These have been designed to operate with a primary potential of 2000 volts, and a secondary potential varying from 165 to 220 volts. The variation is obtained through a dial switch over which passes a contact plate cutting out or thrown in more or less turns of the primary winding and thereby varying the secondary potential. The switch is operated by a wheel handle, and the potential may be varied rapidly in either direction, the contact plate snapping from contact to contact in one direction as well as in the other. The dial switch is applied to the transformer itself instead of being a separate device, and the entire construction is singularly compact.

ACETYLENE GAS GENERATOR.

The flame of the acetylene gas burner is very small, not more than one-quarter perhaps of the ordinary five-foot per hour coal gas burners. Yet it consumes about one-half foot per hour, giving a twenty-five candle power light; ordinary gas giving sixteen candle power. The particular feature which strongly commends the new gas to householders is the ease and cheapness with which a distinct and separate plant may be introduced into any house, a type of which is illustrated herewith.



CRITERION ACETYLENE GENERATOR.

In this type of generator the carbide is separated into comparatively small portions completely isolated from each other, one portion being used at a time, the other portions being practically cut off from contact with any dampness. The generator consists of a stand for carrying the carbide-holder and a gasometer for regulating the supply of water, keeping the gas pressure constant and taking care of the surplus gas. A condenser for cooling the gas is at the base of the gasometer. The water-regulator is placed on the side of the gasometer, from which the water supply is taken, except in large generators, in which a separate water tank is used.

The carbide-holders are made in various sizes and are attached to the stand by pipes which radiate from a central upright, but each holder is on a different level from the others; four, eight or twelve of these holders, according to size, can be conveniently arranged in sets of four, one set above the other, the gasometer being of the same capacity for any number of holders of a given size. Mechanically all movements are central; there is, therefore, no chance of any parts binding and sticking, and thereby causing change of pressure in the gas, or other trouble.

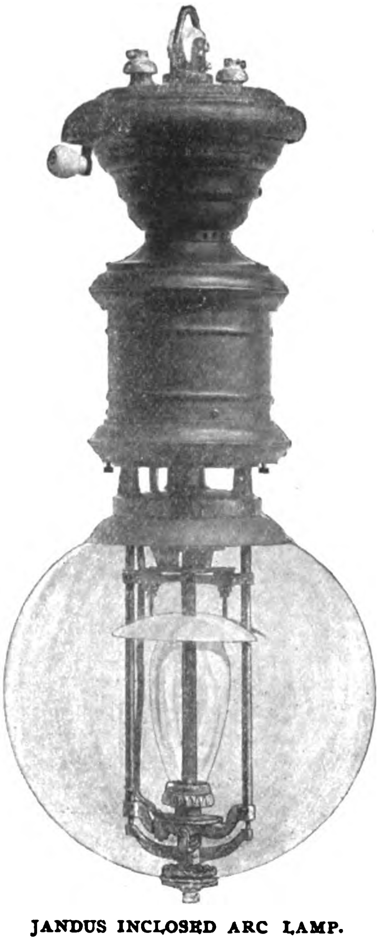
The Criterion generator above described is made by J. B. Colt & Co., 3 West 29th street, New York.

INCLOSED ARC LAMP.

The non-focusing alternating current arc lamp shown in the accompanying illustration is applicable to circuits of from 7000 to 16,000 alternations per minute, and voltages from 100 to 120.

The principal features of the lamp, which is but thirty inches in length, are the ring type of clutch used, the carbon grip and substantial construction throughout. The mechanism is so designed that all joints or pivotal connections between moving members are taut at all times, so that there is no lost motion to take up, either in striking the arc or during the burning of the lamp, thus insuring noiseless operation.

The solenoids are easily removable, and a reactance coil placer is placed in the canopy easy of access for adjusting voltage. The loss in the lamp is but 20 watts when adjusted to the 6 amps. on a 100 or 110 volt line; the consumption in this case is usually from 400 to 450 watts, giving an average efficiency of 95 per cent. The carbons used are ⅛ and 1-16 in. core, each 8 ins. long. By using the stub of the upper carbon for a lower in the succeeding run, but one fresh trim per carbon is necessary. The life of one pair is 80 hours.



JANDUS INCLOSED ARC LAMP.

The above described lamp is made by the Jandus Electric Company, Cleveland, O.

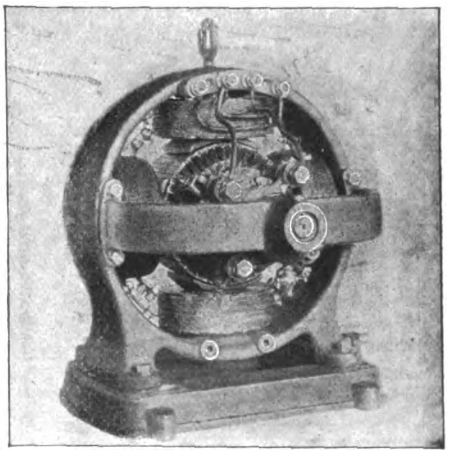
KEYSTONE MULTIPOLAR OPEN-TYPE GENERATORS AND MOTORS.

Realizing the fact that there is a brisk demand for small dynamos and motors that are really reliable, and in which efficiency is not sacrificed to cheapness, the Keystone Electric Company, of Erie, Pa., has placed upon the market such a line of machines.

The field frame is of cast steel and the market has been thoroughly searched for a grade having the best magnetic properties and at the same time capable of pouring perfect castings. Both the outer and field surfaces of the pole piece are bored to exact dimensions, thus securing a truly balanced field, with a minimum of clearance. Substantial pole pieces also serve to reduce the reluctance of the magnetic circuit. The bearings are self-oiling, supported in brackets bolted to the field frame, and so designed as to permit the motor or dynamo to be bolted to the floor, wall or ceiling.

The field coils are wound upon spools, the cylindrical portions of which are carefully drawn seamless copper tubes with flanged ends, which secure the end flange; the tubes fit closely, without driving or forcing, in the turned surface of the pole pieces, thus reducing the length of the poles and obviating any vibration. Another valuable feature of the copper mounting is that its action as a closed secondary reduces the inductive e.m.f. due to field discharge. The coils are wound with strict regard for layers and turns, each bobbin having the same number to a fraction. Each coil is wound in two parts, the terminals being both outside ends.

The ring type of armature is used, and the core is built up of a fine grade of laminated steel which is tested for permeability and hysteretic losses before being accepted from the makers. The complete core is carefully filed smooth, balanced and insulated with layers of mica and rubber cloth. The coils are wound in place tightly by hand, each coil being covered with a strip of fiber, between which and the overlapping teeth a hard wood key is driven which holds the coil rigidly in place, thus affording a superior mechanical construction. This method of winding and securing is particularly desirable with respect to repairs, which can be readily made in localities far from repair shops.



KEYSTONE MULTIPOLAR DYNAMO AND MOTOR.

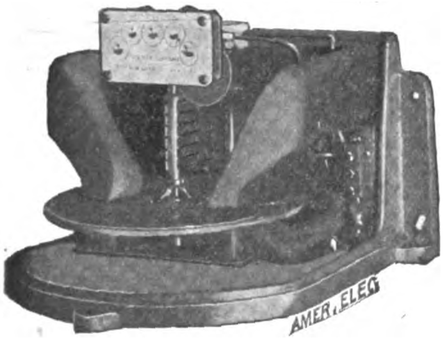
The commutator is made of solid forged bars, insulated with the purest India mica, the segments when completed being powerfully compressed in a heavy clamp. A brush wearing surface has been provided both deep and broad, the current density not being allowed to exceed 30 amps. per sq. in. of brush contact. The brush holders are of the reaction type.

Speed considered, this machine is claimed to be unexcelled in efficiency per pound of material, and is therefore exceptionally well adapted where lightness is a consideration, in portable plants of all kinds, and for wall and ceiling work.

WALKER INTEGRATING AMMETER.

The new Walker integrating ammeter, shown in the accompanying cut, is a direct reading recording ammeter adapted for continuous currents, registering ampere hours. Two powerful permanent magnets act on a thin copper disk rotating between them. On the surface of this disk are mounted three coils, each having a common connection in the disk itself, and presenting their free ends to a long three-part commutator of small diameter. On this commutator rest three broad copper brushes, which in the cut seem to be very stiff and apparently productive of much friction. Such, however, is not the case, and the contact that the brush makes with the commutator, while extremely reliable, is surprisingly light, the friction being negligible.

The greater volume of the current that the meter measures passes through a shunt to the terminals of which the brushes of the meter are connected. The copper disk renders the speed of the meter proportional to its torque, and its torque is proportional to the current in its armature wires, which is, of course, proportional to the main current. Therefore, the instrument measures ampere hours if properly calibrated. By varying the shunt the capacity of the meter can be varied, and in this way it can be supplied in large sizes at low proportionate cost.

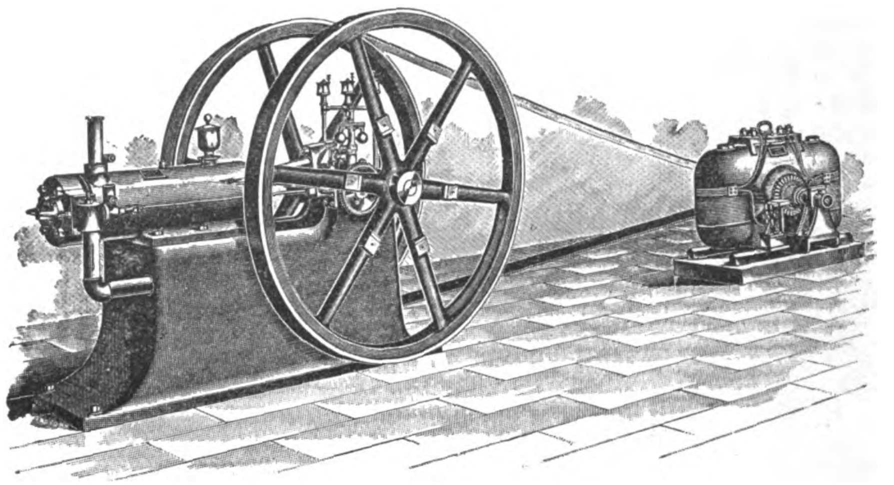


WALKER INTEGRATING AMMETER.

WHITE & MIDDLETON GAS ENGINE.

The gas engine shown herewith, direct-connected to a dynamo, is claimed by the makers to be especially suitable for electric work, and, on account of the simplicity of its construction, not to require expert attendance.

There is no mechanism attached to the crankshaft to control the movements of the engine, excepting the governor, thus adding to the simplicity of the machine. The igniter is simple in design and construction, having no springs or special mechanism to control it. The manufacturers of this engine prefer a low speed, for the reason that this adds to the life of the machine, lessens the amount of lubrication and calls for less skill on the part of the attendant. They also rate their machines according to brake horse power, each machine being tested before being sent out, and a guarantee given as to its gas consumption. This method of rating gas engines by brake horse power is the only proper one, as the indicator card includes the work of three idle strokes, which is negative and varies widely in different makes of engines.



WHITE & MIDDLETON GAS ENGINE.

The engine described is made by the White & Middleton Gas Engine Co., Baltimore, Md.

AMERICAN HIGH-GRADE ARC CARBONS.

That the highest grade of arc carbons—such as are best fitted for constant potential lamps—have in the past been supplied from abroad has by some been held to be little creditable to American carbon manufacturers. In cases where the latter have acknowledged the superiority of German carbons, such a concession has usually been accompanied by the statement that the proper grades of crude material cannot be obtained in this country. On the other hand, it is said that the leading German makers of carbons keep their process of manufacture secret, the mixture of materials being made behind locked doors by a trusted employee or even by one of the firm, and that in view of this the assumption that the component materials differ from what may be procured in this country requires evidence that has not yet been offered.

The latter view has for years been held by Mr. J. S. Partridge, of the Partridge Carbon Company, Sandusky, Ohio, during which time he has almost continually been experimenting with the object of finding a mixture of American material and a process of manufacture that would produce carbons equal to imported ones. Mr. Partridge states that he has recently succeeded in accomplishing his purpose, and at the New York Electrical Exhibition he placed a number of his carbons on trial in various arc lamps burning in the hall. The conditions were sometimes so severe that the ordinary American carbons could not be used at all, but all seem to have been successfully met by the new carbon, according to the testimony of the disinterested persons whose lamps were used, among whom are several makers of arc lamps.

Other evidence of the superiority of the new carbon, which supplements the above practical tests, is offered in a report recently made by Mr. J. S. Wood, a competent electrical engineer and member of of the firm of Wood, Shaw & Company of New York. A pair of carbons were placed in a 110-volt 4½-amp. Bergmann lamp at 11.30 a. m. of May 5, and kept burning until 12.30 a. m. of May 7, a period of 49 hours. At the beginning of the test the length of the carbons was 12 and 5 ins. respectively, and at the end 10 and 4¾ ins., showing a consumption of but 2¼ ins. in slightly over two days. This new grade of carbons will, we learn, be very soon placed on the market.

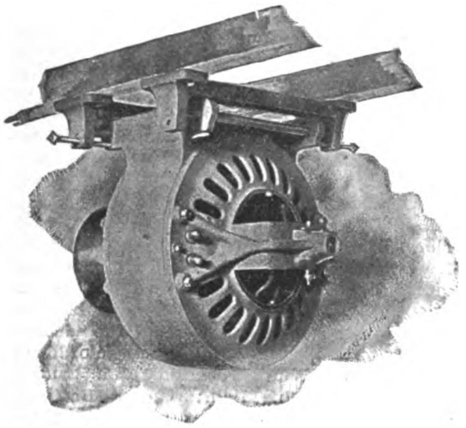
COMMERCIAL IRONCLAD MOTOR.

The accompanying engraving shows a new type of commercial ironclad motor which has just been placed on the market by the Commercial Electric Company of Indianapolis, Ind. As will be seen, it is compact and attractive in appearance, as well as thoroughly protected from mechanical injury, dust and dirt, while the large lids which are placed in the casing above and below the commutator allow of easy access to the brushes when desired.

The method of mounting is especially adapted for ceiling suspension as well as for installation directly on the floor or foundations. When suspended, as shown in the cut, the operation of the belt-tightening device is in no way interfered with. Since there are no bolts to be loosened, the machine can be mounted on its support, as with other ceiling machines.

This type is convenient for belting direct to elevator machines when used in this way, and a special reversible motor and controller is made for this purpose.

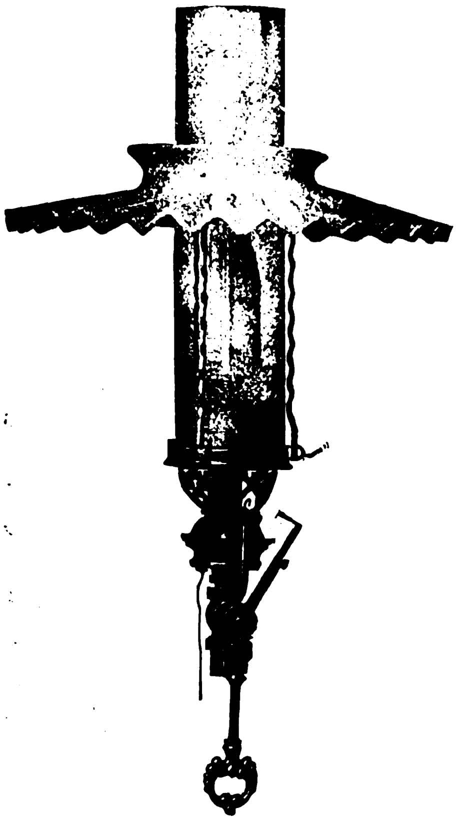
The magnet frame is of steel with circular cores and pole shoes of the same material, thus affording a low resistance air-gap and the greatest possible efficiency of the magnetic circuit. The end casings-which carry the bearings are of cast iron and provided with ample ventilating holes. The shafts are of steel, and the bearings self-oiling, with bronze linings, which are easily renewed. Carbon brush holders of simple construction and large capacity are used, and, owing to a strong magnetic field, sparking with change of lead is avoided.



COMMERCIAL IRONCLAD MOTOR.

ELECTRIC GAS LIGHTING ATTACHMENT FOR INCANDESCENT BURNERS.

For a practical method of lighting incandescent burners, an attachment has been designed which embodies the improvements found in the "Advance" electric gas lighting burner. Among them are the smooth, easy action in lighting, which will not break the mantle; its operation by key in the same manner as the ordinary gas cock, and the fact that there is no possibility of the burner becoming short circuited in extinguishing. An additional feature is an adjustment in the pilot tube, by which the size and height of the pilot flame can be regulated. This obviates the blackening of the mantle, frequently found in burners lit from a pilot tube where too large a flame issues from same.



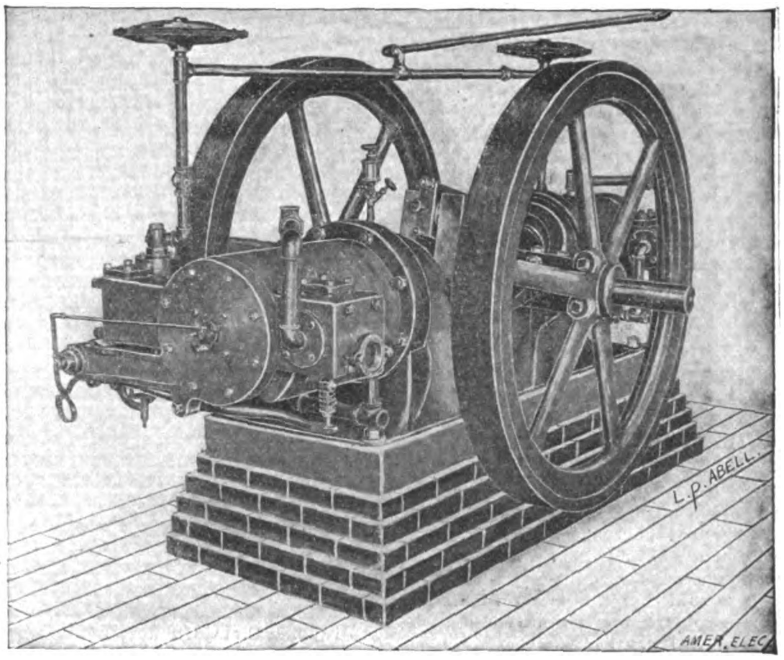
ADVANCE GAS LIGHTING ATTACHMENT.

The attachment can be used with the Welsbach (as shown in illustration), and a majority of the other incandescent burners now on the market, and require but a few moments to attach. The Electric Gas Lighting Company, 193 Devonshire street, Boston, Mass., are the manufacturers of this device.

LAMBERT GAS ENGINE.

In the type of engine herewith illustrated, the Otto cycle is utilized, and to obtain unvarying speed two cylinders are used, facing each other on same bed, and working on separate cranks. The shortening up of the connecting rod gives the piston more travel for the first ¼ revolution, on outward stroke of piston, which results in several advantages, one of which is that the impulse of explosion is not given to the wheels suddenly, thus steadying the motion.

A double-cylinder engine built with a double crank is particularly applicable for driving dynamos. The cranks balance each other, and therefore the wheels can be balanced. The pistons, always traveling in opposite directions, balance each other when their motion is reversed. This plan of building admits of speed without the attending vibration. The accompanying engraving is reproduced from a photograph of a Lambert double-cylinder 50-h.p. engine, manufactured by the Lambert Gas & Gasoline Engine Company, of Anderson, Ind.



LAMBERT GAS ENGINE.

NEW BOOKS.

THE ELEMENTS OF ELECTRIC LIGHTING. Including Electric Generation, Measurement, Storage and Distribution. Ninth edition. By Philip Atkinson, A. M., Ph. D. New York: D. Van Nostrand Company. 279 pages, 104 illustrations. Price, $1.50.

That this book has passed into a ninth edition is evidence that it meets a real need. The purpose of the book is to set forth the various facts pertaining to electric lighting in plain language, devoid of technicalities and mathematics. It is therefore well adapted to the needs of the general reader, the business man and others who desire, without entering into the technics of the subject, to obtain an intelligent understanding of it.

THE POWER CATECHISM. Correct Answers to Direct Questions Covering the Main Principles of Steam Engineering and the Transmission of Power. Compiled from the regular issues of *Power*. New York: Power Publishing Company. 226 pages, 131 illustrations.

This is easily the best catechism of practical steam engineering yet published, combining three essentials in a book of instruction—logical arrangement, pertinent selection of questions, and accuracy united with conciseness in answer. The steam engineer who masters this volume will be amply able to cope with any examination that may be set before him, and able also to undertake with confidence the care and management of a steam plant containing new features that would stagger the man who depends only upon knowledge required from direct experience.

THE ESSENTIALS OF GEARING. A Textbook for Technical Students and for Self-instruction, Containing Numerous Problems and Practical Formulas. By Gardner C. Anthony, A. M. Boston: D. C. Heath & Company. 84 pages, 37 illustrations and 15 plates. Price, $1.50.

Especially addressed to students having no previous knowledge of the principles involved, by such this will be found to be an excellent treatise on the design of gears. All of the various points involved are illustrated, not by diagrams meaningless to the practical draftsman, but by actual drawings of gears.

BUSINESS NEWS.

THE STILLWELL-BIERCE & SMITH-VAILE CO. have moved their Eastern office to 141 Broadway, New York.

MR. HUGO DIEMER, formerly of Diemer & Hebble, Cincinnati, has accepted a position with the Westinghouse Electrical and Manufacturing Company, at Atlanta, Ga.

ALBERT B. HERRICK, consulting electrical engineer, has changed his offices from 150 Nassau Street to 120 Liberty Street, where he will be nearer his clients and have more room for his rapidly increasing business.

THE ELECTRICAL EXCHANGE, Chicago, is meeting with much success in introducing "Midget" Upton arc lamps, both direct and alternating current. Among recent orders from a distance was one from St. Michaels, Alaska.

NAVAL FIGHTERS.—The Central Electric Company, 264 Fifth Avenue, Chicago, has issued a card folder containing a list of all American and Spanish men-of-war, with their displacement, horse power, armament, speed and year built.

THE AMERICAN STOKER COMPANY has removed its offices to Washington Life Building, Broadway and Liberty Street, New York. A new catalogue of the American stoker has just been issued, on which no expense has been spared to make it a work of art.

X RAYS AND ELECTRO-THERAPEUTICS.—The L. E. Knott Apparatus Company, 14 Ashburton Place, Boston, have issued a fifth edition of their pamphlet with the above title, which illustrates and points out the advantages of a number of types of static generators and other apparatus.

THE BUCKEYE ELECTRIC COMPANY, Cleveland, Ohio, has just issued a handsome catalogue of its special coiled filament lamp, which has taken high rank in the market for economy and sustained candle power. The manufacturers offer special inducements to consumers on the basis of yearly supply contracts.

A. O. SCHOONMAKER, 158 William Street, New York, reports a good demand for his mica. He is prepared to cut any special pattern or size, and build to any thickness. His mica washers and bushings are particularly popular for repairing arc lamps. Owing to the large stock carried, shipments can be promptly made.

MR. J. E. KEELYN, president of the Western Telephone Construction Company, Chicago, has secured control of the Graham Electric Company's telephone and switchboard business, including all patents relating thereto. It is said that this is the fifth company whose control has recently been secured by Mr. Keelyn.

WESTERN ELECTRIC BULLETINS.—Bulletin 1F of the Western Electric Co. is devoted to alternating current fan motors, giving a complete description of the type, with illustrations. Bulletin 2F is on ceiling fans for direct current, of which four different styles are illustrated. The descriptions are particularly clear.

PARAGON FANS AND MOTORS.—The descriptive catalogue and price list No. 3 of J. P. Williams, 39 Cortlandt Street, New York, is devoted to Paragon fan and power motors. The Paragon motor, all the parts of which are shown in detail, is one entirely inclosed, thus being particularly adaptable for many uses where the attendance is unskilled.

STEPHEN D. LARGE & CO., 321 Chestnut St., Philadelphia, Pa., successosrs to Large & Twining, report a very gratifying increase in orders for their knife switches and switchboards. They have completed a handsome board for the Beachwood Inn, at Jenkintown, and are now engaged in a rush order for a marble center of distribution for the new steel pier at Atlantic City.

CHARLES WIRT, 1028 Filbert Street, has taken enlarged quarters at the same number, for the extension of his rheostat business. Mr. Wirt has recently issued a new price list and rating of rheostats intended to call attention to the superiority of the Wirt rheostat, particularly in regard to performance under conditions of abuse, such as overloading and sudden heating.

GREENE-WHEELOCK ENGINE. — The American Wheelock Engine Company, Worcester, Mass., have issued a well-illustrated pamphlet, in which the new and improved type of Greene-Wheelock engine is shown and described. The main features of this engine are the Wheelock underneath valve, the Hill cam valve gear and the Greene positive cut-off.

THE CARE OF BOILERS.—All interested in steam generation will find much of value to them in Lord's "Essays upon Boiler Incrustation and Corrosion, Boiler Explosions and the History of Natural Water Contamination." A copy of this interesting pamphlet will be sent upon application to George W. Lord, Philadelphia, to any subscriber of The American Electrician.

LIGHTNING PROTECTION — Switch Boxes.—In circular 102 the D. & W. Fuse Company, Providence, R. I., deal with the protection of telephone and similar circuits against lightning and sneak currents. The principles concerned are clearly explained and their application shown by reference to illustrations. In circular 103 a new type of service switch box is illustrated and described.

THE STANLEY ELECTRIC MANUFACTURING COMPANY has moved its New York offices from 39 Cortlandt Street to the new Empire Building, corner Broadway and Rector Street, where it now occupies quarters more commodious and better adapted to accommodate the conditions of its growing business. The new offices are on the tenth floor, on the Broadway corner, and are both light and pleasantly situated.

THE CENTRAL ELECTRIC CO., Chicago, has removed from 173 Adams St. to 264-270 Fifth Ave., where it now occupies largely increased quarters. The size of the quarters may be judged from the fact that the stock room contains no less than 1,500 bins. A system has been adopted whereby the stock keepers can always be fully advised of the quantity of material on hand, and can assemble orders in the shortest possible time.

THE LYNN INCANDESCENT LAMP CO., of Lynn, Mass., state that nine out of ten of their shipments are to old customers, and that five out of eight are to lighting stations, which they believe demonstrates that station managers are appreciating their efforts to furnish them with a good lamp at reduced cost, and that they are making it possible and profitable for the station manager to use a lamp of a higher efficiency and to replace them oftener.

EUGENE MUNSELL & CO. AND THE MICA INSULATOR CO., of New York and Chicago, last week completed arrangements with the George Worthington Co., of Cleveland, whereby they become distibuters of both "Mica" and "Micanite." Their territory includes the city of Cleveland and some eight or ten of the adjoining counties. A large stock of India and amber "Mica," in the sheet and segments for railway motors, as well as "Micanite" plate, segments, rings, cloth, paper, etc., will be carried to supply the electrical trade in that section.

THE SPRAGUE MULTIPLE-UNIT SYSTEM.—The managers of the Alley L road, of Chicago, which is now installing the Sprague Multiple-Unit system, report that as soon as the steam trains are off the line they will be able to reduce their schedule from thirty-eight to thirty minutes, and that they will save in transportation wages alone more than the total depreciation, and will make the old steam service mileage with 15 per cent. fewer cars. They also report that the strains on their structure are noticeably reduced, and that the increase in their traffic has already added quite a percentage to their receipts.

CORRESPONDENCE INSTRUCTION.—A glance over the course in electrical engineering offered by the American School of Correspondence, Boston, Mass., shows it to be thorough and comprehensive. Among the advisors and instructors are Mr. Charles Thom, who for many years has been at the head of the quadruplex department of the Western Union Telegraph Company, and is a man well known among electricians throughout the country. The school confines its attention exclusively to electrical, mechanical and steam engineering, the instruction in which is made as simple, practical and scientific as possible.

UPTON "MIDGET" LAMPS.—The Standard Thermometer & Electric Co., Peabody, Mass., at present supply Upton "Midget" inclosed arc lamps for both high and low frequencies, properly marked binding posts indicating the connection for one or the other. The lamps are also adjustable for from 4 to 6½ amps., as may be desired. Among recent sales have been large orders to central stations at Taunton and Hudson, Mass.; Tecumseh, Mich.; Green Bay and Oshkosh, Wis.; and among recent orders from Edison stations have been 100 for Los Angeles, Cal. An order has also just been received for 50 lamps from a Mexican Central station.

STREET RAILWAY MOTORS.—Thirty-six double equipments of 35-h.p. motors have been ordered from the Westinghouse Electric and Manufacturing Co., by the Cleveland Electric Street Railway Co. Apropos of Westinghouse motors, in a recent letter the superintendent of a street railway writes that a 30-h.p. Westinghouse equipment has been in service on his road for 592 days, making 200 miles per day, without a single repair to any part of the machine, except renewal of bushings and bearings. The motors were on a 30-ft. closed car, running over the hardest part of the road, with less than five minutes lay-over at either terminus from 6 a. m. to midnight.

ROBERTSON COMPANIES.—The business heretofore conducted under the firm name of James L. Robertson & Sons has been dissolved and two new firms organized. Of these, James L. Robertson & Sons will give their attention to the sale of Eureka, Fairmount square flax and all other packings, Hine eliminators, steam separators and oil extractors, engineer and mill supplies. The Robertson Manufacturing Company will make a specialty of manufacturing indicators and their attachments, together with feed water heaters, grate bars, exhaust heads, damper regulators and other mechanical steam specialties. Mr. James L. Robertson will remain at the head of both concerns, the former of which will include in addition Mr. Frank Robertson, and the latter, Messrs. Jas. L. Robertson, Jr., Wm. Robertson, A. C. Lippincott and Thos. G. Keogh.

AN ELECTRICAL FACTORY FLOODED.—The factory of the Hobart Manufacturing Company, Troy, O., was recently partly submerged, owing to a very peculiar flood. The factory of this concern is located to the south of a large storage reservoir, which supplies power to turbines for pumping the city water supply. The heavy Spring rains recently caused the reservoir to break through the waste way and cut an immense gap in the reservoir banks. A great flood of water poured over the lower part of the city, in which the factory of the Hobart Company is located, and in a few hours the water was several feet deep in the Hobart factory and warehouses. The loss to this company was considerable, as a great part of their stock was flooded, besides 14 dynamos and motors that were completed and ready for shipment. Considerable damage was also done to the office, and, altogether, it was some time before the force could carry on its work without considerable inconvenience. Manufacturing was suspended for four days, while the entire force was engaged cleaning out the mud and repairing the damage wrought by the flood. The Hobart Company are at present, however, working overtime to catch up on their orders.

EXHIBITION NOTES.

THE ELECTRICAL EXHIBITION held at Madison Square Garden, New York, during the month of May, showed much progress over the one held at the Grand Central Palace two years previously, particularly in features of general interest and in its instructional departments, there being more than a score of the latter. That the public appreciated the efforts made to entertain them was shown by an attendance under remarkably adverse weather conditions that probably no other show could have obtained.

Among the exhibits of general interest was that of the Edison ore separator system, which was here first shown in its entirety, and a model plant enabled all of its details to be understood. Another, and perhaps the most interesting exhibit to the general public, was that of a full-size section of the Madison Avenue underground trolley road, over which a fully-equipped car was kept in almost constant to-and-fro motion. All of the details of sub-trolley construction were shown, incandescent lamps being so placed as to make the interior details plain, and the mechanism for taking current from the conduit conductors could be seen in actual work, and was also shown in a separate exhibit. The car used was of the Stephenson make, and was equipped with a complete Walker outfit.

An extremely interesting exhibit was one made by the Safety Insulated Wire and Cable Co., consisting of a large tank, with a glass front, showing applications of submarine cables. The United States lighthouse system of electrically lighted buoys was shown in miniature, and also models of submarine torpedoes. With fish swimming in the tank and tiny electric lamps glowing on the spar buoys, the illusion was perfect.

The exhibit of Mr. W. J. Clarke of the Marconi system of wireless telegraphy always attracted large crowds. This was a working exhibit—a transmitter on one side of the hall operating a Morse receiving apparatus on the opposite side. The signal, "N. Y.," in Morse characters, remittantly obtained by means of a slowly revolving make-and-break wheel, was reproduced at the receiver, and sounded on a gong there.

The Moore system of vacuum tube illumination applied to light the interior of a chapel was perhaps the most novel feature of the exhibition. The chapel was a large and well executed model of a vaulted church, and sufficiently large to seat 50 or more people; the illumination was furnished by vacuum tubes, which followed the contours of the arches or lay in cornices at the junction of the arches with the main walls. An organ at one end of the chapel discoursed sacred music. The light produced an effect so closely approaching that of daylight as to be commented upon by almost all visitors.

OPERATIVE SECTION.

To the electrical engineer, if he corresponds to the definition of Lord Kelvin, and is consequently nine-tenths mechanical engineer, the most interesting part of the exhibition was the operative section in the basement. Here two Babcock & Wilcox boilers, of 265 h.p. each, were located, being part of the boiler plant of 16,000 h.p. now being erected for the Metropolitan Railway Company of New York. The boiler under steam was fitted with the Beeckman system of automatic control mechanical draft, the air being delivered into closed ash pits, and the speed of the fans regulated by the boiler pressure.

Of engines and generators there were the following, all direct connected: A vertical New York Safety 125-h.p. engine, driving a 125-volt Fort Wayne generator; an Armington & Sims engine, driving a 50-k.w. 125-volt Walker generator; 35-h.p. American Ball engine, driving a 25-k.w. generator; a Fischer engine, driving a 75-k.w. Onondago dynamo; and a Woodbury engine, driving a 25-k.w. Eddy generator. In comparison with practice of a few years ago, two facts in connection with these exhibits were conspicuous—all of the generating units were direct connected, and all of the engines were fitted with inertia governors. Most striking of all, however, was the fact that there was no alternating current generator in operation, and it may be added that there were no alternating current circuits in the building, a most singular omission in an electrical exhibition of the present day.

Of heat economizers there was a small but notable exhibit of standard apparatus, mechanical in design and appearance, and far from being mere pipefitters' constructions. A 150-h.p. Green fuel economizer was shown, with scrapers in operation and all principal parts exposed to inspection; a 400-h.p. American economizer, complete in all of its details, and with scrapers in operation; a very complete line of cork heat insulating, exhibited by the Nonpareil Cork Manufacturing Company of Bridgeport, Conn.; Berryman feed-water heaters and purifiers, including the latest type, which was shown alongside an older type of the same capacity but several times larger; 6-in. horizontal and vertical Cochrane steam separators, and a 350-h.p. Cochrane feed-water heater and purifier.

The gas engine department was one of the important features of the exhibition, and attracted much attention. The new Diesel motor was represented by a machine of 20 h.p. direct-connected to a C. & C. generator, the speed being 170 r.p.m. Though not intended for electrical service, and only hurriedly prepared for this purpose, it carried its load of lights with less than 1½ per cent. variation of speed, according to the statement of a representative of the company. Of the single cylinder type, the engine worked on the Otto cycle without secondary expansion, but the principle of high air compression and fuel injection on part of return stroke is used, the high compression leading to a temperature which ignites the fuel—gas or gasoline—upon its admission.

A 32-h.p. and a 4-h.p. Hornsby-Akroyd oil engine were shown, the latter operating a generator, the combination being similar to that used by the United States Government in connection with coast defense protective work. This engine uses heavy mineral oils or kerosene as fuel, and employs no igniter, the heat of the walls of a chamber forming an extension of the cylinder head, performing the function of both evaporator and exploder. The narrow neck connecting this chamber is capable of sectional adjustment, by means of which the time of ignition may be perfectly controlled.

A 70-h.p. Nash gas engine, vertical type, was shown direct connected to a Walker generator. The mechanism was of excellent workmanship, in this respect equaling the highly finished electric light engine. Electric ignition is employed on this type of gas engine, and the speed of the driven machine is kept constant by means of a coupling, which allows of a slip between the driving and drawn shaft, the amount of this slip being controlled by a sensitive centrifugal governor.

DYNAMOS, MOTORS AND ACCESSORIES.

One of the first exhibits noticed on entering the main hall was the display of H. B. Coho & Co., New York, which included a varied and comprehensive arrangement of generating and power machinery. This enterprising concern acts as selling agents for the Eddy Electric Manufacturing Company, the Warren Electric Manufacturing Company, the American Rheostat Company, the Crown Woven Wire Brush Company, Van Horne, Burger & Co., the Translucent Fabric Company, and the Otis Electric Company. The product of all these concerns was included in the Coho exhibit. The manufactures of the firm itself included some excellent switchboard and similar devices. Particularly notable was a switchboard constructed of a sheet of ¾-in. French plate glass, three by five feet square, having mounted thereon a complete switchboard equipment for two dynamos. A large number of Eddy motors, with novel starting boxes, manufactured by the American Rheostat Company, were shown in operation, and also a Warren alternator driven by an Eddy motor and furnishing a multi-volt alternating current.

Located on the center aisle was the space of the C. & C. Electric Company, New York, where a large and excellent display of the very latest types of motors and dynamos was made. The exhibit included several large direct-connected multipolar generators up to 60-k.w. capacity. In the way of motors, several of the new iron-clad inclosed type machines recently brought out by this company were shown. An interesting exhibit was an 18-h.p. double drum hoist. A 60-in. fan operated by a direct connected series motor, with commutated field regulation, also attracted a great deal of attention whenever it was set in operation. The new C. & C. starting boxes were displayed in great variety.

Owing to a great rush of business at the factory, the Bullock Electric Manufacturing Company, of Cincinnati, Ohio, was unable to show any large amount of apparatus; in fact, no apparatus was in operation. Several large direct-connected machines were shown, and the technical visitor was particularly interested in the placards attached to them. These placards state that the machines are guaranteed for twenty-four hours' operation at full load, and will take overloads of 50 per cent without sparking.

A 150-k.w. multipolar direct-connected type generator formed the center piece of the exhibit of the Crocker-Wheeler Electric Company, New York. Around this large unit, which was probably the jumbo of the exhibition, were grouped a great number of smaller sized motors and dynamos manufactured by this company. The neat arrangement was particularly notable, as well as the fact that the motors shown ranged from the smallest production of the company up to the larger sizes in gradual steps. The motors were all arranged according to size, and kept in frequent operation. The new motor starting boxes and rheostats, including mica and iron rheostats for large motors, were particularly noteworthy, and the new Crocker-Wheeler mill motors were much discussed. This space was one of the largest and best arranged at the exhibition.

The Fort Wayne Electric Corporation, Fort Wayne, Ind., had a very comprehensive exhibit, which included the only operative and distributing alternating current generating plant in the exhibition. A 37½-k.w., 60-cycle single-phase alternator was coupled direct to, and driven by, a four-pole motor. The current from the generator was supplied to various exhibits, and also to a lamp bank and switchboard, forming part of the exhibition. A striking feature of this exhibit was an 80-light 2,000 candle-power arc machine, of the latest Fort Wayne design, direct coupled to and driven by a 110-volt motor. Arc and incandescent lamps were also shown in profusion, and the integrating Duncan meters for alternating current attracted much attention.

Although the Walker Company, Cleveland, Ohio, was the sole exhibitor of electric railway apparatus, it may well be said that their display was certainly most comprehensive and thorough. At the main space the latest productions in railway motors were shown, and a fully equipped Peckham street car truck, with motors operated by means of the new solenoid controllers, was a prominent feature. The new recording ammeter was probably one of the most interesting appliances shown at this exhibit. This device is practically a small motor, with three flatly arranged disc-like armature coils, and a permanent steel magnet. In addition to the exhibit at this space, the Walker Company showed at the other end of the main arena a complete section of their new open slot conduit electric street railway. This section of conduit road is full size, and equipped with all the necessary fittings, and a standard

Metropolitan Traction Company car was kept in almost constant operation thereon. The complete arrangement is such that every part of the entire system could be inspected by the visitor, and the exhibit undoubtedly formed one of the most attractive and instructive features of the show. The Walker Company also exhibited a new alternator which attracted a great deal of attention. In this machine the rotating multipolar field has but a single coil, and the fixed armature forms an exterior ring, so that it can be connected for varying voltages.

In the upper gallery, the Card Electric Company of Mansfield, Ohio, showed three large motors and dynamos of their very latest inclosed type. The largest of these is a 25-h.p. slow-speed 110-volt machine. These machines are built for heavy service, and are thoroughly protected in every way. A notable feature is the removable commutator cover, making this part of the machine thoroughly accessible, and yet well protected. The Card starting boxes, used in conjunction with these motors, are of a most excellent design, operating on under or overload. A single double-wound magnet, acting on two trip armatures, one for overload, the other for underload, is used for both of these functions.

Almost 150 fan motors were shown in operation at the exhibit of the Paragon Fan Company, represented by Mr. J. P. Williams, New York. The motors were arranged on a wooden pyramid, and when in united operation caused a disturbance in the atmosphere which was felt far and near. A placard stating "The hand that rocks the cradle rules the world," which was attached to a child's cradle operated by a small Paragon motor, attracted the feminine visitor.

Probably one of the most varied and general exhibitions of electric motive power was made by the Sprague Electric Company, New York. In fact, the Sprague exhibit might well have served as a complete exhibit of electric motors and their application. Elevator apparatus was shown in great profusion, from the small automatic house machine to the very largest production, as shown by one of the machines for the Central London Underground Railway. This machine is of the duplex tandem worm gear drum winding type, and has a capacity of 80,000 lbs., at 100 ft. per minute. About fifty of these machines will be installed. The motor exhibit also included a Sprague screw elevator machine, and a large Miele printing press operated by a direct-connected Lundell motor, sidewalk, hoists, &c. An interesting feature of the exhibit was a large pipe organ, with electric blowing apparatus. In addition to the motor display, various small generating sets were shown, including Lundell dynamos and the standard interior conduit system, with its various accessories.

ARC LAMPS.

The exhibition of arc lamps formed one of the really striking and brilliant features of the exhibition, and the supremacy of the inclosed arc lamp was particularly notable.

The products of the International Arc Lamp Company, New York, represented by Mr. George R. MacIntire, were almost everywhere. Starting with the immense "arkolier" in the center of the arena, containing twenty-four MacIntire inclosed arc lamps in three tiers, down to the small baby lamps at some of the booths, MacIntire lamps shone from all sides. They were placed in many of the booths, and attracted a great deal of attention, not only owing to the compactness of design, but also to the fact that the control and operation of the lamp is due to a single series solenoid operating a ball clutch, without any other mechanism whatever. Mr. MacIntire, like his lamps, was omnipresent, and always ready to explain the fine points of his wares.

A.-B. arc lamps were exhibited in the space occupied by Elmer P. Morris in the gallery, by the Adams-Bagnall Electric Company, Cleveland, Ohio. The exhibit included a large variety of lamps intended for 110, 220 and 500 volt constant-current service. A 220-volt inclosed lamp, burning singly across the line, was an interesting feature of the exhibit. A marine arc lamp which burns 125 hours at one trimming was also shown. This lamp is used quite extensively on lake steamers.

The Excelsior Electric Company, Brooklyn, N. Y.; the Fort Wayne Electric Corporation, Fort Wayne, Ind., and the Walker Company, Cleveland, Ohio, also showed their latest production in inclosed and other arc lamps.

A departure from the usual lines in the construction of arc lamps was shown at the exhibit of J. Jones & Son, New York, in which the usual electro-magnetic mechanism has been entirely displaced. This lamp, as the "Toledo,' is controlled by a hot wire. Its excellent operation and extreme simplicity of construction seemed to convince all who inspected it that hot wire lamps have a future.

The exhibit of the Ziegler Electric Company, Boston, Mass., which was made at the space occupied by Stanley & Patterson in the gallery, included some novel projecting and focusing lamps. The Empire stage lamp —which is particularly attractive and novel— has the two carbons at right angles. Fourteen of these lamps were used in the illumination of the Garden tower. The new inclosed arc lamp for various circuits was also shown.

STORAGE BATTERIES.

The exhibit of storage batteries was confined to a large and very comprehensive display made by the Electric Storage Battery Company, Philadelphia. A great deal of credit is due to this concern for the thorough object lesson which had been arranged. The various types of storage batteries manufactured by the company, from the largest down to the smallest, were shown, many of which are in constant operation.

One of the very large cells built for the Chicago Edison Company was of particular interest. The cell was mounted in a case with glass windows, which clearly showed the eighty-three plates. It has a capacity of 6,000 amperes at a one-hour discharge rate. A fully-equipped storage battery launch, of the latest design, manufactured by the Electric Launch Company, was also shown. By no means the least interesting feature of the company's exhibit was the very large Willyoung X-ray coil, giving a 12-in. spark, which was operated by portable batteries. The welding experiment, which was shown at intervals, illustrated the immense capacity of the company's 11-F. cell. This single cell was kept constantly charged, and heavy leads were taken from it to an adjacent welding machine, in which the current from the single cell melted heavy eight-penny steel wire nails, and afterward re-welded them together. The current taken at times amounted to from 1,000 to 1,500 amperes.

CARBONS AND CARBON SUPPLIES.

The various exhibits of carbon and carbon supplies were all located on the gallery floor. The variety of carbon supplies shown was certainly most complete.

The National Carbon Company, Cleveland, O., showed a great variety of carbon productions, among which was a large assortment of electric light and other carbon rods, including some exceptionally large carbon bars or rods used for smelting purposes. The exhibit also included various carbon cells manufactured by the company, among which were the "Klondike" and the "National Fuller." A special gas engine cell has an e.m.f. of one volt with an extremely low internal resistance. Large sizes of this cell give a current of about 20 amps. on short circuit. Various carbon supplies for telephone and similar purposes were also displayed.

The Partridge Carbon Company, Sandusky, O., had a large exhibit of self-lubricating carbon brushes, arc light and other carbons. Their interests are well taken care of by Wood, Shaw & Co. A new electric light carbon for inclosed arc lamps recently developed by this company will surely effect an important advance in inclosed arc lamps.

The Crouse-Tremaine Company, Fostoria, O., showed almost everything in carbon products. Very massive carbons for smelting and electric furnace work were of particular interest.

The LeValley Vitae Carbon Brush Company, New York, N. Y., exhibited LeValley Vitae carbon brushes at their space in the gallery.

The interests of the Washington Carbon Company, Pittsburg, Pa., were being well looked after by the Ward Electric Construction & Supply Company, whose space was located on the gallery.

INCANDESCENT LAMPS.

Almost adjacent to the Madison avenue entrance was the exhibit of Thomas A. Edison, Jr. The main feature of his exhibit was an immense disc of light, about seven to eight feet in diamater, formed by the various types of Edison, Jr., lamps. These were arranged in concentric circles, and when illuminated threw out a perfect blaze of illumination. Lamps of all sizes and shapes and for all purposes were shown, and the exhibit undoubtedly was one of the most striking illustrations of the variety of modifications to which the incandescent lamp is susceptible.

On the gallery floor was the exhibit of the Fostoria Incandescent Lamp Company, Fostoria, O. The space occupied by this concern was most artistically decorated, the prominent feature being Fostoria miniature lamps almost completely covering several columns arranged about the edge of the space. The exhibit includes Fostoria standard lamps of all candle powers; duplex double-candle power, a special four-filament, 200 candle power, and railway, fancy, etched and other lamps. When in full swing the exhibit was one of the really brilliantly illuminated of the smaller exhibits.

The lamp exhibit made by the K. & W. Company, Pittsfield, Mass., was located on the main floor. A great variety of lamps manufactured by this company was shown, and a very artistic sign, made up of miniature Hardy lamps, drew the attention of the visitor to this exhibit. K. & W. arc lamps, cut-outs, commutator lubricating compound and brushes were also shown.

A novel incandescent lamp was shown by the Fort Wayne Electric Corporation, of Fort Wayne, Ind. The tip at the large end of the globe is eliminated, giving the globe a smooth finish, and the exhaustion of the bulb is accomplished from the terminal end instead of the usual tip end, as in other lamps.

ELECTRIC PUMPS.

Entering the main arena from the Madison avenue entrance, the visitor saw before him an immense exhibit of pumping machinery which could not fail to attract his attention. The exhibit was made by Henry R. Worthington, N. Y., and could well have been called a World's Fair display. It included almost every conceivable form of pump operated by electric power, from a large duplex machine used for elevator or town supply work, down to the smallest of electric house pumps. The large electric pump is peculiar in the fact that a worm gear connection is used between motor and pump mechanism. The space occupied by the Worthington exhibit was the largest of any single exhibitor, and included over one thousand square feet.

INSULATED WIRE.

One of the most artistic exhibits was that of J. A. Roebling's Sons' Company, Trenton, N. J. The large space occupied by this concern was very elegantly arranged and divided into two rooms, one of which was filled with wire exhibits, the other being used as a reception room. The latest wire products, including Columbia rail bonds, were shown.

The exhibit of the Safety Insulated Wire & Cable Company, New York, was located in the gallery. An interesting feature which hibit. Another interesting feature which aroused a great deal of interest was a short section of submarine cable, such as would be used for telephonic connection between New York and London, with the instruments of the present day. The copper core of this cable has a cross section of 32,000,000 circular mils, and the whole diameter of the cable, including the insulation of 2 ins. and armor of 1½-in. steel rods, is about 20 ins. No information was given as to when this cable is to be installed, and it would be interesting to know its cost per mile.

The Montauk Multiphase Cable Company, N. Y., had a well-arranged exhibit on the arena floor, and showed various forms of its automatic fire-alarm cable. This cable combines ordinary distributing wires, which may be used for telephone or other purposes, with a thermostatic wire, so that automatic fire protection is afforded wherever the cable is placed throughout the building. Frequent tests at the booth aroused many favorable comments. Samples of insulating wires and cables of Habirshaw make were not displayed, but able representatives of the company were very much in evidence on the main floor.

INSTRUMENTS, FITTINGS, SUPPLIES, ETC.

Zimdars & Hunt, the well known manufacturing and contracting concern of New York, had an exhibit on the main arena floor which for artistic design was probably unexcelled. Inside of a railing made up of copper busbars, with a large switch blade serving as a gate, was a most complete array of well-designed and excellently finished switches, panel boards, feeder boards and the latest developments in the way of other switchboard appliances.

Quite close to the main entrance was the exhibit of J. Jones & Son, New York. This well-known firm manufactures and deals in all sorts of electrical supplies. Panel boards, switches and similar appliances manufactured by the concern were artistically arranged upon display boards, and a model switchboard was particularly worthy of notice, owing to the excellence of arrangement and design. A display was made of a variety of electric heating appliances. A popular attraction was supplied by a very large Toepler-Holtz machine, which was frequently in operation.

Stanley & Patterson, New York, exhibited on the gallery floor almost everything, from an electric bell to a delicate galvananometer, with a general run of supplies between. This well-known supply house also represented the Ziegler Electric Company of Boston, and the combined exhibits of the two concerns brought together a most interesting lot of electrical apparatus. Stanley & Patterson exhibited general house supplies for almost every conceivable purpose, while the Ziegler Company showed some decided novelties in arc lamps, experimental electrical apparatus, instruments, etc.

Switchboard appliances, panel boards, switches, circuit breakers, etc., were also displayed by H. B. Coho & Company and F. A. LaRoche & Company, New York. Both of these concerns showed a number of very excellent and novel panel boards. Motor starting rheostats were also shown in great profusion at the H. B. Coho space. The American Rheostat Company's latest productions were found here in great variety, and in many instances being in actual service. The new over and under load motor starting rheostat and the elevator starting rheostat were worthy of particular notice.

A large display of junction and panel boxes and fittings for interior conduit systems was made by the Bossert Electric Construction Company of Utica, N. Y. The space occupied by this concern was large, and the appliances were very tastefully arranged on artistic exhibition boards. The new steel box panel boards have many features of peculiar merit, which elicited much favorable criticism.

H. B. Kirkland, New York, had a composite exhibit on the main floor, including switches and cut-outs, manufactured by the Hope Electric Appliance Company of Providence; Cutter switches and circuit breakers, manufactured by the Cutter Electric Manufacturing Company, Philadelphia, and a good sized pyramid made up of Circular Loom flexible tubing.

E. P. Morris, whose space was located at the extreme Fourth Avenue end of the gallery, had probably a larger number of interests to look after than any other exhibitor. At Mr. Morris's space were the exhibits of the Card Electric Motor Company, Mansfield, Ohio; Adams Bagnall Electric Company, Cleveland, Ohio; Highland Electro-Chemical Manufacturing Company, Connellsville, Pa.; Keystone Electric Instrument Company, Philadelphia, Pa.; Warren Electric & Specialty Company, Warren, Ohio; Garton-Daniels Electric Company, Keokuk, Ia.; Kosmic Oil Filter Company, Easton, Pa.; D. J. Sinclair, Caledonia, N. Y.; Simonds Manufacturing Company, Pittsburg, Pa.; Forest City Electric Works, Cleveland, Ohio, and W. B. Cross, Brockton, Mass. Mr. Morris seemed to find no difficulty in handling this great variety of electrical material to suit everybody.

A decided departure in interior conduits was shown at the exhibit of the Silex Insulation Company of New York. It consists of an exterior iron pipe tube concentrically arranged around an interior brass tube with an interlining of silex powder held in position by mica plugs. The exhibit was on the main arena floor, and tube samples were very ornamentally arranged.

The Crown Woven Wire Brush Company had in the space of H. B. Coho & Co. a complete exhibit of its dynamo and motor brushes, many of which were also used on machines throughout the hall.

The H. B. Camp Company, Aultman, Ohio, displayed a variety of their vitrified clay conduit pipes, and also samples of their steel armored insulating conduit.

An excellent display of electrical measuring and indicating instruments was shown at the space of the Weston Electrical Instrument Company, Newark, N. J. Almost every conceivable type of measuring and indicating instrument was shown. On a panel at the back of the exhibit several very large ammeters were mounted, and attracted a great deal of attention.

The Whitney Instrument Company was represented by Machado & Roller, New York. Whitney instruments were shown in great variety in two large cases, and the excellent finish and design were much admired. This exhibit was in the space of the C. & C. Electric Company. Samples of the new A. E. G. incandescent lamps, for which Machado & Roller are American agents, were also shown here.

CAR TRUCKS, WHEELS AND TOOLS.

The puncture proof qualities of porcelain goods manufactured by the firm of R. Thomas & Sons' Company, East Liverpool, Ohio, was most comprehensively displayed by a series of tests with a potential of 60,000 volts, alternating current. For this purpose a Westinghouse testing transformer was used. The results obtained show that the Boch insulator manufactured by the concern has an enormous potential resisting ability. A great variety of porcelain insulators and other electrical fittings were shown, and the attendance at the booth was always large when tests with the 60,000-volt transformer were in progress.

The possibilities of porcelain as applied to

electrical fittings and cut-outs was very fully shown by the excellent exhibit of the Peru Electric Manufacturing Company, Peru, Ind. This company showed a line of cut-out blocks with fuse and attachment plugs, which, with the exception of metal parts, are made entirely of porcelain. A large assortment of porcelain insulators and Hercules and Laclede batteries were also shown.

MISCELLANEOUS.

Instruction by correspondence was well discussed at the booth of the International Correspondence Schools, of Scranton, Pa. The booth was well illuminated, showing various samples of students' work.

Probably one of the most attractive spots in the exhibition was the space of the Electrical Engineer Institute of Correspondence Instruction, New York. This is not due to any surpassing artistic arrangement, but to the fact that this enterprising institution had equipped its booth as a popular electrical laboratory, and nightly experiments and demonstrations were given by Mr. J. Sachs. A large number of experiments of the most interesting and instructive nature were shown, and the freely distributed book gave the layman a very clear idea of the so-called mysterious electrical manifestations and applications. Mr. Sachs also gave lectures under the auspices of the institute in the concert hall three or four times each week. The crowds around the booth seemed to show that the layman, electrical artisan, and even in some cases the electrical expert, wishes to know more than he does about electricity. Many new students were enrolled.

The Edison products were well taken care of by the Edison Electric Manufacturing Company of New York. The exhibit included Edison fan motors for battery and electric light circuits, Edison medical transformers for direct and alternating current, and a general line of electro-medical apparatus. The orginal Edison phonograph was also exhibited at this space, with the very latest improvements. Phonograph concerts were given at intervals in the concert hall, and always brought a large attendance.

Some artistic and novel electric lighting appliances and fixtures were shown by the Faries Manufacturing Company, Decatur, Ill. Their universal lamp holders, shades and window display fixtures attracted much attention, and engineers were much interested in the Faries boiler tube cleaner. The Manhattan Electric Storage Battery Company, New York, manufacturers of the Manhattan electric lamps supplied from storage battery, also had an exhibition in this space.

School for Electrical Engineers

AMERICAN SCHOOL OF CORRESPONDENCE

(Chartered by the Commonwealth of Massachusetts)

TEACHES ONLY ENGINEERING < STEAM / ELECTRICAL / MECHANICAL

OUR COURSES are thorough and practical.
OUR ADVISORY BOARD consists of experts of world-wide fame.
OUR INSTRUCTORS are graduates of the best technical schools.
OUR TERMS are low and within reach of every wage earner.

The school offers an excellent opportunity for the ambitious man to secure a practical education in his chosen field, and in these days of lively competition the best position is given to the man having the best trained mind. Therefore a man who is anxious to better his position and increase his pay cannot afford to let this opportunity for self-culture slip from him.

Special Offer to Readers of "American Electrician."

33⅓ % REDUCTION

For the next thirty days we will give 33 1-3 per cent. deduction from our regular tuition fee to all readers of American Electrician.

FOR 30 DAYS.

Write for our new handbook containing schedules of courses, names of instructors, pages from instruction papers, etc.

Over 60,000 lights' capacity in large Brush arc dynamos sold. A large proportion of them using Multi-circuit Dynamos.

The newly designed Brush dynamos have the following capacities: 55, 80, 100, 125, 240, 300, 2,000 candle-power lights; 45, 85, 120, 160, 1,200 candle-power lights.

Brush arc lamps were first used in 1877. More of them being sold to-day than ever before.

Many stations have exchanged all their small units for large Brush arc dynamos. Among them in lights' capacity are:

Buffalo	4,250
Brooklyn-Citizens	3,360
Newark, N. J	3,000
New Orleans	2,250
Cleveland	2,150
Philadelphia Brush	1,500

BRUSH MULTI-CIRCUIT 125-LIGHT ARC DYNAMO—1897.

Two or more separate circuits run direct from one dynamo with any distribution of load on the different circuits. The advantages are absolute flexibility in handling of circuits; reduction of high voltages on circuits run from large dynamos; use of large units with corresponding increase of efficiency; saving in floor space, oil, belts, shaftings, pulleys, attendance.

Experimental Science.

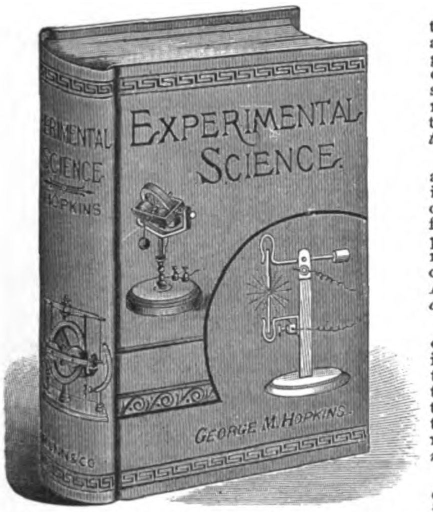
By GEO. M. HOPKINS.

Seventeenth Edition, Revised and Enlarged. 840 Pages. 800 Illustrations. Elegantly Bound in Cloth.

Price, by mail, postpaid, $4.00; Half Morocco, $5.00.

This is a book full of interest and value for all who desire to obtain a practical knowledge of physics.

What is said of "Experimental Science."



"The electrical chapters of the book are notably good, and the practical instruction given for building simple electrical machinery may be safely carried out by those—not a few—who like to make their own apparatus."—*Electrical World.*

"All teachers of science are aware that real knowledge is acquired best by the student making experiments for himself, and any one who points out how those experiments may be easily made is doing excellent work."—*English Mechanic and World of Science.*

"The work bears the stamp of a writer who writes nothing but with certainty of action and result, and of a teacher who imparts scientific information in an attractive and fascinating manner."—*American Engineer.*

"The portion of the book devoted to dynamic electricity covers over one hundred pages, and is extremely interesting and valuable."—*Brooklyn Standard-Union.*

MR. THOMAS A. EDISON says: "The practical character of the physical apparatus, the clearness of the descriptive matter, and its entire freedom from mathematics, give the work a value in my mind superior to any other work on elementary physics of which I am aware."

PROF. D. W. HERING, University of the City of New York, says: "I know of no work that is at the same time so popular in style and so scientific in character."

PROF. W. J. ROLFE, of Cambridgeport, Mass., writes: "The book is by far the best thing of the kind I have seen, and I can commend it most cordially and emphatically."

Hundreds of cordial recommendations from eminent Professors and Scientific men.

Power Distribution FOR Electric Railroads.

By LOUIS BELL, Ph. D.

This book presents the latest practice of the leading engineers in both America and Europe, and discusses heavy railroad service and that by alternating currents as well as street railway or tramway practice proper. It is illustrated by a large number of diagrams and half-tone engravings.

PRICE, $2.50. Postage prepaid.

Our Classified List OF Electrical Books

IS YOURS FOR THE ASKING.

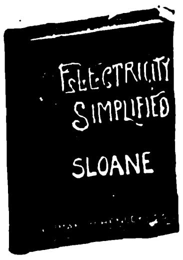
It contains carefully prepared notes on the character and scope of the contents of books on all branches of electrical science, and is of great assistance in the selection of the best books on any subject.

FOR SALE BY

AMERICAN ELECTRICIAN COMPANY,
HAVEMEYER BUILDING, NEW YORK.

Electricity Simplified.

Fully Illustrated. $1.00.



This work is the simplest ever published on the subject of Electricity, and does something not hitherto accomplished. Electricity is in many respects unexplained by the scientist; to the ordinary man it is all a mystery. The object of "Electricity Simplified" is to make the subject as plain as possible.

"This book is intended for the use of those whose former education has not qualified them to follow understandingly, or with any degree of interest, the abstruse and technical works of the author whose volumes are the main sources of our information on these abstruse subjects. The author has certainly furnished a book which will be found to explain in simple language many of the fundamental principles and resulting phenomena of electricity."—*Electrical World.*

Arithmetic of Electricity.

Fourth Edition. Illustrated. Price, $1.00.

ARITHMETIC OF ELECTRICITY
SLOANE

A Practical Treatise on Electrical Calculations of all kinds, reduced to a series of rules, all of the simplest forms, and involving only ordinary arithmetic; each rule illustrated by one or more practical problems, with detailed solution of each one. Followed by an extensive series of Tables.

"We have already reviewed 'The Arithmetic of Electricity' in these columns. The best testimony of the nature of its reception by the public is the early issuing of a third edition. The object of the work is to give a practical review of the mathematics of electricity within the scope of those who are not conversant with algebra and the higher mathematics. It comprises a large number of rules, illustrated by one or more examples each, while, in order to remove from it anything of the empirical aspect, a chapter is devoted to demonstrations of the rules which require it."—*Scientific American.*

American Electrician.

Vol. X. New York, July, 1898. No. 7.

AN ELECTRIC RAILWAY STORAGE BATTERY PLANT.

THE BUFFALO RAILWAY COMPANY'S STORAGE BATTERY PLANT.

The Buffalo Railway Company has recently installed in its Niagara Street power house a large storage battery for the purpose of regulating the fluctuating load due to the 300 or more cars operated from that point, to carry the peak of the load, and to serve as a reserve of power in case of the failure of the supply from Niagara Falls. The station contains steam generating units of a total capacity of 7000 h.p., and four rotary transformers, each of about 500 h.p. capacity. These are fed with alternating current at 25 cycles per second from the transmission lines of the Niagara Falls Power Company, and deliver direct current at 550 volts to the railway circuit.

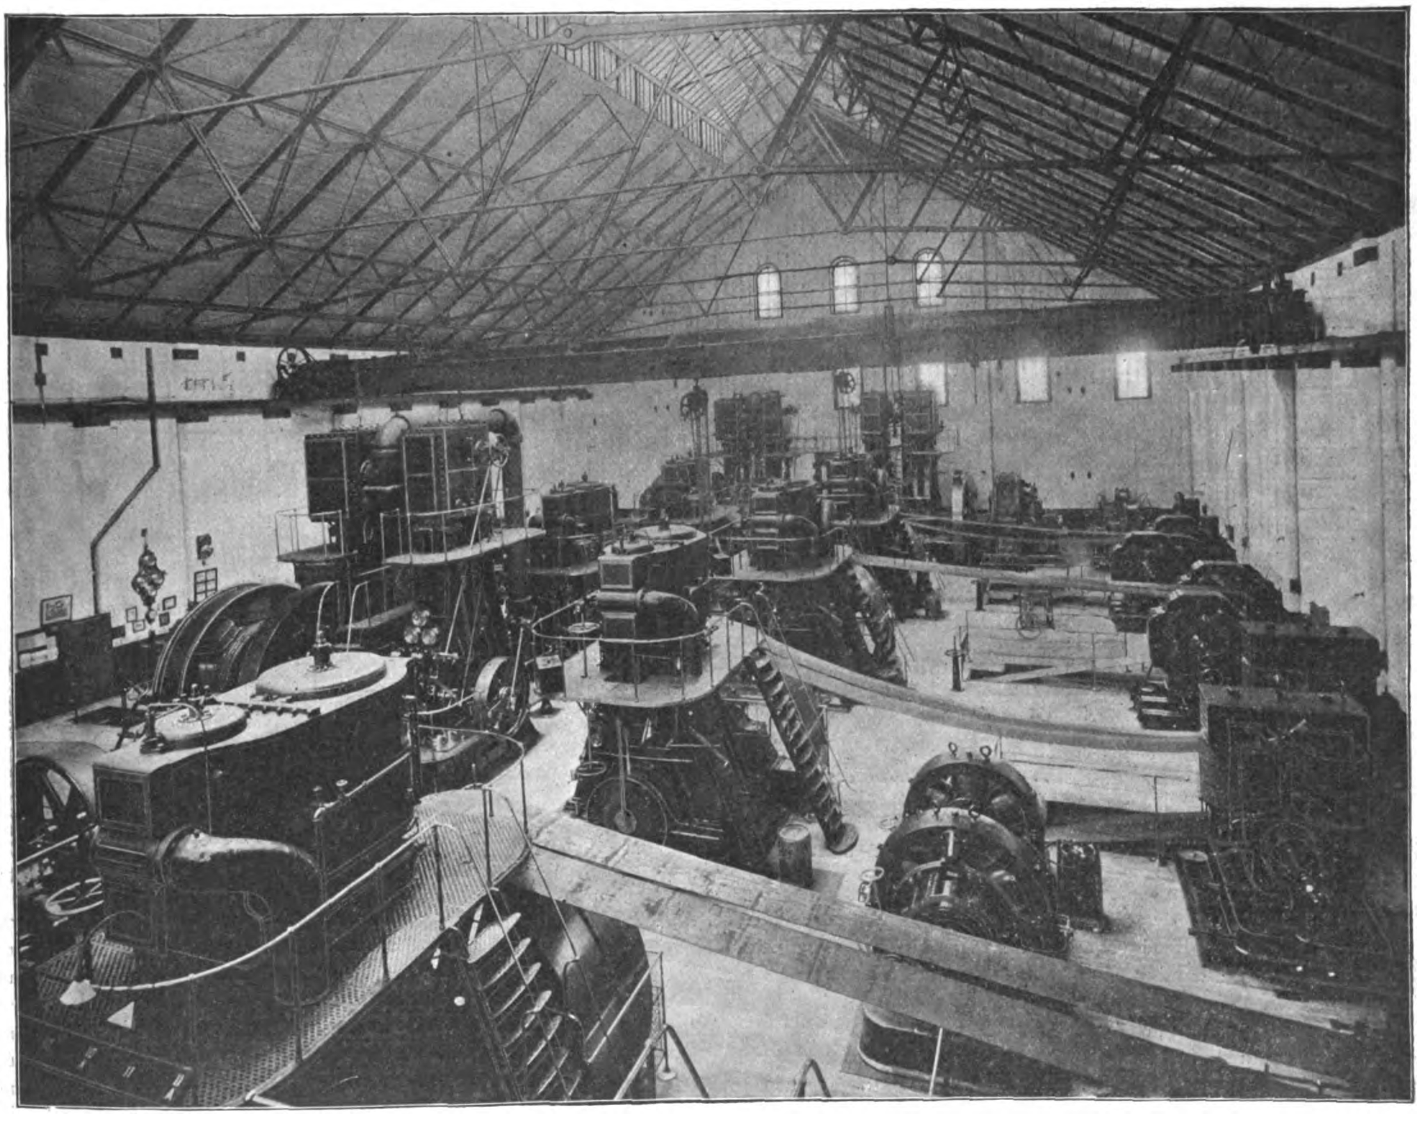

FIG. 1.—VIEW OF GENERATING ROOM.

The power station of the Buffalo Railway Company is an interesting example of electric railway development. It was built early in this decade, when its equipment consisted of 300-h.p. cross compound, high speed engines, each belted to a 200-k.w. Edison bi-polar generator. The next equipment was 200-k.w. Thomson-Houston four-pole machines, and the next General Electric 800-k.w. generators, direct connected to vertical engines. The final additions to the station before the introduction into Buffalo of Niagara Falls power, consisted of three of these vertical direct-connected units. A general view of the interior of the station is given on this page, in which these three types of machines are shown, and with them, in the farthest right hand corner may be seen two of the four 500-k.w. rotary condensers receiving power from the Niagara Falls circuit, and used to supplement the steam plant.

The storage battery consists of 270 cells of the "chloride" type, having a present capacity of about 1200 h.p. when discharged in one hour. As may be seen from the illustration, the cells are not completely filled with plates, but room has been left for the enlargement of the battery by the addition of extra plates, the ultimate capacity of the tanks being for plates sufficient to give 2000 h.p. at one hour's discharge. The tanks for the battery are made of ash, dovetailed together and lined with sheet lead. Heavy porcelain insulators mounted on wooden skids support the tanks, the whole resting on the concrete floor of the battery house. This is a one-story brick building, having a concrete floor and plastered ceiling, the roof being supported on iron columns. The floor slopes gently to one side for drainage, and ventilation is accomplished by means of roof openings and windows. Wooden car mats are laid in the aisles between the rows of cells as an insulation.

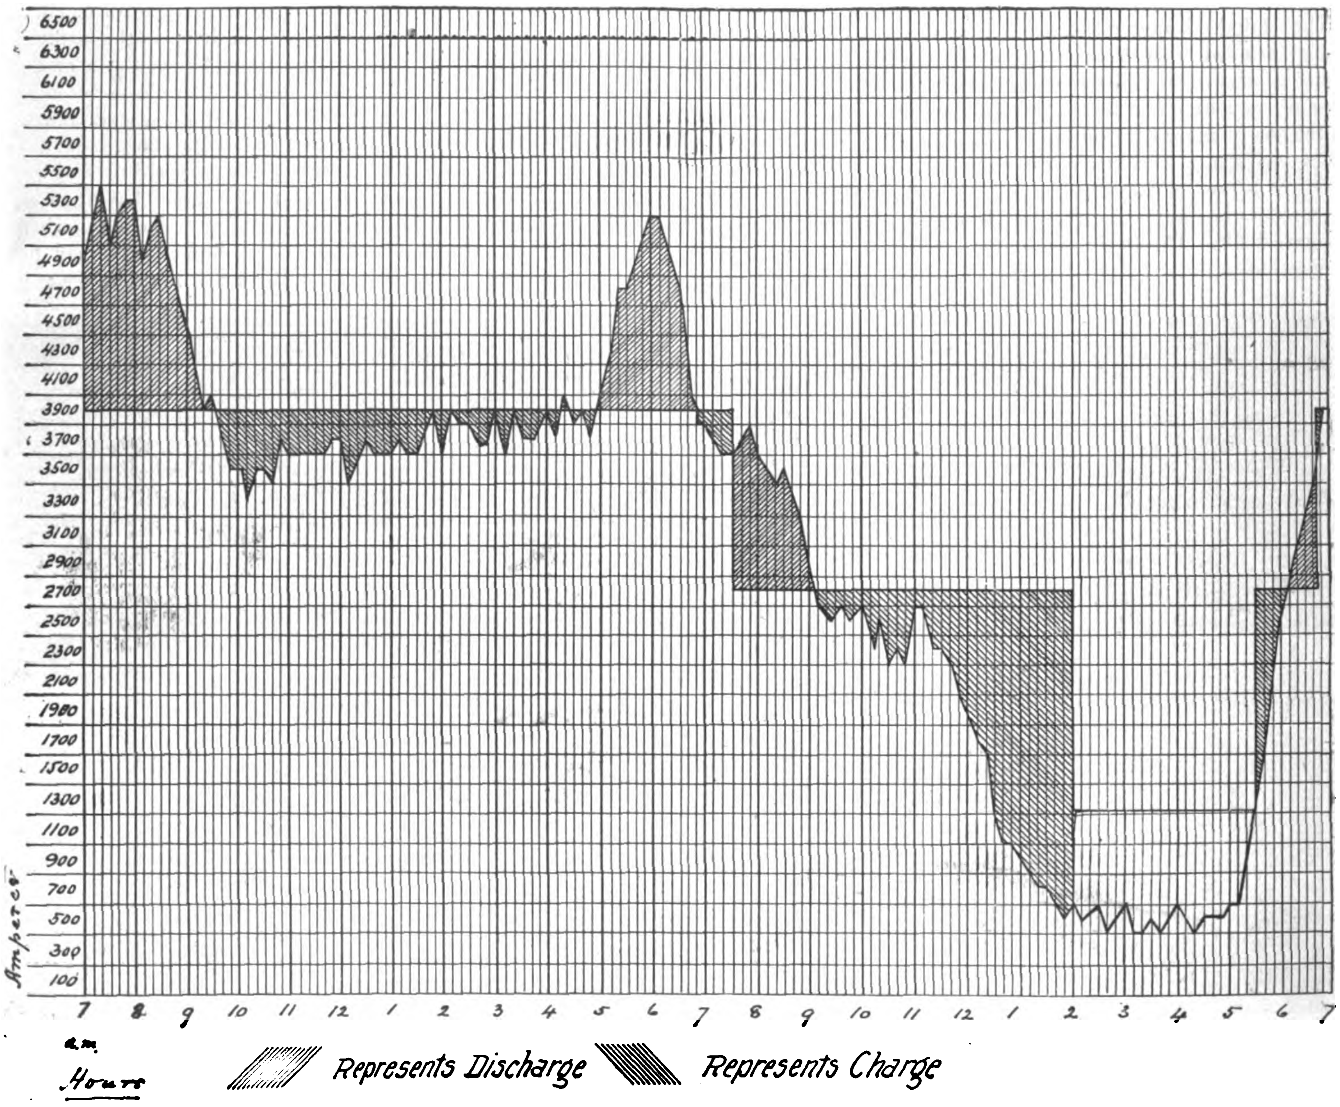

FIG. 2.—CURVES OF CHARGE AND DISCHARGE.

As the illustration shows, all the cells are in one tier and on one level, and the arrangement of the conductors is the simplest possible. All the conductors are of copper covered with lead by a process which results in a thin and firm coating. No trouble has been experienced so far from the gases and spray due to heavy charge rates, and the men working about the battery seem to suffer no inconvenience from them.

The battery is connected at its positive terminal to the main positive bus of the station, and at its negative terminal through a motor-driven booster, having a capacity of 2500 amps. at 70 volts to the ground. The functions of this booster are various, and its construction worthy of special attention. The motor end is an ordinary 6-pole type of motor, working at 500 r.p.m. from the main bus-bars. This is direct coupled to the compound wound booster, which has two commutators of very large size, each carrying six sets of eight brushes. By this arrangement currents as large as 3000 amps. have been sent through the booster without undue sparking. The machine is provided with a center bearing and the usual self-oiling arrangements, and is, as the illustration shows, of very solid mechanical construction.

As the booster is used sometimes to assist the charging of the cells, and sometimes to help their discharge, it is necessary to vary its terminal voltage from zero to a maximum in either direction. This is done by varying the e.m.f. at the terminals of the shunt winding by means of an ingenious switch. In the central position of the switch the e.m.f. at its two points of contact with the resistances is the same, and no current flows in the shunt. At either of its terminal positions the shunt is actuated by the full 550 volts, the direction of its magnetization depending on the position of the switch. The booster can thus be set to either charge or discharge the battery, or in the position of neutral action, by turning the switch lever on the battery switchboard.

During a 24 hours' run the battery is fully charged by the rotary transformers at night and is switched in for service about 5:30 A. M. The peak at 8 A. M. is taken by the battery, which then runs practically as a regulator until the evening peak comes on. At about 7:30 P. M. the steam engines are shut down and the rotary transformers carry the load until the engines are started again at about 6:30 the next morning. Before the installation of the battery it was not possible to shut down the engines except from 11 P. M. until 5 A. M., when the load falls off to about 600 h.p. With the battery it is possible to shut down the engines and run on the rotaries alone for 12 hours in each 24, and for 18 hours on Sundays, while the engines are operated on a constant load while running—the condition of highest economy. During the night all four rotaries in the station are kept fully loaded charging the battery, except from 2 to 5 A. M., when two of them are shut down and the battery cut off to give an opportunity to clean the booster and the rotaries. At these hours the two rotaries that are left running carry the whole load.

When the battery is completed by the installation of the remaining plates it will effect a still further reduction of the steam power consumption and add materially to the economy of the station.

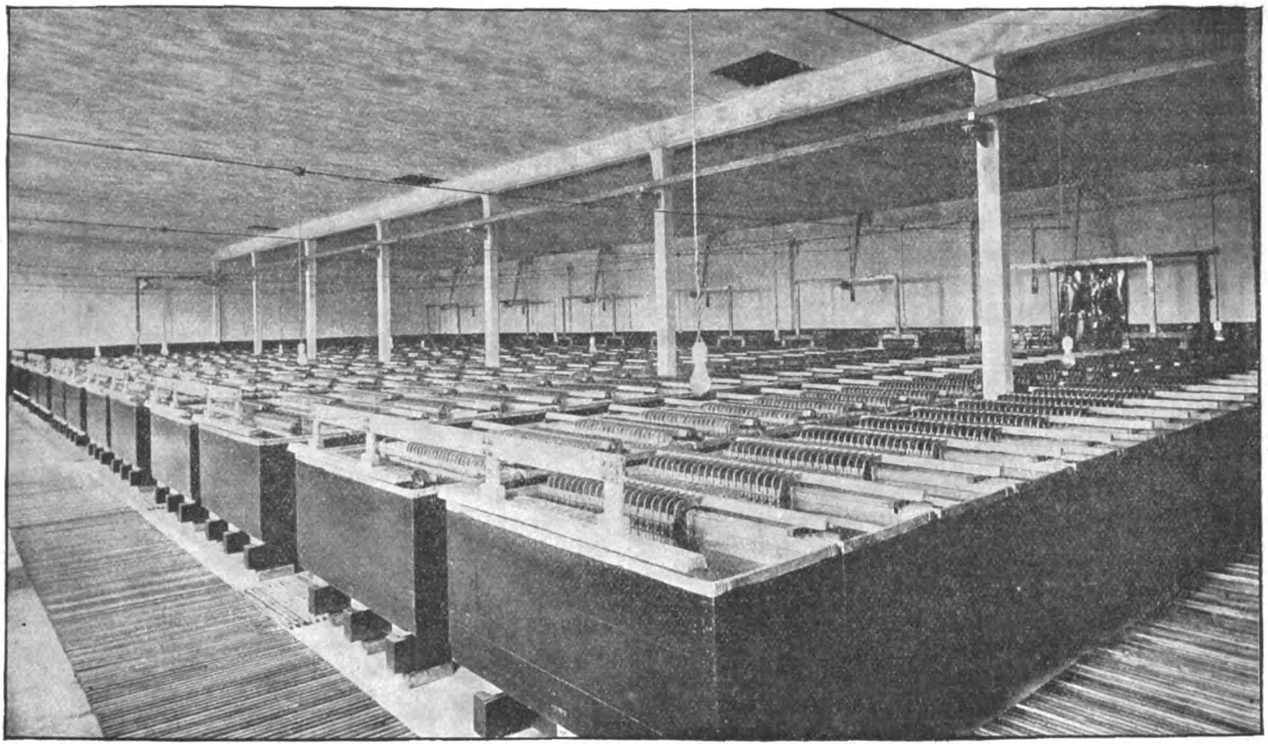

FIG. 3.—STORAGE BATTERY ROOM.

This installation possesses a peculiar interest in being the first and largest user of Niagara power. The current is received as three-phase alternating current at 11,000 volts and 25 cycles per second and transformed to two-phase at the proper pressure for rectification by the rotary converters. In connection with the storage battery this system of supply is almost ideal for its flexibility and closeness of regulation. The voltage at the station does not vary more than 2 to 3 per cent under the extreme and sudden variations of load due to the exigencies of railway service, and shows a steadiness that would be regarded as excellent in a lighting station.

The storage battery was built and installed by the Electric Storage Battery Company, of Philadelphia, and the booster was furnished by the Western Electric Company, of Chicago.

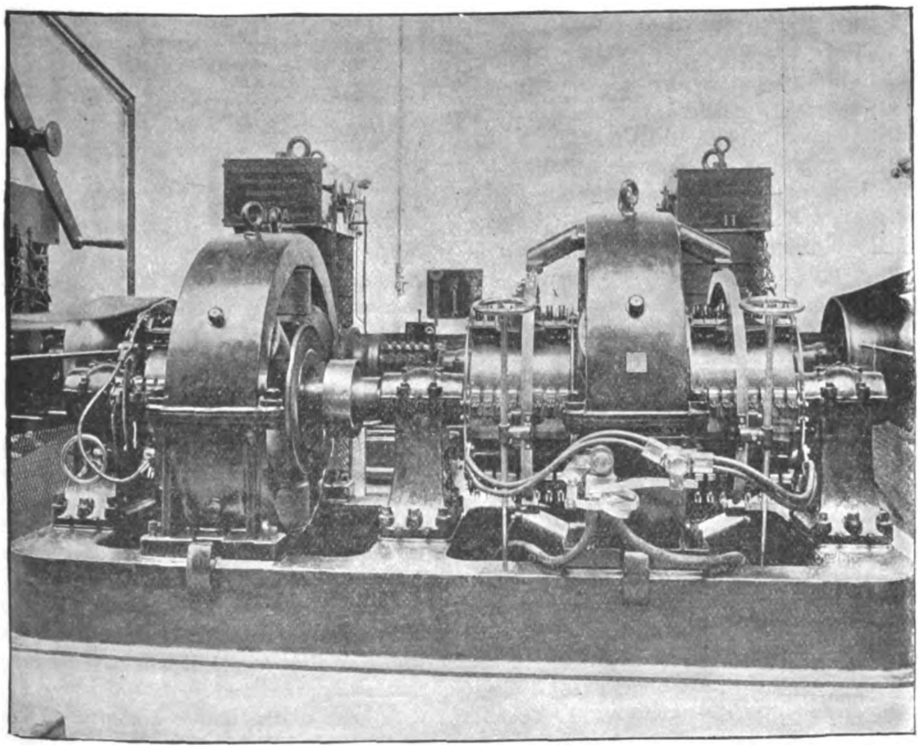

FIG. 4.—MOTOR DRIVEN BOOSTER.

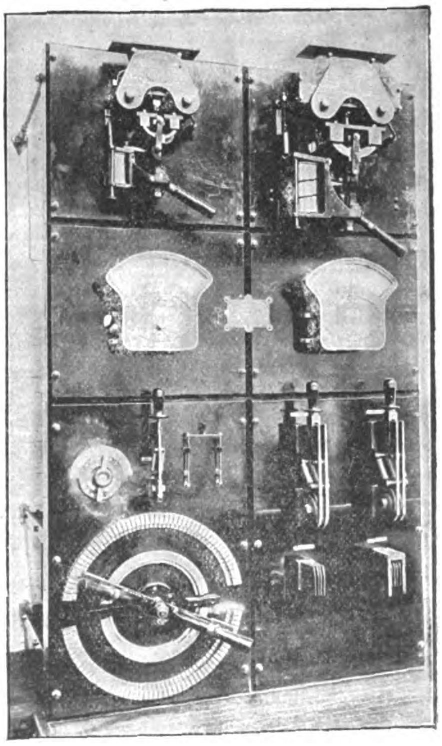

FIG. 5.—TWO PANELS OF SWITCHBOARD.

"SCIENCE ABSTRACTS."

The high promise contained in the first number of "Science Abstracts" is more than fully borne out by the subsequent issues of this valuable monthly publication. The fifth number, or that for May, contains 130 abstracts, and though the publication is devoted to general physics, light, heat and electrical science, the latter subject occupies no less than fifty-six of the seventy pages comprised, the heads being electricity—electro-chemistry and chemical physics—general electrical engineering—dynamos, motors and transformers—power distribution, traction and lighting. The publication is issued under the direction of the English Institution of Electrical Engineers and the Physical Society of London, with Mr. J. Swinburne as honorary editor and Mr. W. R. Cooper as managing editor. Among the committee of seven in charge are Profs. Ayrton and S. P. Thompson, Mr. J. Swinburne, Mr. R. E. B. Crompton and Capt. W. de W. Abney, all well known names in electrical science. The list of abstractors comprises fifty-one names, all men of standing as scientists or engineers. The publications from which abstracts are made comprise the leading scientific and engineering periodicals of the world, as well as the transactions of the various learned bodies of Europe and America. Much attention is given to engineering literature, and the abstracts, more frequently than otherwise, refer to matters of practical interest. As an exhaustive epitome of the advance of physical and electrical science the world over, this publication is invaluable.

POWERING SMALL CRAFT.

DETERMINATION OF THE POWER, DIAMETER AND PITCH OF SCREWS TO PROPEL SMALL BOATS.

We frequently receive inquiries concerning the power necessary to propel small craft of given dimensions, and asking information as to the proper diameter and pitch of screws for the same. There have been no reliable data on these points in print, and in view of the evident need for such data, a high authority on the subject was applied to, who very kindly furnished the information embodied in this article. The data concerning screws are of particular value, being the result of recent experimental work.

The shape of a boat and the relation of its length to the speed have so much influence, that no absolutely definite rules can be given for determining the power, much depending upon judgment in choosing the value of the constant K given in the formula below.

In order to simplify the calculations as much as possible, we give the Admiralty horse power displacement formula[*] in the following form:

$$H = \frac{AB}{K} \text{ .... } (1)$$

in which H is the horse power required. The value of A, corresponding to the weight of the boat fully loaded, is taken from Table I. For example, if the weight of the boat and all its contents at normal load is 4000 lbs., the value of A is 1.47. The value of B is taken from Table II. and corresponds to the speed in statute miles per hour. For example, if the speed is to be nine miles per hour, the value of B will be 477.

Table I.—Values of A.

Weight, lbs.	A	Weight, lbs.	A
500	.397	12.000	3.05
1,000	.584	13,000	3.23
1,600	.765	14,000	3.39
2,000	.926	15,000	3.53
3,000	1 21	16,000	3.71
4,000	1.47	17,000	3 86
5,000	1.68	18,000	4.04
6,000	1.93	19,000	4.16
7,000	2.13	20,000	4.30
8,000	2.33	21,000	4.44
9,000	2.53	22,000	4.58
10,000	2.71	23,000	4.72
11,000	2.88	24,000	4.86

For selecting values of K, no very exact rules can be given, and much must be left to the judgment. In general, the value will depend on three things—length, speed, and form. Other things being equal, it will be greater as the length is greater, less as the speed is greater, and greater as the form is finer. The values for small craft, as here considered, and at ordinary full speeds, are usually from 100 to 150, while as the length becomes greater or speed relatively less, the value increases, until in large ships at proportionately moderate speeds, values from 250 to 300 are reached.

Table II.—Values of B.

Speed, Miles.	B	Speed, Miles.	B
5	84	12	1,131
6	141	13	1,439
7	225	14	1.798
8	335	15	2 212
9	477	16	2,686
10	655	17	3,216
11	872	18	3,818

The influence of length and speed on the problem lies in the relation of the one to the other. As a general guide, it will perhaps be safe to say that so far as length and speed are concerned, speeds in miles per hour not greater than the square root of the length in feet may be considered as moderate and as warranting the higher values of K. Thus, if the length is 50 ft., a speed of 7 miles per hour would be moderate and a value of 150, or perhaps even more, might be used. As this speed is exceeded, the value must be decreased in order to provide for the relatively greater amount of power, and with a fairly fine form it may be expected to come down to 100 or thereabouts for speeds about twice the square root of the length in feet or, in the present case, for a speed of about 14 miles per hour. For a 25-ft. boat the two corresponding speeds would be about 5 and 10 miles respectively.

The influence of form on this value must also not be forgotten. Two aspects of form must be considered, the relation of length to breadth and the degree of longitudinal fullness. The narrower the boat for her length and the finer the form longitudinally, the greater the value of K, and vice versa.

To determine the diameter and pitch of the screw involves the trial solution of the two following formulas:

$$p\,N = \frac{88\,(\text{speed in miles per hour})}{(1 - s)} \quad (2)$$

$$H = \left(\frac{d}{10}\right)^2 \times \left(\frac{P\,N}{100}\right)^3 \times k\,l \text{.......} \quad (3)$$

where H=indicated horse power determined from formula (1); d = diameter of screw in feet; p=pitch of screw in feet; N = revolutions per minute; k = a factor depending on the slip, taken for Table III; l = a factor depending on the ratio of the pitch to diameter of screw, taken from Table IV.; s = apparent slip of the screw—apparent slip being the ratio of the distance moved over to the distance which the screw would travel were there no slip. Owing to the fact that the screw may work in water following a boat, the apparent slip is usually less than the real slip in the water engaged by the screw.

Table III.—Apparent Slip Factors.

App. Slip.	k	App. Slip.	k
.10	.28	.24	.42
.11	.29	.25	.43
.12	.30	.26	.43
.13	.31	.27	.44
.14	.32	.28	.45
.15	.34	.29	.46
.16	.35	.30	.47
.17	.36	.31	.47
.18	.27	.32	.48
.19	.38	.33	.48
.20	.39	.34	.49
.21	.39	.35	.50
.22	.40	.36	.50
.23	.41	.37	.51

Table III. is for screws with four blades of oval form, and having an actual area of about .35 of disk area. For three blades of the same form, the value of k should be multiplied by .85, and for two blades, by .65.

Table IV.—Pitch Ratio Factors.

Pitch Ratio.	l	Pitch Ratio.	l
.90	.941	1.14	.707
.92	.917	1.16	.692
.94	.893	1.18	.677
.96	.872	1.20	.663
.98	.850	1.22	.650
1.00	.830	1.24	.636
1.02	.810	1.26	.624
1.04	.792	1.28	.611
1.06	.773	1.30	.599
1.08	.756	1.32	.587
1.10	.739		
1.12	.723		

There is little reason for expecting any marked variation in efficiency with change in the number of blades, and the selection of this feature is largely a matter of fancy. It may be noted, however, that for given power, speed, pitch-ratio and slip, the less the number of blades the greater the diameter and the less the revolutions. We have here, therefore, a means for assisting in the adjustment of the diameter and revolutions to any desired values, as discussed below.

As an example we will take the case of a boat 34 ft. long and having 7 ft. beam, the speed to be 10 miles per hour. Not knowing the weight, it will have to be calculated approximately.

A boat of the above dimensions would most probably have a draft of 18 ins. and a displacement coefficient of about .5. That is, the volume of water it would displace is equal to the product of the length, beam and draft, multiplied by .5; or volume $= 34 \times 7 \times 1.5 \times .5 = 178.5$ cu. ft. As the weight of one cubic foot of fresh water is 62.5 lbs., the above volume corresponds to a displacement of 11,156 lbs., which displacement is equal to the weight of the boat and its contents when drawing 18 ins. If salt water, the weight is 64 lbs. per cubic foot.

---

[*] The Admiralty formula is $H.\ P. = \frac{D^{\frac{2}{3}}\,S^3}{K}$, where D is the displacement in tons of 2240 lbs., and S the speed per hour in knots of 6080 ft.

In regard to the values of the displacement coefficient, the following considerations may be noted.

The values for small pleasure craft are usually found between .35 and .50. In rare cases of very full or bluff forms, the value may rise to .55 or .60. In selecting a value attention should be paid to the fullness in both the longitudinal and the transverse direction. If the form is fine and sharp longitudinally, and if there is considerable rise amidships from the keel outboard, the coefficient will be quite low, probably between .35 and .40. If the form is fine longitudinally, but the bottom is rather flat from the keel outboard, making a rather full midship section, the value will probably be found from .40 to .45. About the same values may also be expected with a form less fine longitudinally, but with considerable rise to the bottom, while as the form becomes more full, either transversally or longitudinally or both, the value of the coefficient will rise to the higher limits.

It must be especially noted that these coefficients relate to the boat without the keel. The draft used must therefore not include the keel, or if, as given, the keel is included, the latter must be subtracted. The volume of the keel may then, if desired, be computed separately and added to that of the main portion of the boat.

From Table I. we find that the value of A in formula (1) corresponding to 11,000 lbs. is 2.88; and from Table II. we find the value of B corresponding to 10 miles is 655. As the form of the boat is rather full as indicated by the displacement coefficient .5, the value of K will be taken at 100. Substituting in (1), we have

$$H = \frac{2.88 \times 655}{100} = 18.9, \text{ or say } 19 \text{ H P.}$$

To determine the dimensions of the screw, let us assume a slip ratio of 20 per cent, or .20. Then since the speed is 10 miles per hour, we have from formula (2)

$$pN = \frac{10 \times 88}{.8} = 1,100.$$

Next, we will assume that the diameter is to have the same value as the pitch—that is, the pitch ratio will be 1—which gives (Table IV.) .83 for l; from Table III. we find that the value of k corresponding to an apparent slip of .20 is .39. Substituting these three values in (3), we have,

$$19 = \left(\frac{d}{10}\right)^2 + \left(\frac{1,100}{100}\right)^3 \times .39 \times .83$$

$$\text{or, } \left(\frac{d}{10}\right)^2 = .0441$$

from which we find $d = 2.1$ ft., or 25.2 ins.

Since the pitch ratio is 1, the pitch will be the same as the diameter, or 25.2 ins. Also, since the value of pN is 1100, we have $pN = 2.1 \times N = 1100$; whence we find N, or the revolutions per minute, to be 524.

If the above propeller is considered too large or the speed too low for an electric motor, we may try a higher slip and a lower pitch ratio, or .25 for the former, and .9 for the latter. The value of k is therefore .43, and of l, .941.

From formula (2) we therefore have,

$$pN = \frac{10 \times 88}{.75} = 1173.$$

From formula (3) we have

$$H = 19 = \left(\frac{d}{10}\right)^2 \times \left(\frac{1,173}{100}\right)^3 \times .43 \times .941$$

or $\left(\frac{d}{10}\right)^2 = .0291$, and $d = 1.71$ ft., or 20½ ins. Since the pitch ratio is .9, the pitch (p) is $.9 \times 1.71 = 1.54$ ft., or 18.5 ins.; and since $pN = 1173$, the revolutions per minute are 762.

In the selection of a value of the apparent slip, s, the following considerations should be borne in mind:

For the best efficiency it is desirable to use values from .15 to .20. Larger values will result in a loss of efficiency. The loss, however, is not large until excessive values, such as 35 or 40 per cent, are reached. On the other hand, the larger the slip the less the diameter for given power and the higher the revolutions for given pitch-ratio. It may thus become necessary to use large values of the slip in order to reduce the diameter, or to increase the revolutions, as may be desired. While such a course is, therefore, open to the designer, it must not be forgotten that it entails a loss of efficiency rapidly increasing, as values above .30 or .35 are reached. A control over the resulting values of the diameter or revolutions may thus be exercised through the slip, but due regard should be had to the efficiency, and values greater than .25 should not be used unless special circumstances warrant a sacrifice of efficiency to other ends.

The values of the pitch ratio commonly met with in craft of the kind we are now considering are usually not far from 1, slightly more or less. From the fundamental equation it may be seen that the less the pitch-ratio the less the diameter with a given slip, and hence the less the pitch and the greater the revolutions for given speed. The diameter and revolutions may, therefore, be modified by an approximate variation of the pitch ratio, as well as by modifying the value of the slip, and between the two, such values of diameter and revolutions as are desired may usually be obtained, unless the conditions are such as to prevent their realization within the range of usual practice.

As a further illustration of the above principles, we will take the case of a boat 30 ft. long, 5 ft. beam and having a draft of 2 ft. in salt water, the speed to be 7 miles per hour. The displacement volume will then be,

$$30 \times 5 \times 2 \times .4 = 120 \text{ cu. ft.};$$

consequently, the weight will be

$$64 \times 120 = 7680 \text{ lbs.}$$

From Table I. we find, by interpolation, that the value of A which corresponds to 7680 lbs., is 2.27; and from Table II., the value of B which corresponds to 7 miles, is 225. Assuming a value of 110 for K, and substituting in formula (1), we have

$$H = \frac{2.27 \times 225}{110} = 4.64.$$

Selecting a slip of .25, and substituting in (2), we have,

$$pN = \frac{7 \times 88}{(1 - .25)} = 821$$

Taking a pitch ratio of 1, and four blades, from Table III. we have $k = .43$, and from Table IV., $l = .83$. Therefore, from (3)

$$4.64 = \left(\frac{d}{10}\right)^2 \times \left(8.21\right)^3 \times .43 \times .83$$

$$\left(\frac{d}{10}\right)^2 = .0235, \; d = 1.53$$

Consequently, the diameter of the screw is 1.53 ft., or 18.36 ins. Since the pitch ratio is 1, the pitch is also 18.36 ins., and since $pN = 821$, the revolutions per minute are 537.

If the pitch ratio were .9, we would have

$$4.64 = \left(\frac{d}{10}\right) \times \left(8.21\right)^3 \times .43 \times .94$$

$$\left(\frac{d}{10}\right)^2 = .0208, \; d = 1.44$$

The diameter is thus 1.44 ft., or 17.3 ins.; the pitch, $.9 \times 17.3 = 15.6$ ins.; and the revolutions, $821 \div 1.44 = 631$.

If we take three blades, we shall have for $s = .25$, a value of $.43 \times .85 = .365$, and consequently for a pitch ratio of .9,

$$\left(\frac{d}{10}\right)^2 = .0245$$

which will give a diameter of 18.8 ins., a pitch of 17 ins., and 582 revolutions.

Suppose one has a boat which it is wished to equip electrically. The first thing to be determined is what displacement is available for the motor, battery and fittings. This may be done by taking out all unnecessary weights and finding the weight in men to bring her down to the smallest permissible freeboard. If there is steam machinery aboard the weight of this, of course, must be estimated and added to the available weight.

With the displacement thus found, calculate as above the horse-power at the desired speed.

In Table V. are given the approximate weights of a type of slow-speed boat electric motor, made by the Riker Electric Motor Co., Brooklyn.

TABLE V.

WEIGHTS OF SLOW-SPEED SERIES MOTORS.

H. P.	Revolutions.	Weight.
1,200	1,200	80
1,000	1,000	140
1,000	1,000	175
800	800	250
600	600	625
400	400	1,100

A storage battery cannot be procured in the market that will weigh less than 100 lbs. per horse-power hour. If, for example, the horse-power calculated is 4.64, this should be increased about 10 per cent to account for motor losses (part of which may be considered as allowed for in the value of the horse-power calculated, which takes into account shaft and engine friction). This gives 5.10 h.p. of battery, or 510 lbs. for each hour the boat is under way, or sufficient for a run of 7 miles. If it is desired to have a capacity for 5 hours' run, about 2500 lbs. of battery will thus be required.

The voltage of the motor will depend upon the type of battery selected. In the above case, if the cells weigh 100 lbs. apiece, the number will be 25, giving a voltage of 50 and a discharge rate of about 75 amps.

◆

COMMERCIAL DYNAMO AND MOTOR TESTING.

BY W. H. RADCLIFFE.

It has become an established fact, that any one to make a success of electrical engineering at the present time must have a thoroughly practical as well as a theoretical knowledge of the subject. The testing-room of any electrical company manufacturing generators, motors, etc., affords an excellent opportunity for one to become familiar with the handling of machines, their defects and remedies, and the many details that are so valuable in after practice. It is the object of this paper to give a general outline of the work connected with a course such as most of the large electrical companies offer to a man who is fortunate enough to be admitted, and a few of the most important points that will come within his notice.

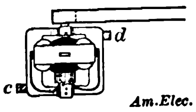

FIG. 1.—LINING A MACHINE.

Assuming that a machine to be tested is brought to a room properly fitted up for that purpose, before it can be lined up it must be fitted with a pulley of such a size that when belted to the testing machine permanently installed, both will be able to run at their rated speeds. A few turns of the belt will show if the machines are in line, after which two blocks of wood nailed to the floor, as shown at c and d in Fig. 1, will be all that is necessary to keep the machine in place.

After the fittings, that is, the brush-holders, brushes, etc., have been attached, the brushes may then be set and weighted; in other words, adjusted to the commutator and given the proper pressure, which should be no more than is actually necessary for a good contact, as too much pressure raises the temperature of the commutator bars. If carbon brushes are used they are then sandpapered to present a smooth surface to the commutator. The motor or generator, whichever it may be, is then ready to be wired for testing.

If the machine is a direct-current shunt motor, readings of volts armature, amperes armature, volts field, amperes field and speed are taken at no load and full load, maximum field strength being given the motor during the entire test. A four-hour heat run at full load then follows, readings as above being taken every half hour. At the end of the heat run, a no-load reading is again taken, the machine shut down and temperatures obtained of armature, commutator-bars, field spools, leading and trailing pole-tips, bearings, frame and room. A core-loss reading—that is, a reading of volts armature and amperes armature of the motor with belt off and running at the same speed and field current as in the last heat run reading—completes the test. Resistances of armature and field are measured before and after every test.

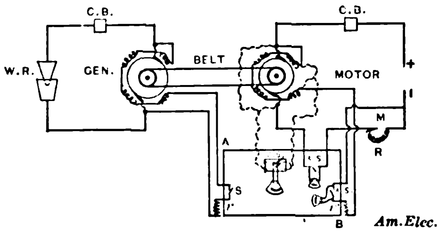

FIG. 2.—TEST OF DIRECT CURRENT SHUNT MOTOR.

In Fig. 2 is shown a diagram of the wiring necessary for the above. A B represents the testing-table on which the ammeters and volt-meters are joined into circuit, as are also the regulating resistances, r and R, in the fields of the two machines. Both ammeters and voltmeters are so arranged as to be cut out of circuit when not in use by means of switches A S and V S, respectively. The voltmeter switch, V S, is double-pole, double-throw, and by means of this volts armature and volts field may be read on the same meter. Switches marked S are main switches and are used to open and close the circuit; M being the motor starting switch, introduces a resistance, R, which it gradually cuts out in closing. W R represents an adjustable water resistance; and C B circuit breakers, one of which is placed in each armature circuit. The above notation also applies to the wiring diagrams that follow.

In testing a series motor, we have a machine which must of necessity be loaded at all times to keep it from speeding up. In this case, the heat run, temperatures after heat run and core-loss reading, are all that can be recorded. The core-loss reading may be taken by separately exciting the series field with the same current the machine takes at full load, the voltage across the armature being varied until the rated speed is obtained.

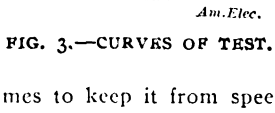

FIG. 3.—CURVES OF TEST.

The wiring for a series motor is the same as shown in Fig. 2, with the exception of the field circuit. As the current in the series field is the current in the armature, and the "drop" of the series field is very low, the wiring in Fig. 2 for volts field and amperes field is not here necessary.

In referring to direct-current generators, let us take for example the commercial test given a compound-wound machine, as we will then have all the characteristics of a series or shunt-wound generator, combined with the compounding.

This test may be divided into four parts—the cold test, heat run, compounding test hot, and the hot test. The first reading in the cold test is of volts armature, amperes armature, volts field and amperes field, with normal speed at no load and full shunt field strength, the brushes being at the neutral point. The second reading is values of the above at no load, normal voltage (brushes at full load position); and in the third, at full load, full series field strength and shunt field as in second reading. The fourth and last reading of the cold test is at full load with a German silver shunt across the series field; the current in the shunt field being given the same ratio to the full load volts as existed between the current in the shunt field and no load volts, in the second reading. A four-hour heat run with this adjustment is then made, readings as above being taken every half hour. The machine at the end of this time is shut down and temperatures taken as in the previous cases. It is then compounded as follows:

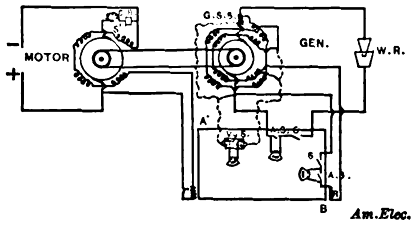

FIG. 4.—TEST OF DIRECT CURRENT COMPOUND GENERATOR.

First, a no load reading at normal voltage is taken, speed, as usual, being kept normal. Next, a full load reading with the German silver shunt so adjusted across the series field as to give full load normal voltage, with the same resistance in shunt field as in previous reading. The readings following are at ¾, ½, ¼, 0, ¼, ½, ¾ and full load, respectively, the load being varied by varying the resistance in the armature circuit.

The curves plotted from these readings take the form shown in Fig. 3. The difference between the volts at no load, that is, between A and C, vary between 3 and 5 per cent; while at full load, between B and D, the difference is usually less than 2 per cent—the rise each time, of course, being due to residual magnetism in the field. There are but two readings taken in the hot test, both at no load; the one, with shunt field adjusted to give one-half no load volts; the other, with maximum shunt field, the brushes in the latter case being moved to the neutral point. The resistances measured during the test are of series field, shunt field and armature, cold; series field, shunt field and armature after heat run; shunted series field, and series field alone, after compounding.

The wiring for a compound-wound generator is shown in Fig. 4, r, the resistance in the motor field is used in keeping the speed constant. G S S represents the German silver shunt. The rest of the notation being the same as in Fig 2, no further explanation is necesssary.

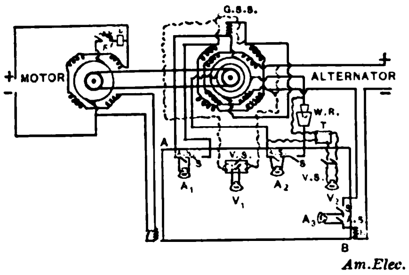

FIG. 5.—TEST OF ALTERNATOR.

The commercial test on any alternating current generator is as follows: Cold test, readings of volts armature, amperes armature, volts separately excited field, amperes separately excited field, volts series field, amperes series field, with normal speed at no load and maximum current in separately excited field. The next reading is values of the above at no load, normal voltage; then a reading at full load, maximum resistance in rheostat shunting series field and the same current in separately excited field, as in the previous reading.

The current in the separately excited field is now adjusted to give full load normal voltage, with the series field shunted as above. A six-hour heat run is made under these conditions, readings being recorded every half hour. The temperatures taken at the end of the run are of armature core surface, armature core vent ducts, armature coils, armature binding wires, armature spider, commutator bars, collector rings, leading and trailing pole tips, separately excited field, series field, bearings, frame and room.

The compounding test hot consists of readings of volts armature, amperes armature, etc., at no load, normal voltage; then full load on each successive step of rheostat shunting series field. In the hot test, readings are taken at full load, normal voltage, also at no load, current in separately excited field, as in the previous full load reading. Resistances are measured before and after test, of the armature, separately excited field, series field and of rheostat shunting series field.

In Fig. 5 the necessary wiring is shown. At A_1 we obtain the direct current in the series field taken from the commutator, i, of the alternator; at A_2, the direct current in the separately excited field; at A_3, the alternating current taken from the collector-ring, c_1, of the alternator; at V_1 the voltage across series field and the voltage across separately excited field; at V_2, the alternating voltage across the collector-rings stepped down through transformer, T.

The commmercial test on induction motors is, first, power required when running light, i. e., with belt off, the readings recorded being volts, amperes and speed. Next, maximum output of the motor, in which readings of volts, amperes and speed of motor, together with volts armature, amperes armature, amperes field and speed of generator are taken just before the motor "breaks down" from overload. A four-hour heat run at full load then follows; volts, amperes and speed of motor, together with temperatures of frame and room being recorded every half hour. Temperatures of the following parts are taken after the heat run: Field lamination surface, field conductor's surface armature spider, bearings, frame and room. Counter-torque readings are then obtained by running the load machine as a motor, belted to the induction motor on open circuit. The first reading is of volts armature and amperes armature required with the same field current and speed as used on the load machine when taking the motor's maximum output. The second reading is of volts armature and amperes armature required with the average field current and speed, as used on the load machine during the heat run. The third and fourth readings are taken under the same two conditions with the belt off. By adding the watts lost in counter torque, with belt on, to the maximum output wattage and to the heat run wattage, we obtain the true power of the motor in each case.

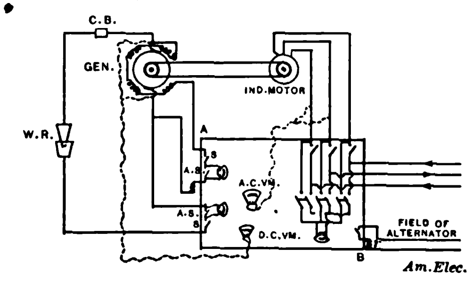

FIG. 6.—TEST OF INDUCTION MOTOR.

The diagram of connnections for this test is shown in Fig. 6. By the arrangement of switches shown at right of table in the alternating circuit, the current in each of the three legs can be measured on the same meter, by closing the double-pole switch and opening the single-pole switch in that leg. The voltage across any of the three legs being the same, an alternating current voltmeter connected across any two of the legs is sufficient. This voltage is kept constant during the entire test by the varying resistance, r, in the field of the alternator. For counter-torque readings the only change necessary in the wiring is in the armature circuit of the generator. This is opened at any point and attached to the supply circuit. The water resistance is used as a starting rheostat for the generator, now to be run as a motor, and is afterward adjusted to obtain the desired speed.

The resistance of the field of the induction motor is measured before and after testing. All machines should receive an insulation test at 500 volts and a high potential test many times in excess of their normal voltage before leaving the room.

◆

THE INDUCTION MOTOR.

BY ALFRED E. WIENER.

STRUCTURE OF INDUCTION MOTOR.

When a copper core is pivoted within a rotary magnetic field, formed by a number of equal coils placed at equal angular distances around a cylindrical field-core and traversed by either two or three alternating currents of phase-differences of 90 deg. or 120 deg., respectively, it will be dragged into uniform rotation by the reaction of eddy currents induced in its mass by the revolving magnetism. Since, however, currents induced in a solid core always take the path of least resistance, their direction is not necessarily that which causes the greatest reactive effect. In order to compel these currents to yield their maximum influence for the production of rotative force, the copper core must be suitably subdivided into a number of separate conductors, short-circuited amongst themselves, and placed perpendicular to the direction of the field-flux as well as to the direction of rotation.

The currents induced in these conductors are proportional to the intensity of the magnetic flux producing them, and since the flux is the greater the smaller the magnetic reluctance of its path, it follows that the strength of the induced currents can be increased by reducing the reluctance, the latter being accomplished by surrounding the conductors by a mass of soft iron, laminated in the direction of the magnetic flux. Thus by imbedding a system of short-circuited copper conductors into slots formed in a laminated iron core, as shown in Fig. 1, the maximum reactive effect of the induced currents is obtained and a powerful turning force, or torque, is the result.

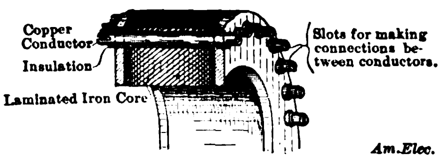

FIG. 1.—STRUCTURE OF INDUCTION MOTOR ARMATURE.

An electric machine which for its rotative power depends upon this reaction, upon a revolving magnetic field, of currents induced by this field itself, is called a *rotary field motor*, or an *induction motor*.

The velocity of rotation of the revolving magnetism depends upon the frequency (number of cycles per second) of the alternating currents supplying the field-winding and upon the number of poles in the field-frame, and can be numerically expressed as 120 times the quotient of the former by the latter quantity. (See Table I.)

TABLE I.
SPEED OF ROTARY FIELD FOR DIFFERENT NUMBERS OF POLES AND FOR VARIOUS FREQUENCIES.

Number of Poles.	Speed of Revolving Magnetism, in Revolutions per Minute, when Frequency is:											
	25	30	33⅓	40	50	60	66⅔	80	100	120	125	133⅓
2	1,500	1,870	2.000	2,400	3,000	3,600	4,000	4,800	6,000	7,200	7,500	8,000
4	750	900	1,000	1,200	1,500	1,800	2,000	2,400	3,000	3.600	3,750	4,000
6	500	600	667	800	1,000	1,200	1,333	1,600	2,000	2,400	2,500	2,667
8	375	450	500	600	750	900	1,000	1,200	1,500	1,800	1,875	2,000
10	300	360	400	480	600	720	800	960	1,200	1,440	1,500	1,600
12	250	300	333	400	500	600	667	800	1,000	1,200	1,250	1,333
14	214	257	286	343	428	514	571	686	857	1,029	1,071	1,143
16	188	225	250	300	375	450	500	600	750	900	938	1,000
18	167	200	222	267	333	400	444	533	667	800	833	889
20	150	180	200	240	300	360	400	480	600	720	750	800
22	136	164	182	217	273	327	364	436	545	655	682	720
24	125	150	167	200	250	300	333	400	500	600	625	667

The speed of the armature, unless power is supplied from without, is always less than the velocity of the revolving field, owing to hysteresis in the armature-core, friction, air-resistance, etc. It is due to the ensuing relative motion between armature and field that lines of force are continually being cut, and that, in consequence, e. m. fs. are set up in the armature conductors. This difference in speeds of armature and field, which is called the *slip*, varies from 40 to 1 per cent of the field-velocity, according to the size and design of the motor. (Table II.)

TABLE II.
SLIP OF INDUCTION MOTORS.

Capacity of Motor, H.P.	Slip, at Full Load, per cent.	
	Usual Limits.	Average.
⅛	20 to 40	30
¼	10 " 30	20
½	10 " 20	15
1	8 " 20	14
2	8 " 18	13
3	8 " 16	12
5	7 " 15	11
7½	6 " 14	10
10	6 " 12	9
15	5 " 11	8
20	4 " 10	7
30	3 " 9	6
50	2 " 8	5
75	1 " 7	4
100	1 " 6	35
150	1 " 5	3
200	1 " 4	25
300	1 " 3	2

While in an ordinary electric motor the armature receives the incoming current from the line, in an induction motor the currents flowing in the revolving part are induced by the action of the rotating field-magnetism and are short-circuited among themselves; hence, no electrical connections between the armature and line are required, and these machines, therefore, have the great mechanical advantage of needing no commutators, collector-rings, contact-brushes or flexible connections.

Owing to the difference in opinion as to which part of a dynamo electric machine should be called its armature—some holding that the field is that part in which the magnetism is fixed in direction while in the armature it changes with respect to the metal mass*, while others have the notion that the revolving part should be called the armature, whereas correctly the armature should be defined as that part in which reaction takes place due to electromagnetic induction, while the field magnet is that part in which are set up the magnetic lines of force, the presence of which causes that electro-magnetic action of the armature—some confusion exists in this respect with regard to alternating current machinery, some forms of them having field frames with stationary, others with moving, magnets, and in still others it is neither the magnets nor the armature, but a separate part, which revolves. In order to avoid misunderstandings as to what part of the machine is meant, in descriptions of alternating current apparatus some writers therefore make the distinction from the mechanical, and not from the electro-magnetical point of view, referring to the stationary part as the *stator*, and to the revolving part as the *rotor*. In the induction-motor, consequently, the field-magnet is the stator, while the armature is the rotor.

The size of an induction motor depends upon the speed desired, and is given by the peripheral velocity of the armature, which ranges between 1000 and 7000 feet per minute, according to the capacity of the motor. In Table III the practical and average values of this velocity are given:

TABLE III.
PERIPHERAL VELOCITY OF INDUCTION MOTOR ARMATURES.

Capacity of Motor, H.P.	Peripheral Velocity, in Feet per Minute:	
	Usual Values.	Average.
⅛	1,000 to 3,000	2,000
¼	1,000 " 4,000	2,500
½	1,000 " 5,000	3,000
1	2,000 " 5,000	3,500
2	2,000 " 6,000	4,000
5	2,000 " 7,000	4,500
10	3,000 " 7,000	5,000
50	4,000 " 7,000	5,500
100	5,000 " 7,000	6,000
200*	6,000 " 7,000	6,500

*And over.

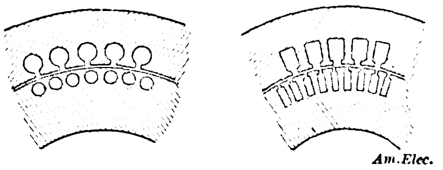
Both the field-magnet and the armature of an induction motor are built up of soft sheet-iron punchings provided with holes, or slots, to receive the windings. Two usual forms of field-punchings and two common varieties of armature-discs are shown in Figs. 2 and 3.

The number of slots in the field-frame depends upon the size of the motor, upon the number of poles and on the number of phases, for, it must be a multiple of the product of the latter two. For motors up to 200 h.p. capacity the number of slots per pole per phase usually ranges from 1 to 5 for three-phase machines, and from 1½ to 8 for two-phase machines. From the following Table IV. the proper number of slots for any particular case can readily be taken:

TABLE IV.
NUMBER OF SLOTS IN FIELD-FRAME OF INDUCTION MOTORS.

Capacity of Motor.	Number of Poles.	Slots per Pole.	Slots per Pole per per Phase.	
			Two-Phase.	Three-Phase.
⅛ H.P. to 1 H.P.	4 to 8	3 4	1½ 2	1 —
½ H.P. to 1 H.P.	4 to 6	5 6	2½ 3	— 2
2 H.P. to 5 H.P.	4 to 10	5 6	2½ 3	— 2
	4 to 6	7 8 9	3½ 4 4½	— — 3
6 H.P to 50 H.P.	6 to 12	7 8 9	3½ 4 4½	— — 3
	4 to 8	10 11 12	5 5½ 6	— — 4
50 H.P. to 200 H.P.	10 to 20	7 8 9	3½ 4 4½	— — 3
	8 to 12	10 11 12 13	5 5½ 6 6½	— — 4 —
	6 to 10	14 15 16	7 7½ 8	— 5 —

According to this table, a 100 h.p. three-phase induction motor, for instance, when wound for six poles, has 5 slots per pole per phase, or a total number of 5x6x3 = 90 slots. If the motor has eight poles, the table gives either 4 or 5 slots per pole per phase, that is, either 96 or 120 slots, respectively. In case of ten poles, either 3, 4 or 5 slots per pole per phase can be taken, making the total number of slots either 90 or 120 or 150, respectively. For twelve poles, the number of slots per pole per phase is either 3 or 4, and accordingly we have 96 or 144 slots. Finally, if the number of poles is greater than twelve, the unit 3 must be employed; hence, in case of 16 poles, for example, we find 3x16x3 = 144 slots.



FIGS. 2 AND 3.—FORMS OF PUNCHINGS OF INDUCTION MOTORS.

In the armature, in order to avoid dead points at starting and to insure smooth action when running, it is important to choose the number of slots such as to make the number of armature conductors per pole per phase prime to the number of field slots per pole per phase. In small motors—up to 5 h.p.—there is usually but one conductor per slot and the winding is usually executed in the "squirrel-cage" fashion, necessitating no consideration as to the regularity of the end-connections; hence, the above condition can be fulfilled by making the number of armature-slots, which in motors up to the size mentioned commonly ranges between seven and nine times the number of poles, any integer not divisible by the number of poles. The slot-numbers thus obtained are compiled in Table V.:

---

* See Sylvanus P. Thompson, "Polyphase Electric Currents," p. 113.

TABLE V.

NUMBER OF ARMATURE SLOTS FOR SQUIRREL-CAGE INDUCTION MOTORS UP TO 5 H.P. CAPACITY.

Number of Poles, p.	Limits of Slots-Number, 7 p. to 9 p.	Number of Armature-Slots.
4	28 to 36	29, 30, 31, 33, 34, 35, 37.
6	42 " 54	43, 44, 45, 46, 47, 49, 50, 51, 52, 53.
8	56 " 72	57, 58, 59, 60, 61, 62, 63, 65, 66, 67, 68, 69, 70, 71.

In case of larger motors, which often have two or more conductors in each armature-slot, and in which the winding is connected up in two or more parallel circuits, the number of slots must be chosen a multiple both of the number of pairs of poles and of the number of phases, so that the end-connections are all of the same length, or of as few varieties as possible. The following Table VI. gives armature-slot numbers corresponding to fields having from eight to sixteen slots per pole.

TABLE VI.

NUMBER OF ARMATURE-SLOTS FOR INDUCTION-MOTORS OF CAPACITIES OVER 5 H.P.

Number of Field-Slots per Pole	Number of Armature-Slots. (n_s = Number of Field-Slots).
8	$\frac{5}{4}$ n_s. or ³ n_s.
9	$\frac{4}{3}$ n_s.
10	$\frac{9}{8}$ n_s. or $\frac{3}{2}$ n_s.
12	$\frac{5}{4}$ n_s. " $\frac{4}{3}$ n_s.
14	$\frac{9}{7}$ n_s. " $\frac{3}{2}$ n_s.
15	$\frac{6}{5}$ n_s. " $\frac{4}{3}$ n_s.
16	$\frac{9}{8}$ n_s. " $\frac{5}{4}$ n_s.

They are expressed as multiples of the number of field-slots, and comply both with the last-named condition and with the rule of making the number of armature-slots per pole per phase prime to the number of field-slots per pole per phase. In their selection the possibility of re-using the same armature-disc for different numbers of poles and phases has been had in view.

The height, h_s, Fig. 4, of the field-slots varies from 1 to 1½ times the radial height, h, of the frame, according to the size and design of the motor. Their width (which is determined by dividing the field-circumference by the slot-number obtained from Table IV., and by subtracting, from the result obtained, the thickness of the tooth, the latter, in turn, being given by the condition that the flux-path through the teeth must be of an average area equal to, or greater than, the area of the path in the solid portion of the frame) is ⅛ to ½

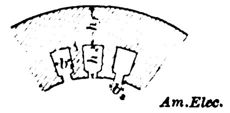


FIG. 4.—DIMENSIONS OF FIELD FRAME.

the height, except in case of circular slots. The width of the opening, b'_s, varies from $.3b_s$ to the entire breadth, b_s, of the slot.

The height of the armature slots usually is between .7 and .9 that of the field slots, while their width, which is found by a process similar to that for determining the field-slot, ranges between ¼ and ½ the height, provided the slot is not a circular one.

The thickness, h_f, of the solid portion of the frame, and the radial depth of the armature core are determined by the requisite magnetic flux and by the flux-density which is best adapted for the case under consideration. The hysteresis loss in iron increases as the 1.6th power of the density, and is proportional to the frequency; and the eddy current loss is proportional to the square of the density and also to the square of the frequency. Hence, in order to avoid an increase of the losses and a consequent decrease of efficiency, accompanied by greater heating, the flux-density in a given motor must be taken the smaller the higher the frequency at which it is to be worked. In Table VII. the practical and average values of the flux-density for motors of various sizes and for different frequencies are compiled:

TABLE VII. FLUX-DENSITIES FOR INDUCTION MOTORS.

Capacity of Motor, HP	Flux-Density, in Lines of Force per Square Inch.					
	For Frequencies from 25 to 40.		For Frequencies from 60 to 100.		For Frequencies from 120 to 180.	
	Practical Values.	Average.	Practical Values.	Average.	Practical Values.	Average.
⅛	12,000 to 18,000	15,000	10,000 to 15,000	12,500	7,000 to 11,000	9,000

† And over.

ARMATURE WINDINGS AND CONNECTIONS.

BY PROF. ARTHUR L. RICE.

FORCED WINDINGS.

The case now to be considered is how to wind an armature which was designed for a multiple-path winding so that it shall have a two circuit winding.

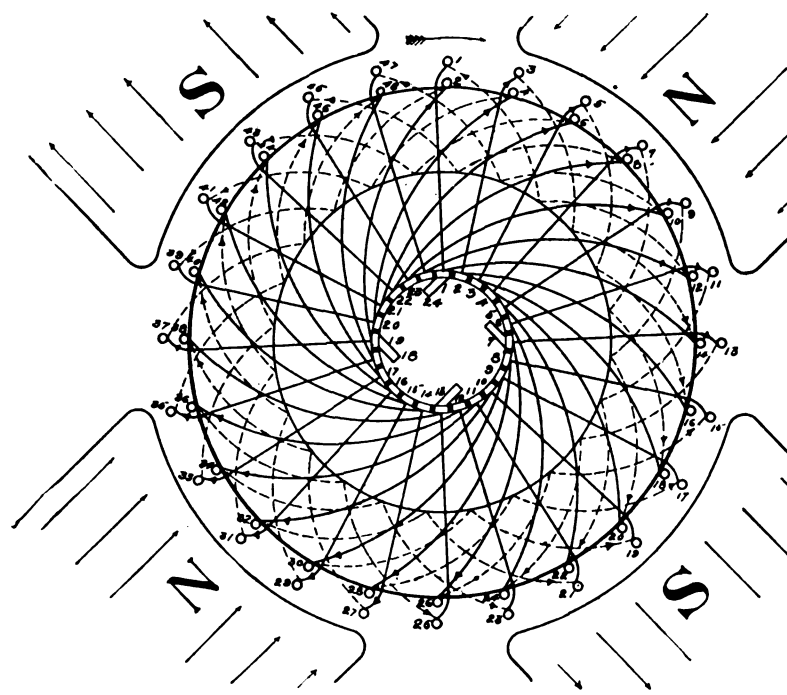

FIG. 1.—FOUR-POLE, DRUM, FOUR-CIRCUIT, LAP WINDING.

Take the case of the armature in Fig. 1; it has 48 conductors wound into a four-circuit armature, with a lap winding; the front pitch is 13, the back pitch 11, which gives a retrograde winding, and the armature is supposed to be of formed coils, laid into slots.

If it be desired to change this to a two-circuit wave winding, the condition is: $48 \pm 2 = 4$ x pitch; 46 or 50 = 4 x pitch; and in neither case will the pitch be a whole number. The number of conductors used must be changed. If one coil, i. e., two conductors, be left unconnected, the utilized conductors become 46 in number; $46 \pm 2 = 4$ x pitch; 48 or 44 = 4 x pitch; and the pitch = 12 or 11. Since for a two layer machine the average pitch must be odd in order to connect from one layer to the other, and also since the coils of Fig. 1 are wound with 11 pitch, it will be best to choose 11 for the pitch both front and back. As but 46 conductors, or 23 coils, are to be used, only 23 commutator bars

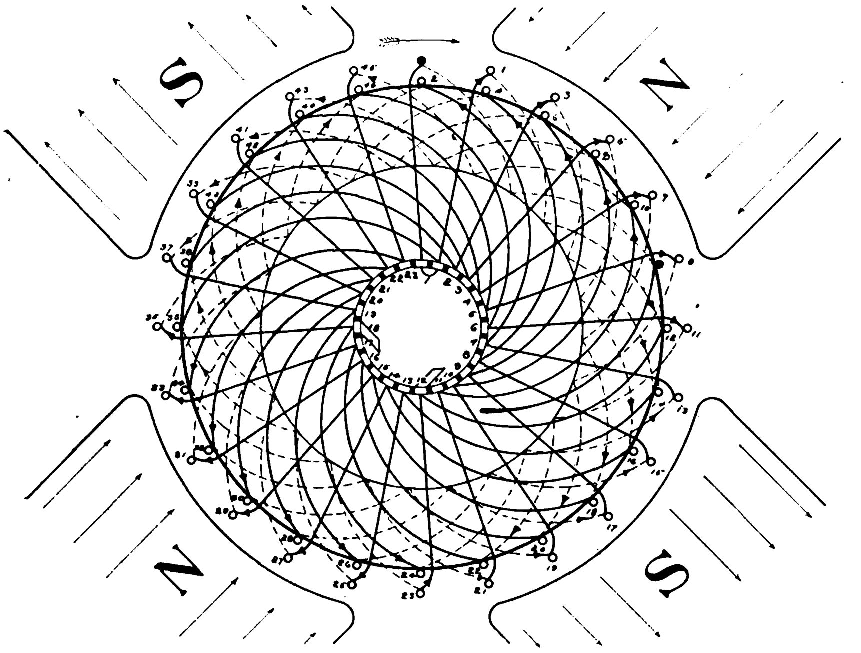

FIG. 2.—FOUR-POLE, DRUM, FORCED TWO-CIRCUIT, WAVE WINDING.

will be needed, so that it will be necessary to leave one bar as well as one coil dead. Obviously, in a formed coil armature, the two conductors to leave unused must be so chosen that they will be sides of the same coil.

It is immaterial which coil is dead ended, and the coil should be put in place, for the sake of mechanical balance, the same as if it were to be used. In Fig. 2 the conductor which would have been No. 1 has been left in the dead coil, so that its number is moved along to the next conductor in the same layer; this makes the numbers come staggered, until the dead wire, 11, ahead, which would have been No. 12 in the under layer is passed, when the numbers catch up and become regular. The bar which would have been No. 1 is short circuited to one of those adjacent; it is of no importance which one, because the dead bar is simply a space filler and becomes really a part of the bar to which it is joined. The connection is then from bar 1 to conductor 1, on the back to conductor 12, on the front to bar 12, thence to conductor 23, to conductor 34, to bar 23 and so on, having connected in four conductors between the two adjacent bars.

It makes no electrical difference what is done with the ends of the dead coil; generally one of them is joined in its regular place in the commutator bar, and that bar is made dead; the other end is doubled back on itself and covered with insulation, as indicated in Fig. 2.

By tracing out the direction of the e. m. fs. the brushes are found to belong on bars 12 and 18 at points midway between poles, as was to be expected. They are at 90 deg., or 6 bars apart; there are four conductors joined in between two bars, as noted above; hence between brushes there are $4 \times 6 = 24$ conductors, about half the active wires on the armature, and the machine will have two circuits as required, though slightly unbalanced.

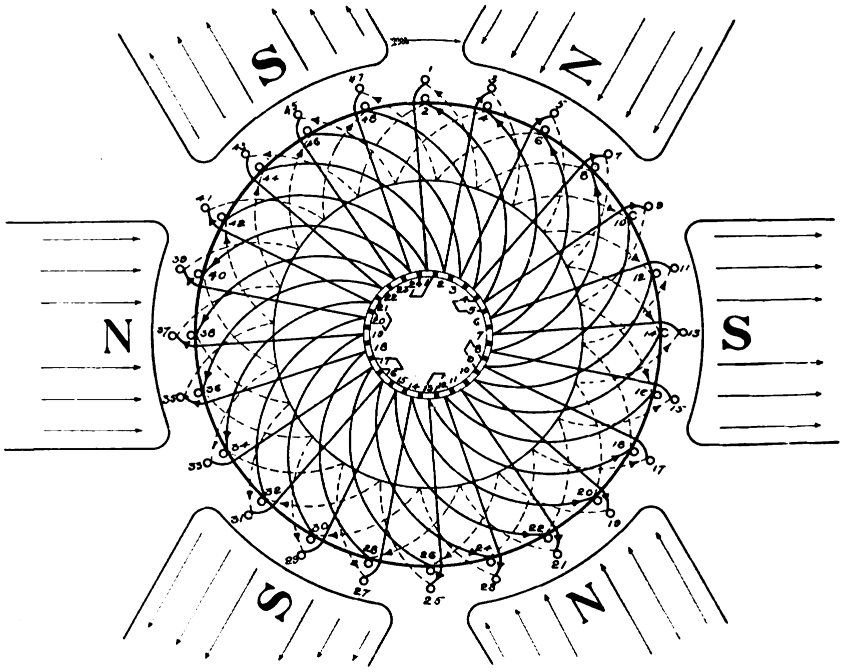

FIG. 3.—SIX-POLE, DRUM, SIX-CIRCUIT, WAVE WINDING.

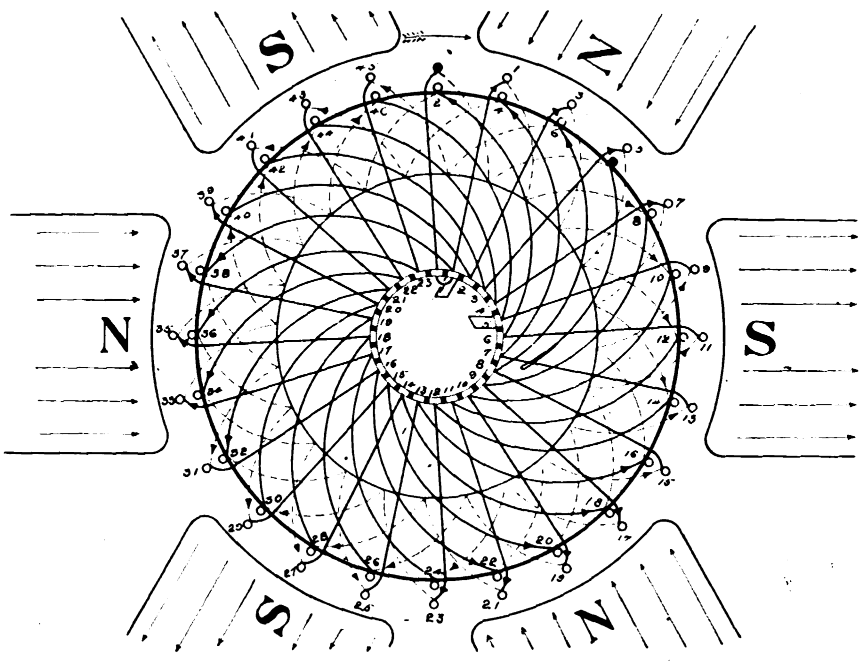

FIG. 4.—SIX POLE, DRUM, FORCED TWO-CIRCUIT, WAVE WINDING.

Suppose a six pole machine, with 24 slots, is to be wound with two layers, first with six circuit armature, second with two circuit. The number of conductors will be $24 \times 2 = 48$; the pitch will be:

$48 \pm 6 = 6 \times$ pitch; 54 or $42 = 6 \times$ pitch; pitch = 8 or 7. Let 7 be chosen so as to pass from one layer to the other. There will be 24 bars to connect with the 24 coils. The connections will be from bar 1 to conductor 1, on back to conductor 8, on front through bar 8 to conductor 15, on back to conductor 22, on front through bar 15 to conductor 29, on back to conductor 36, on front through bar 22 to conductor 43, on back to conductor 2, on front to bar 5 and so on, as shown in Fig 3.

The brushes are found to belong on bars 1, 5, 9, 13, 17 and 21, and the circuit just traced from bar 1 to bar 5 contains eight conductors, one-sixth of the number on the armature, so that the winding is correct.

For the second case the condition will be: $48 + 2 = 6 \times$ pitch; 50 or $46 = 6 \times$ pitch; and no even pitch can be found. But, if two conductors and one bar be omitted, $46 + 2 = 6 \times$ pitch; 48 or $44 = 6 \times$ pitch; and the average pitch can be made 8. This will necessitate using uneven, odd pitches front and back such that the average shall be 8; 7 and 9 are the most natural numbers to use and have the advantage that, if 7 be made the back pitch, the coils can be wound the same as for the first case, and only the connections to the commutator need be changed.

In Fig. 4 the conductor which was No. 1 in Fig. 3, is left dead and the odd numbers moved ahead one wire; the even numbers are the same as in Fig. 3 until No. 8, which was connected to No. 1, is reached, when that one is left dead and the rest of the even numbers are set ahead one place. The bar which was No. 1 in Fig. 3 is short circuited to the one which connects to conductor 1 in Fig. 4. The dead wire in the outer layer is connected to the dead bar and the other end of the coil is doubled back and insulated. The connection runs from bar 1 to conductor 1, on the back to conductor 8, on the front to conductor 17 by way of bar 9, and so on. By the time that bar 2 is reached six conductors have been connected up. The brushes are found to go on bars 1 and 5 at four bars apart, hence there are $4 \times 6 = 24$ conductors in one path through the armature, and $46 - 24 = 22$ in the other. These numbers are about half of the total number of connected conductors, hence the armature will have two circuits, but they will be somewhat unbalanced, as was the case in Fig. 2. In neither case will the unbalancing be serious enough to cause trouble.

NATIONAL ELECTRIC LIGHT CONVENTION

CHICAGO CONVENTION OF THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

The convention of the National Electric Light Association, held at Chicago, June 7, 8 and 9, was in many respects one of the most satisfactory in the history of that organization, though differing both in attendance and the character of the proceedings from other conventions of recent years. Apparently, with increasing years, the association becomes more dignified. At this meeting the exhibits of supplies and the dealers in electrical goods were conspicuously absent, and the lack of their presence detracted somewhat from the usual gayety of the convention. Contrasted with the meeting at Niagara Falls last year, this convention was more business-like, and, though the attendance was smaller, the character of the papers appealed more directly to the managers of electric light stations than the somewhat academic essays read last year.

The success of this convention was in large part due to the character of the subjects discussed, and their important bearing upon the electric lighting industry. A tone of supreme common sense pervaded the discussions, and showed that the business of electric lighting has become conservative in its later years—a gratifying evidence of its solidity.

There were no excursions or entertainments except an enjoyable reception tendered the visiting members by the electrical fraternity of Chicago. The hospitality of the Chicago Edison Company, the Metropolitan West Side Elevated Road, and the South Side Elevated Road, whose stations were thrown open to the visitors, was greatly enjoyed.

No little of the success of this meeting is due to the efforts of Mr. Samuel Insull, the retiring president of the association. As president of the Chicago Edison Company, Mr. Insull is in touch with the central station business in one of its most comprehensive developments. Easily the foremost man in the electric lighting industry in the United States, he was able to show the members the workings of one of the finest systems extant, and to arouse interest in the topics of discussion by his thorough knowledge of their details.

Of the discussions, the most interesting was that following Mr. Rice's paper on the "Cost of the Generation and Distribution of a Unit of Electricity," though the old question of alternating vs. direct-current supply from central stations came in for no small share of attention. Of the papers read all are abstracted here save Professor Goldsborough's on "Transformer Economy."

ALDEN M. YOUNG, PRESIDENT N. E. L. A.

The lecture on "Electricity Direct from Coal," delivered by Mr. Joseph Wetzler on Wednesday evening, was largely attended and greatly enjoyed.

In the election of its officers for the ensuing year the association displayed its usual excellent judgment.

Mr. Alden M. Young, the new president, was born at Hadley, Saratoga County, N. Y., September 6, 1853. After leaving school he entered the telegraph business and was manager for the Atlantic & Pacific Telegraph Company, in 1870, at Fort Plain, N. Y.; in 1871 at Saratoga, in 1872 at Syracuse, in 1873 at Albany, 1874-77 at Buffalo, and in 1878-79 at New York City. In 1878 he went to Connecticut and organized the telephone company at Waterbury, and was its manager for about ten years.

In 1883 Mr. Young became interested in electric lighting, and a little later organized in Waterbury its first and only electric lighting company. In 1892 he obtained a controlling interest in the Waterbury Horse Railroad Company, and in 1893 this company, now the Waterbury Traction Company, absorbed the electric lighting company, and now lights the city of Waterbury and operates the only electric street railway in the city.

In 1890, taking up the private business of Mr. Young, the New England Engineering Company, of Waterbury, was incorporated, for the purpose of installing electric light plants, electric railways and power stations. By this company electric light plants have been installed in Connecticut at Norwich, New Britain, New London, Stamford, Naugatuck, Bristol, Thomaston, Seymour, Branford, Westport, Stafford Springs, Rockville, Putnam, and at Palmer, Mass.; at Poughkeepsie, Catskill, Hudson, Canajoharie, N. Y.; at Paterson, Elizabeth, Dover, Somerville, Morristown and Boonton, N. J., and at other points.

Mr. Young is at present president of the New England Engineering Company, of Waterbury; secretary of the Waterbury Traction Company, president of the Central Railway & Electric Company, of New Britain, Conn.; secretary of the Norwich Gas & Electric Company, of Norwich, Conn., and an officer in a dozen more electric companies in the States of Connecticut, New York and New Jersey.

Within a few months Mr. Young and a number of prominent capitalists organized the Kings County Electric Light & Power Company, of Brooklyn, N. Y. This company is now completing a central station of the most approved and modern type. Mr. Young has always been actively connected with the National Electric Light Association, and last year served as its first vice-president.

Mr. E. W. Rollins, the first vice-president, is largely interested in electric lighting properties in Colorado, and has been for a long time president of the Denver Consolidated Electric Company. Mr. F. A. Gilbert, the second vice-president, is the president and general manager of the Boston Electric Light Company and an officer in many other electrical corporations in the New England States. The executive committee for the ensuing year are Messrs. Samuel Insull, Chicago; Samuel Scovil, Cleveland, Ohio; H. M. Atkinson, Atlanta, Ga., and F. A. Copeland, La Crosse, Wis.

PRESIDENTIAL ADDRESS.

In his opening address President Insull

first discussed the interesting topic of standard vs. special machinery, and pointed out how the user is directly interested in the low cost of production of machinery on the part of the manufacturer. When specifications are made calling for special machinery they convert the factory, in effect, into a jobbing shop, cutting down its capacity, increasing the cost for labor and lengthening the time required to produce a given article. From the manufacturer's point of view the capacity of the plant is reduced and the interest and general expense cost made higher, so that the selling price must be increased or the shop run at a loss.

Continuing upon the subject of standard specifications, Mr. Insull said that the designing engineer who adapts his requirements to the standard apparatus of a first-class manufacturer is able to produce a plant of more satisfactory character and one more economical to operate than if he had been influenced by the desire to use machinery he could claim as his own.

After a general discussion of the subject of rates of charge for the product of the electric light station, Mr. Insull spoke at length on the topic of municipal control and ownership of semi-public industries. Pointing out that self-interest and the necessity of getting a return on the investment are the first essentials to the economical administration of large enterprises, he said:

"While I do not pretend to claim that electric lighting companies are beyond reproach, I wish to point out that many of the evils complained of as pertaining to corporate management are the direct results of the enforcement of unwise conditions through legislative action. Ill-advised efforts are often made by legislative bodies to secure advantages in the direction of control which cannot be obtained without giving an equivalent in protection to the industry. This causes the investor to feel that his property is being attacked and compels him to resist such legislation. The result is a feverish agitation, crimination and recrimination, between the would-be improvers of municipal government and the owners of corporate properties without reaching a conclusion satisfactory to either. The fallacy of the so-called reformer's theory results from looking only at what he calls the injurious effects of corporate management without taking into account its indisputable benefits. He does not seek for the cause of the trouble. If reformers will take accurate account of all the points in the problem they will discover that the evils complained of result from errors in legislation designed to determine the relations between municipal bodies and electric lighting companies. It seems to me that the claim that municipal operation is the universal cure for all diseases for which electric lighting companies are supposed to be responsible merely proposes the substitution of political in the place of industrial management."

Naturally this raises the question whether the political control and administration of affairs in various cities is efficient and economical as compared with the management of private concerns. The misunderstandings that have arisen from time to time between the managers of electric light companies and the communities they serve should disappear if the relations between the two are founded on a basis of public control with corresponding protection to the corporation operating the industry. The idea generally held that competition is the true regulative force which holds down the charges for current made by the companies is not true. Competing companies invariably come together, and the interest cost on their product, far the most important part of its cost, is high both by reason of the duplication of plant and the high rates necessarily paid for money during the period of competition.

Exclusive franchises under proper control furnish the most equitable arrangement for both company and public. Taxing franchises by demanding a percentage of the company's gross receipts is an inequitable way to raise revenue, since the tax is, of course, added to the charge for service by the company, and its customers thus bear the burden of a tax which benefits the whole community. In a proper scheme of public control another point that should not be omitted is a condition making it mandatory upon the community to buy the plant at a fair valuation if it is ever decided to undertake municipal ownership of this industry. Otherwise the inequitable condition of the municipality competing with its licensee who has been led into investing money and developing the business prevails, which amounts to the destruction of private property without compensation in the attempt to secure a public benefit.

In conclusion Mr. Insull said that he would summarize the position that he thought the association would take in just two sentences:

"First—Franchises granted to public service corporations should secure them the same degree of protection in their rights to their property as is enjoyed by other investments.

"Second—Public control of charge for service based on cost plus a reasonable profit, and eliminating the factor of competition, is the proper safeguard for the interests of users, taxpayers and investors."

COST OF GENERATING AND DISTRIBUTING A UNIT OF ELECTRICITY.

The paper read by Mr. Calvin W. Rice on the cost of producing and distributing a unit of electricity does not lend itself readily to abstraction. In discussing the total investment per k.w., Mr. Rice stated that in America the variation of investment ranges from $700 to $200 per k.w., a few plants showing figures outside these limits. In the great majority of cases the cost is below $400. Some railway plants show costs lower than $75 per k.w., but these figures refer to stations alone, while the corresponding figures for lighting stations include distributing plants also.

While great stress is nowadays laid upon efficiency, this is less important than either reliability or good regulation. The latter means the ability to use high efficiency lamps, and the possibility of saving in the lamp is greater than that shown by boilers, engines or dynamos. The value of accessories in the reliability of the plant and the saving in labor and attendance is very important. The waste from steam-driven accessories is often enormous, as figures quoted from a report on the steam consumption of auxiliary apparatus on a U. S. cruiser show.

The distribution system, now that many places require its installation underground, becomes a very great item of expense, and hence no material for its construction not of the most perfect reliability should enter into discussion. Mr. Rice dwelt upon the importance of prolonged tests, using high power and large capacity test instruments.

Comparisons of the cost of operation of plant per unit output per year show that the cost of plant to produce 1 k.w. hour per year is about 50 cents. In this connection the most important point is load factor. A long quotation was made from a paper recently read before an English association giving data upon the influence of the load factor on the total cost of generating a unit. From the tables given another interesting point was brought out, namely, the number of units generated by various plants and unaccounted for. The percentage loss ranges from 5 to nearly 48, and while the majority of this loss is necessary to the distribution, still a large part of it might be saved by due attention to this feature.

An interesting average of the cost of coal and contract price for arc lamps in forty-six States containing about 1000 stations was shown, from which it appears that the average yearly hours of burning were 3326, the average cost of coal $3.03, and the average contract price $101 per year. The average cost per hour is given at $.034 and the light per hour for one cent as 580 nominal c.p.

In conclusion an interesting summary of a number of plants using steam and water power under various conditions was given in the form of tables, which contain much valuable and interesting data.

PUBLIC LIGHTING IN RELATION TO PUBLIC OWNERSHIP AND OPERATION.

In a paper with the above title Mr. Alex. Dow set forth a policy which he regards as the best to be followed by companies engaged in public lighting. He said:

"This paper is written to set before the association a proposed policy. It is not a new policy in its parts, neither is it an untried policy. It is applicable immediately to public lighting; that is to say, to the lighting of streets and public places under contract with, or on account of, a municipality. Ultimately its application may be more extensive.

Mr. Dow then cited the example furnished by the history of electric lighting in the city of Detroit. In February, 1896, the city of Detroit owned 1500 arc lamps, and was operating 1492 of these in the work of street lighting. In the same month the successor of the Brush Electric Light Company, which installed the original twenty-two lamps in 1883, and which, until 1890, lighted the streets under contract, owned 1049 arc lamps, and used in private lighting 433 of that number. Another company, organized in 1890 to compete with the Brush Electric Light Company, owned 1330 arc lamps and was using in private lighting thirty-eight of these. In each case there accompanied the arc lamps a sufficient number of dynamos, engines, boilers, etc., and a building fully equipped for the operation of the number of lamps stated. At the same time the city had in use 134 towers, which had been formerly owned by the Brush Company, and the other company was in the act of taking down and removing from the streets 104 similar towers, which had formed a duplicate of the Brush Company's equipment. The necessary lines to connect lamps distributed over a large city had been owned by all three. The city had in use 329 miles of overhead wires, connecting to its 1492 lamps. Neither of the companies had owned such a great mileage of line, but one had taken down lines and poles which had supplied 719 lamps, and the other was in the act of removing lines and poles which had connected 1279 lamps.

Of all this equipment more than two-thirds is to-day a useless asset. Dynamos that cost $2400 would not now bring $240. In the case of the second company the loss was even greater. Towers that had been erected at great cost had to be taken down and sold for scrap iron. Clearly these conditions, that reduced machinery and lines capable of supplying 2000 arc lamps to their junk value, involved a loss to somebody, and equally certain is it that there was a loss to the community at large. In this case the greater part of the loss was borne by investors in the city of Detroit, and after correcting for the inflation of securities and other affecting causes it amounted to not less than $400,000. It was submitted as a principle not admitting dispute that the duplicating an effective plant is an economic error entailing loss of available capital to the extent of the duplication.

"I submit as a direct application of the principle last stated, that competition for public lighting contracts, for the execution of which there is already an effective equipment in existence, is not legitimate business. The corollary of this statement is that the price at which public lighting is to be performed must be determined by some acceptable means other than competitive bidding. In this there is a departure from the established method of municipalities, which now depend on competition for the setting of prices on all public services performed by contract.

"In the absence of some other acceptable means of setting a proper price for public lighting by contract, public opinion will not tolerate the suppression of competition."

Again referring to the case of Detroit, Mr. Dow showed how the second company coming in secured a three-years' contract for the public lighting. It soon became apparent that the company could not go on beyond the term of three years at the same price, but would have to meet the competition of the original contractor, attempts to combine the two interests failed until the two plants were practically duplicates.

Of course the public became advised of the cessation of competition and the advocates of municipal ownership made the most of the facts and added much fiction. Long before the contract had expired it was plain to any careful observer that it could not be renewed at anything like the former figure and that the tendency of public opinion was strongly to municipal ownership. It was a period of "reform" one of those periods when the taxpayers insist on calling the particular bosses of the hour to an accounting.

The suppression of competition was thus inevitable, since its continuation meant a cumulative loss to those engaged in it. Possibly the public might have been made to see this, but to prove that competition was impossible would not have been enough; it must be further proved by offering good service at an acceptable price that competition was unnecessary. In this way the state of things that resulted in a municipal plant originated and grew.

After reciting the cases of a number of cities where cessions on the part of the contracting companies led to continuance of profitable contract relations, the difference between public and private lighting was taken up. The fact that electric light is the cheapest and best for street lighting, and by no means the cheapest for private lighting, was brought out, and a number of figures of cost of gas and electric light in various cities given. From these figures it was argued that the lighting of the streets in the best way, being a public necessity, is properly a function of the municipality, and the production of this light is a business in which it can rightfully engage at the public expense; but the very nature of electric light makes its private application a luxury enjoyed only by a part of the population.

Of causes tending to the contrary one is that the contracting plant may have little or no private lighting. Some other plant in the city may do all or most of the private business. This condition of affairs can be only temporary, the consolidation of the two plants being an economic necessity certain to arrive in time.

The public believes consolidation against the public interest, but this is an error, and the way to prove it such is to give the public the surplus profits of consolidation in the shape of lower rates or better service—or both.

Among other causes handicapping the contractor is the unwillingness of cities to make long term contracts, but the worst burden the contractor has to carry is excessive capitalization.

Having thus recited his premises Mr. Dow drew the conclusion that the best policy for the association to adopt is the following:

"1. That a municipality may properly provide for public lighting either by the ownership and operation of an electric lighting plant, by the operation of a contractor under lease of a municipally owned plant, or by contract with the owner of a private plant.

"2. That the supply of electric light to private users is not properly a municipal function.

"3. That the performance of public lighting under contract by a private plant in connection with the supply of electric light to private users is essentially the method of least expense.

"4. That the existence of two electric lighting plants in the same territory is an economic error tending to increase the cost of production, and thereby the selling price, and that the maintenance of competition is to the detriment of the public.

"5. That public lighting by contract should be performed at the lowest price consistent with a reasonable profit on the value of the investment; that no electric lighting contractor should demand more than such a profit, and that each municipality should protect the contractor in the enjoyment of his profit, and against impairment of his investment, in order that a minimum profit may become reasonable.

"6. That in order to adjust prices in the absence of competition it is necessary that costs be ascertained and prices approved by a competent authority, acceptable to the public as well as to the contractor.

"7. That in the absence of a constituted authority competent to ascertain costs and prescribe prices, members having public lighting contracts under consideration should endeavor to have the adjustment of the contract price undertaken by a temporary commission, or arbitration committee, who will adopt as the basis of adjustments the principles set forth, particularly in number five above.

"8. That there is no essential difference in the organization of municipally owned plants requiring a different analysis of costs from that which is proper for private enterprises, and that the publication of the costs of municipal lighting plants properly analyzed is beneficial to the electric lighting industry. Further, that the similar publication of the costs of private plants is desirable, but is at present impossible because of its advantages to actual or possible competitors."

GENERAL DISTRIBUTION FROM CENTRAL STATIONS BY ALTERNATING CURRENTS.

Mr. Herbert A. Wagner read a paper with the above title in which he discussed at length the advantages of alternating current distribution for central station work. In introducing the subject Mr. Wagner said:

"I may startle many by stating frankly the discouraging fact, which has been barely whispered at times, that, judged by the standards of the magnificent Edison properties in many of our larger cities, few alternating current central stations in the United States have been a success. The fault lies, not with the alternating current itself, but with its application. Its few apparently inherent deficiencies, such as the difficulties of operating motors and arc lamps, have been shown to have been only awaiting discovery and development, and were at our disposal almost as soon as these important divisions of central-station service were operated with success from the Edison three-wire system. These can, therefore, hardly be held responsible for the difference in the commercial results obtained with the two systems.

After briefly reviewing the methods in general use for the distribution of electrical energy Mr. Wagner made a strong plea for the use of the methods of the Edison three-wire stations in alternating work. The distinguishing characteristics of this system, the use of pressure wires and the feeder and main system, the perfection of detail that has been the result of many years of intelligent effort, are all equally applicable to an alternating system. In the ordinary method of distribution by alternating current, where the pressure is regulated at the bus-bars or by means of a compensator, the line and transformer losses unite to cause variations in the pressure at the lights. With a system employing pressure wires running from the secondaries of transformers located at the ends of the feeders the pressure on the low-tension distributing system could be kept very constant, and the use of individual transformers abandoned. These feeder transformers would be worked at high average load, thus raising the average efficiency and improving the first cost of transformers. By increasing the copper loss and decreasing the iron loss in these transformers their average efficiency may be greatly improved.

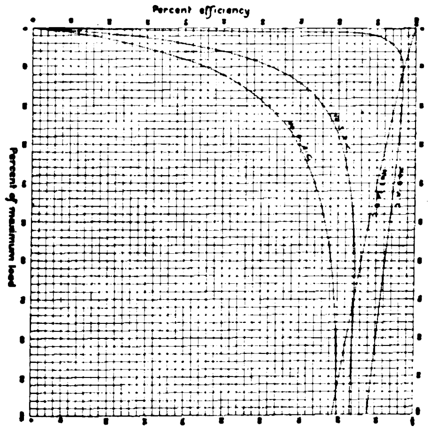

FIG. I.—CURVES OF DISTRIBUTION EFFICIENCY.

"Having provided against any interference with the regulation of the system by the transformer drop, we can afford to increase that to the heating limit of the copper. In this way, a 100-k.w. transformer can be built with an average efficiency of over 98 per cent. The entire transformer loss can, moreover, be more than made up by the less loss in feeders, which we would naturally have with alternating current.

"This system was conceived several years ago, and it has since been my good fortune to have an opportunity to install a system of this kind on a large scale, which is now in very satisfactory operation. It is laid out exactly as a three-wire Edison system would be, except that there are no subfeeders. A network of mains is planned as if for use with direct current. The feeders are all designed for 110-k.w. maximum load at 1100 volts, and at each feeder end is placed a 110-k.w. transformer feeding into the three-wire network in the same manner and at the same points as with the direct current system. The transformers are located in manholes of suitable design. From the secondary terminals of each transformer, pressure wires are run back to the station. Each feeder has an independent regulator by which the pressure can be raised or lowered. There are no primary mains, nor any connection whatever between the primary feeders. The regulators perform two functions. They are used to maintain the proper pressure as indicated by the voltmeters and to divide the load between transformers in any way desired as indicated by the feeder ammeters. It is possible to shift the entire load from one transformer and feeder to an adjacent transformer in this way without sensibly affecting the pressure on the system, and an equal division of load between transformers can be readily maintained at all times if desired. This is a very important consideration when very heavy loads or overloads are to be carried. The distribution of load on any large system is constantly changing as new customers are connected, and in large Edison stations certain feeders often become so overloaded that it is found necessary for their safety to put resistance in series with them to force some of the current to other feeders. The possibility of overloading any individual feeder beyond its share is absolutely provided against in the system described.

In Fig. 1 are shown four curves of station distribution efficiency. No. 1 is that of a representative Edison three-wire, direct-current station. No. 2 is the new alternating current system described. No. 3 is the usual alternating current system employing separate transformers for each customer or for adjacent customers, the best modern transformers being used. No. 4 shows the same system, but with the average transformers found on the lines of most existing stations. These curves were plotted from the following data obtained from actual practice.

	No 1. P. C.	No. 2. P. C.	No. 3. P. C.	No. 4. P. C.
Feeder loss	24	8	10	10
Main loss	2	2	2	2
House wiring loss....	1	1	1	1
Transformer loss, iron	—	.23	6	12
Transformer loss, copper	—	2.7	1	.5
Total loss at maximum station load.	27	13.93	20	25.5
Efficiency at maximum station load...	78.7	87.9	83.3	79.6

The efficiencies of distribution at assumed average loads are shown to be as follows:

P. C.	No. 1. P. C.	No. 2. P. C.	No. 3. P. C.	No. 4. P. C.
Load, 25..................	94.1	95.8	78.4	66.6
Load, 20..................	94.8	96.2	75.3	61.4
Load, 15..................	96.1	96.5	70.3	54.3
Load, 10..................	97.3	96.4	61.9	45.1

At maximum load it will be noticed that the efficiency of alternating current No. 2 is 10 per cent higher than No. 1, the direct current. This means that the same energy can be delivered with 10 per cent less capacity in generators, engines and boilers, or a difference of 10 per cent in the first cost of generating plant. It is pertinent to remark here that alternating-current generators also have a much greater margin for overload for short periods than direct-current generators. The efficiency at average load, or the all-day efficiency of the No. 2 alternating-current system, is also shown to be appreciably higher than the direct-current. In large central stations the average load is generally found in practice to vary from about 15 to 20 per cent of the maximum, and it will be noted that from 12 per cent average load up, No. 2 curve for the special system of alternating-current distribution shows a higher efficiency than the direct-current.

The extension of direct-current systems by the use of alternating-current generators, transformers and rotary converters was then touched upon, and some figures given to show that the same results could be accomplished better by the use of alternating currents throughout. The objections to the use of the alternating current were discussed under the heads of efficiency, regulation, the operation of arc lamps, and motors, the special applications of current, and last but not least, the application of storage batteries to regulate the station load and smooth out any variations in the curves of voltage. In conclusion a method for the operation of series arc lamps from the alternating high pressure mains was outlined and a system in which 2300 arcs are thus operated described.

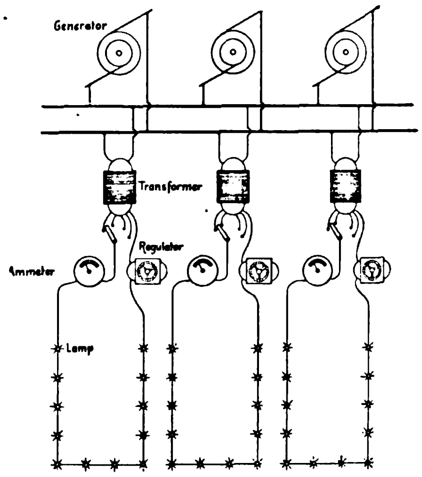

FIG. 2.—ALTERNATING CURRENT SERIES ARC LIGHTING SYSTEM.

"The circuits are each provided at the station with a regular step-up transformer of a maximum capacity of 4000 volts and 10 amps., and the feeders to these transformers are treated on the switchboard in the same way as the feeders for incandescent lighting. It is quite usual for one generator to carry 2000 of these lamps. The lighting is satisfactory to the city and the lamps give better service than when operated by direct current. There has been a very marked saving in fuel and attendance. The i.h.p. per arc lamp is considerably less than with the direct-current arc lamps operated in the usual manner. Fig. 2 shows this system in diagram. In summing up the case for the alternating current Mr. Wagner gave the following list of points of marked superiority of this variety of current:

"Highest possible efficiency of distribution and operation.

"Best regulation.

"Largest territory desired readily supplied from one station.

"Comparatively small cost of feeders, effecting enormous saving in investment.

"Least cost of real estate.

"Cost of installing and operating substations entirely avoided.

"The only system in which all classes of service can be supplied from one type of generator.

"Greatest flexibility."

GENERAL DISTRIBUTIONS FROM CENTRAL STATION BY DIRECT CURRENTS.

Mr. Louis A. Ferguson read a very interesting paper with the above title, the greater part of it being devoted to a description of the station system of the Chicago Edison Company.

Speaking of the general problem of the availability of direct or alternating current for any particular case, Mr. Ferguson said that the trend of engineering opinion and practice to-day is toward the use of the alternating current for the feeding of outlying districts, while the best results have been obtained in the neighborhood of the stations by direct-current distribution.

Proceeding to describe the new system of the Chicago company a number of interesting figures were given, showing the output of the four stations that comprise the system, which is one of great magnitude.

"The total low tension direct current k.w. hours output for the stations for the fiscal year of 1897 was 15,255,466, divided as follows:

	Low Tension Kilowatt Hours.	Per Cent. of Total.
Station No. 1.......	11,335,618	74.3
Station No. 5.......	2,314,473	15.2
Station No. 2.......	808,158	5.3
Station No. 4.......	797,217	5.2
	15,255,466	100.0

	Maximum Station Voltage.	Yearly Average Station Voltage.
Station No. 1.......	149.	126.2
Station No. 5.......	142.5	129.6
Station No. 2.......	125.0	119.0
Station No. 4.......	123.5	120.1

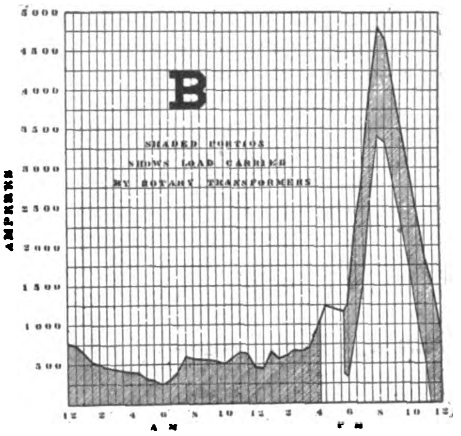
"The pressure at the feeder ends throughout the system is maintained at 115 volts on each side of the three-wire system. Although the maximum station pressure is 149 volts, the average pressure of all stations for the year is 126.2 volts, giving an average loss of pressure of 11.2 volts or 8.8 per cent, which means an average yearly efficiency of distribution of 91.2 per cent from the station switchboards to the customer's meter.

"The center of distribution in the business district of the city is at Adams Street, between Clark and La Salle Streets. Station No. 1, which furnishes 74.3 per cent of the total low tension output, is located 3340 ft. distant from the center of distribution at Adams Street. Station No. 5, which furnishes 15 per cent of the total low tension output, is located 4500 ft. from Station No. 1, and 3000 feet from the Adams Street sub-station.

"These two stations furnish all the low tension output for the district bounded by the river on the north, Harmon Court (approximately) on the south, Lake Michigan on the east and the river on the west. They also furnish all the energy for the entire low tension system of the city during the hours from midnight until dusk the following afternoon, and a portion of the output of districts No. 2 and No. 4, from dusk until midnight daily, and ultimately they will furnish all the output of the territories mentioned, and all of the energy required for alternating transmission lines into the outlying districts of the city and its suburbs.

"The distribution of current from these two stations to the underground network is as follows:

"From Station No. 1 to the Adams Street sub-station is laid an immense trunk line known as the Adams Street trunk line, having a total cross-sectional area of 66,000,000 c.m., 28,500,000 c.m. being ordinarily connected on the positive and negative sides and 9,000,000 c.m. in the neutral. The length of this trunk line is 3340 ft., and is made up of fifteen special Edison tubes, each 3,000,000 c.m. area, laid directly in the ground, and fourteen 1,500,000 c.m. stranded rubber insulated, lead covered and juted cables drawn into cement lined iron ducts. The trunk line on leaving Station No. 1 goes down a shaft sixty feet, thence through a brick tunnel built especially for it in the river bed to the east side, where it rises again in another shaft sixty feet into the tunnel house, where a small switchboard is located. The portion of the trunk line in the shafts and tunnnel, which is 430 ft. in length, is made up entirely of cables. Where the cables hang vertically in the shaft, the cable is supported by the iron armored sheathing clasped between iron plates on a heavy cast iron ring. The copper conductors thus hang in a sort of basket, the strain being distributed throughout the length of the cable. At the tunnel house the cables connect with fifteen 3,000,000 c.m. single-pole Edison feeder tubes, and together with the fourteen 1,500,000 c.m. cables are mounted on racks in a large subway, into which the duct line enters about 200 ft. east of the tunnel house. At intervals of about 500 ft. manholes are built in the Edison tube portion as well as in the conduit portion of the trunk line, thus affording a quick means of locating low insulation points as they develop. Each of the tubes and cables is provided with an amperemeter at Station No. 1, and with switches at both ends so that they may be completely disconnected from the system in case of trouble. Two of the 3,000,000 c.m. tubes are provided with throwover switches and arranged so that they may be quickly connected either to the positive or neutral or negative or neutral at will. All of the cables are provided with throwover switches on both ends, so that they may be operated either as positive or negative at will, thus providing for any possible contingency that may arise. At the Adams Street sub-station the trunk line feeds into the main bus-bar in the distribution room, and from the switchboard forty-two feeders radiate to various points in the business district, ranging in size from 250,000 c.m. to 1,000,000 c.m., and in length from 290 ft. to 2831 ft., the average size being 485,000 c.m., and the average length of feeder 1373 ft.



LOAD DIAGRAM OF CHICAGO SUB-STATION.

"The maximum current in amperes carried over the trunk line and distributed from the Adams Street sub-station last December was 34,400 amps.

"Station No. 2, which is now really a rotary transformer sub-station, is 17,500 ft. from Station No. 1, and 14,300 ft. from Adams Street sub-station. The load diagram "B" shows the amperes delivered to District No. 2, the cross hatched portion representing the current furnished through the rotary transformers and the unshaded portion representing the current furnished by the dynamos in Station No. 2, the dynamos and rotary transformers operating in parallel on the three-wire system. The upper curve shows the total amperes delivered to District No. 2.

"District No. 2 is supplied from Station No. 1 by means of a converse rotary transformer connected to the 250-volt direct current bus-bars, converting to three-phase alternating current at about 160 volts. By means of step-up transformers this is raised to 4500 volts, and at this pressure the energy is transmitted by three-phase underground transmission line to Station No. 2, where it is reduced by step-down transformers to about eighty volts and converted by means of rotary current transformers to direct current at about 115 volts.

"For the permanent conversion of Station No. 2 into a sub-station a pair of special 200 k.w. generators are being installed, directly coupled to the existing 600 h.p. triple expansion engines in Station No. 1. Each generator is provided with a commutator and a set of three collector rings, and are designed to deliver from the same armature direct currents and three-phase alternating currents, the direct current sides of each pair of machines being connected in series to form a three wire unit, and the alternating current sides, after passing through transformers stepping up to 4500 volts, being connected in multiple. The alternating current from these machines will be taken to supply the transmission line to Station No. 2, and the balance of the capacity of the machines will be delivered directly into the main direct current bus-bar of Station No. 1, thus keeping the unit operating at full load and maximum efficiency during its run.

"Uniformity of pressure throughout an incandescent electric lighting system is absolutely essential to commercial success.

To accomplish this different methods have been proposed at different times. It often happens that the original plan of distribution, laid out by the constructing engineer, does not meet the requirements, after several years' growth of the business, for in all cities lighting business may localize at certain special points, and so demand a remodeling of the existing system of conductors, or require some means of correcting for the inequalities of pressure that are due to the unevenly distributed load."

After describing the underground system in vogue with the Edison companies, he said:

"The parallel operating of the generators greatly simplifies the maintaining of uniform pressure regulation at the lamps, since when several units are connected to the common bus-bars the regulation for the entire system may be effected by careful attention to one unit, whereas in alternating current stations where the generators do not operate in parallel it is necessary, in order to even approach the uniformity of pressure regulation which exists in direct current systems operating in parallel, to regulate the pressure accurately on each unit, which is seldom done in practice. Besides the better regulation possible with parallel operating of the dynamos, a further distinct advantage is derived from the economy effected by proper division of load among the units in the stations, this being particularly marked when the distribution systems are also interconnected. Each unit, irrespective of size, may be usefully and efficiently employed at the period of maximum load, and the amount of idle or uneconomically employed investment is reduced to a minimum."

The same ground taken by Mr. Wagner in the paper above was further elaborated by Mr. Ferguson. The engineer expecting good regulation and its consequent advantages must follow the lines indicated by the experience of the large city central stations, whether direct or alternating current be used.

"One of the advantages to be derived from the use of direct current distribution as distinct from alternating current distribution, is the employment of storage batteries. They may be adopted for use in various ways, in sub-stations in outlying districts where the load factor of the district is very small, in the central stations themselves to deliver the entire output during period of minimum load, at the centers of distribution for discharging during the peak, as auxiliaries in rotary transformer sub-stations for discharge use at the time of the maximum load in the main central station. In addition to any one of the various ways which the battery may be employed, it always acts as a reserve, guaranteeing the consumer good service, in much the same manner as a bank surplus is a guaranty to the depositors in cases of financial emergency.

"Batteries are economically valuable in connection with the distribution of direct current in systems whose load curve has an average peak width of not more than two hours, since the investment required for storage batteries to carry the peak having an average width of less than two hours is less than the investment required in steam and electrical machinery to do the same work. The storage battery also has the same value that exists in the case of moving machinery as a reserve in meeting sudden increases of load, provided such increase of load does not continue for a sufficient period to wholly discharge the battery and insufficient time remains for recharging before the ordinary load peak of the system appears at the regularly appointed time.

"The steam and electrical machinery is rated by the h. p. or k. w. and the duration of the load peak does not influence the value of the investment since the machinery may be operated for the full twenty-four hours at its maximum capacity. The storage battery, however, is rated by the h. p. hour or k.w. hour and the investment is nearly directly proportional to the number of hours during which it discharges the maximum capacity, so that if we required the battery to be prepared to carry the full peak prolonged for seven or eight hours every day the investment in battery would be enormous as compared with steam and electrical machinery to furnish the same k. w. hours output.

"The storage battery has a very distinct value, which is seldom recognized and employed to its full advantage, when located at the central distributing point of a system with feeders radiating to various points in the network. The battery may be provided with two or more end cell switches, so arranged that they may be connected in multiple and feed into the main distributing feeder bus, or, they may connect also to one or more auxiliary bus-bars with a different number of cells in series, feeding into each bus thus providing two or more potentials at the center of distribution. It will be found that when only one pressure is maintained at the center of distribution during the time of maximum load of a large district that the pressure at the ends of the short feeders will be somewhat higher than the standard and they will be overloaded, and at the end of long feeders the pressure will be lower and the feeders underloaded, although the pressure variation at other times may be negligible. Under such conditions the storage battery becomes exceedingly valuable, for by arranging it to operate at two or more potentials, the long feeders may be connected during the time of maximum load to the auxiliary bus or buses and additional current forced over them, utilizing their full capacity and maintaining a uniform feeder end pressure by means of an investment in end cells very slight as compared with the investment in additional feeders and mains required to accomplish the same result.

In conclusion Mr. Ferguson stated that it was his opinion that the useful field for alternating current distribution is not in large cities, but rather in the scattered suburban districts and in small towns where commercial lighting, elevator service and power forms but a small part of the demand and where the first cost of the direct current system would be prohibitive. The successful central station of the future will be one intelligently combining the use of the two kinds of current.

COST OF PRODUCING ELECTRIC POWER BY WATER POWER FROM THE LACHINE RAPIDS, CANADA

In a paper having the above title Mr. W. McLea Walbank gave some interesting figures of the cost of generating electric power at the great Lachine Rapids installation near Montreal. The hydraulic installation is one of great magnitude and cost in the neighborhood of $1,000,000. As the head is low, vertical shaft turbines were used, six being geared to each of twelve dynamos of 750-k.w. each, generating three-phase current at 4400 volts. Of the total installation forty-eight wheels are already in place, and the head and tail races, dams, etc., and the power house are completed. The transmission line is about 5 miles long, the current being received at a sub-station where it is stepped down to 2300 volts for distribution.

"In estimating the cost of producing power from the Lachine Rapids, the writer does not take into consideration the cost of distributing power, for this would be the same in either case, whether the prime mover was a water wheel or a steam engine. He will therefore confine himself to the cost of developing water power and delivering that power on the bus-bar at the sub-station, exclusive of the generator. He will add the cost of transmission line from the source of power to the sub-station in the city, because this is directly attributable to water power plants.

"There will also be included the step-down transformers to bring the pressure equal to that required for local distribution, namely, in the neighborhood of 2000 volts.

"He will also charge the water power with the drop or loss in power from the rapids to the sub-station.

"The writer therefore considers, in justice to the Lachine Rapids plant, it would be necessary to give, first, the cost per k.w. per year for the portion of the plant at present installed and connected to generators ready for operation, and, second, what the cost will be per k.w. per year when the whole water power development is in operation.

"First—The total cost of water rights, dams, hydraulic machinery, power house, transmission line, step-down transformers, etc., is $957,200.

"Power developed, 4000-k.w. at the generator. Allowing 10 per cent loss, there will be delivered at the substation bus-bar 3600-k.w., which is equivalent to $263.83 per k.w., capital cost.

This, at 6 per cent., would be equivalent to	$15.96 per k.w.
Depreciation of $300,000, which will more than cover the cost of that portion of the plant subject to depreciation, rated at 5 per cent and spread over 3,600 kilowatts, would be equivalent to	4.17 per k.w.
Operating expenses, including labor, repairs, insurance, amounts to $10,275 per annum, which, divided into 3600 kilowatts, is equivalent to	2.85 per k.w.
Making a total cost per kilowatt on a 24-hour day basis, per year....	$22.97 per k.w.

"Second—The total cost per kilowatt with the whole water power plant in operation.

"Before giving these figures the writer would like to explain that the figures herewith quoted are reliable for the cost of the completed plant, inasmuch as the same is at present under contract with reputable firms.

"The total capital cost with seventy-two wheels installed will be $1,113,273.

Power developed after deducting all losses will be 13,500 k.w. at the sub-station bus-bar, equivalent to $82.46 per kilowatt capital cost, which, at 6 per cent., represents (per annum)................	$4.95 per k.w.
Depreciation per kilowatt will equal	1.68 per k.w.
Operating expenses, including labor, repairs, oil and waste and insurance, if taken upon the same basis as already existing, will amount to $20,453, equivalent to	1.51 per k.w.
Making a total for a 24-hour run per annum of................	$8.14 per k.w.

From the foregoing the writer trusts that he has shown that where reliable water power can be obtained within reasonable distance from power centers it can be made to produce cheap electric current, to say nothing of the great advantages the city must derive therefrom, not only commercially, but viewed from a sanitary standpoint as well, as the use of electric power thus generated is the best smoke consumer yet invented.

It will be noticed that the operating expenses, as well as the depreciation per k.w., in the latter case is very much reduced, and it is a remarkable feature how constant our operating expenses are, even at present, being practically the same with full load as with no load.

In connection with these figures it might be stated that coal used in Montreal and vicinity is what is known as Nova Scotian coal, and costs $3.50 per ton for run of mine.

REPORT OF COMMITTEE OF STANDARD CANDLE POWER FOR INCANDESCENT LAMPS.

This committee, of which Dr. Louis Bell is chairman, reported as follows:

Your committee has been able to have tested in the most careful manner through the courtesy of Professor W. L. Puffer, of Boston, 16-c.p. incandescent lamps from eleven different makers. The lamps were obtained directly from the makers or their authorized agents, and were known to be for test.

These lamps were all sold for 16-c.p., 110-volt, no watts specified, and may be fairly assumed to represent the product which would be shipped to consumers who did not desire the lamps for test, although one batch of lamps came with the bases marked to show the point to be turned toward the photometer screen.

On test these lamps, thirty-three in all, averaged 14.1 mean normal c.p. and about 11.7 mean spherical c.p. Only one batch of three averaged over 16 normal c.p. One batch fell below 11 normal c.p. and two below 12 normal c.p. Five makers fell below 14.5 normal c.p. The highest average of any batch was 16.99, the lowest 10.82. The average consumption of energy was almost exactly 4 watts, the lowest 3.78 watts per candle, and two batches ran over 5 watts. It should be noted that the voltage was determined by a Weston voltmeter freshly compared with Clark cells, and each lamp was run at its marked voltage (110).

A separate series of tests showed that these lamps on the average gave their greatest mean c.p. when measured under rotation with their axes tilted 44 degs. and 24 minutes from the vertical toward the photometer, thus confirming closely your committee's estimate of 45 degs. as a proper angle. A series of tests on proper speed of rotation showed that the best results were obtained with a speed of 200 to 250-r.p.m, and that the lamps would readily stand this speed.

Many of the lamps showed bad spherical distribution, which seems to be quite needless, since it is merely a matter of proper proportioning the form of the filament.

Of an equal number of batches of 32-c.p. lamps, only one batch averaged 32 normal c.p., the majority falling to from 26 to 28 c.p. The 32-c.p. lamps averaged slightly greater efficiency, but were otherwise much like the 16-c.p. size.

From this investigation the fact stands out that the incandescent lamp sold for 16-c.p. is, on the whole, a lamp which is often giving considerably less than its rated c.p. even when new. Some of these lamps would probably show a temporary increase of c.p. after, say, fifty hours' burning, but the committee has not extended the research in this direction as yet, and adheres to the opinion that the initial c.p. is the only practicable commercial test, and any increase consequently is simply to be regarded as a device for keeping the lamp a little longer from its inevitable decay.

From these and other data kindly furnished by manufacturers and obtained from various other reliable sources your committee is convinced that the need of a uniform rating is even greater than is concluded in the preliminary report of last year, and that a rating test, in order to be effective, must involve measurement of c.p. of lamps in more than one direction. Neither mean horizontal, nor mean spherical c.p., nor c.p. in any one direction will define a lamp well enough to warrant adherence to the rating. Your committee therefore recommends that incandescent lamps be required to conform both to a standard mean normal c.p. and to a mean c.p. when involved with the axis tipped 45 degs., this representing the spherical distribution. It recommends that the limits for the mean normal c.p. be 15 and 17.5-c.p. Unless the minimum be as high as 15 there will certainly be found a tendency to produce lamps near the lower limit. The 45 degs. should be at least 85 per cent of this minimum. This is not an excessive requirement, and will tend to prevent working near the lower limit of horizontal c.p., unless with a lamp very good in other respects.

Your committee has blocked out a standard form of photometer, a type of which it proposes to build, test and put at the disposal of the association with directions for proper use.

It suggests that testing be by sample, a lot of ten lamps being taken from each barrel. Of these no lamp when run at its marked voltage shall show less than 15 or more than 17.5-c.p., mean horizontal, when rotated at 200 to 250-r.p.m.; and no lamp shall give when thus rotated at 45 degs. inclination less than 85 per cent of the above minimum.

NORTHWESTERN ELECTRICAL CONVENTION

The convention afloat of the Northwestern Electrical Association was a decided success, not only with respect to the object for which that body exists, but also as furnishing the members and guests a most agreeable excursion and an instructive tour of industrial inspection.

The excursion steamer "Northwest" sailed from Chicago early Friday afternoon, June 10, and in the evening a stop was made at Milwaukee for delegates. The next evening at 8 o'clock the boat arrived at Sault Ste. Marie, and a meeting immediately after was held at the Hotel Iroquois. A warm welcome was extended by the Mayor in an address, and an electrically illuminated arch in the street testified to the sentiments of the citizens. On Sunday a visit was made to the works of the Lake Superior Carbide Company, to the electric power plant of the Lake Superior Paper & Pulp Company, and the electrically operated lock of the great canal, built by the Canadian Government.

The steamer left Sault Ste. Marie at 2 P. M., and early the next morning arrived at Hancock. Taking a train, the delegates visited the wire mills of the Tamarack and Osceola mines and the smelting and stamping works of the Calumet & Hecla mines and the Superior power house, returning to the vessel in the afternoon and sailing at 4 P. M. for Duluth.

Early on Tuesday morning the ship arrived at Duluth, where Mayor Truelson delivered an address of welcome. In the evening a banquet was held at Superior, and at noon on Wednesday a train was taken for Minneapolis, where a dinner was given to the delegates, at the Mercantile Club, by Mr. Morgan Brooks, which was followed by a drive through the parks, ending at the railroad station, where a train was taken for Chicago.

About 100 delegates and guests were in attendance. Sessions aboard the "Northwest" were held on Saturday and Monday, and in the Duluth City Hall on Tuesday.

Mayor Truelson, of Duluth, in his address of welcome, spoke of the fact that at Sault Ste. Marie there are 200,000 h.p. waiting development, and suggested that this power should be harnessed to reduce the best iron ore in the world, which is found in inexhaustible quantities close at hand. As an instance of the great industrial development of that section, he said that the Calumet & Hecla mines and others in the near neighborhood paid out no less than $600,000 monthly in wages.

At the Hotel Iroquois, Sault Ste. Marie, Prof. Elisha Gray delivered an entertaining address, which was enlivened by a number of amusing reminiscences of the early days of electricity. In conclusion, he said that he did not know what the outcome of electricity is to be, but he is sure that we have not reached the end by any means. He thinks that some now living may see the time when the steam engine will be done away with, when the energy which is stored in wood and coal will be converted directly into electricity without passing through the state of heat.

One of the most interesting addresses of the excursion was an impromptu one delivered by Mr. Ischisuke Fujioka, of Tokio, Japan. After some courteous remarks on the pleasure which he had experienced on the trip, Mr. Fujioka took opportunity to say a few words about lightning, which was the topic of the morning's meeting. He said that barbed wire was run on the pole lines of the Tokio-Edison three-wire system, and there has not been a single instance of damage done, although Japan is very often visited by severe thunder storms. Thus far many of the so-called lightning arresters have failed to give good satisfaction in Japan, but he considers that an efficient form of this device should be installed upon long transmission lines.

During the passage Mr. F. E. Barker, Gas Commissioner of Massachusetts, was invited to address the convention, and chose as a subject the mutual relations of municipalities and electric light companies. The government, he said, whether State or municipal, is just as strongly bound to perform certain duty toward the companies as the companies are to render certain other duties to the municipality and the public. A company's ability to satisfactorily serve the public is generally proportional to the degree of prosperity it enjoys, and the kind of service which comes from an impoverished concern to whose embarrassment misdirected official effort may have contributed, is frequently well-nigh a public misfortune. He referred to the fact that some managers, unfortunately, are apt to narrowly and unwisely assume that because the public gives them certain advantages all are therefore theirs, and that they are under no obligation to share any of them with the public.

As to the growth of municipal plants in Massachusetts, he said that most of them have been built where private capital saw no inducement to go. There are two or three cases where this has not been true; in one the company induced the town to buy its plant; in another the company refused to accommodate the public and a municipal plant was a natural result; in still another the business seems to have been assumed as a matter of politics.

Following are abstracts of the papers read before the convention:

PURIFICATION OF WATER.

Mr. Dow read a paper on the purification of water, describing a method employed in his station. The station uses two vertical fire tube boilers, each containing about 1800 small tubes, and of 30-h.p. capacity each. In order to get pure water for these boilers, two tanks or cisterns were made of brick or Portland cement, 46 ft. in diameter, and 6 ft. deep. The cistern is filled with water from the hot well of the jet condenser used, and at the same time a small amount of whitewash is added. The exact amount is determined by adding a few drops of a weak solution of silver nitrate to a little of the water in a tumbler, when a red precipitate will be formed if a sufficient amount of lime has been added. After the water is settled in the tank for about half an hour, a solution of soda ash is added, and then if the water is at all muddy a very little alum is also added. Within an hour the water begins to turn a greenish blue, and within two or three hours it may be drawn from the top if necessary, though it is preferred to allow twelve or fifteen hours for settling. The function of the whitewash is to precipitate the soluable bicarbonate of lime in the form of a normal carbonate which is insoluble; soda ash is added to precipitate the sulphate of lime and the excess of whitewash. At first only whitewash was used, but when it was found that a tenacious scale was deposited soda ash was added, after which no scale was formed, and the very small amount of precipitate which finds its way to the boiler never cakes, but remains as a mud until blown off.

MECHANICAL DRAFT.

Mr. W. B. Snow read a paper on mechanical draft, in which he brought arguments to bear showing that the substitution of a fan for a chimney as a means of draft production is a distinct advance in the economy of steam generation. Not only does its application insure an economic gain, but in both its installation and operation there are certain conveniences which are to be considered as distinct advantages, although it may be almost impossible to determine their definite economic values. Mr. Snow considers that under certain conditions a combination of force and induced draft may be found desirable.

Among the advantages of mechanical draft is that it is both positive and flexible. The fan is always at its best, can be instantaneously pushed to its utmost, and does not have to wait for a hotter fire to produce a stronger draft. When properly installed, a fan should be provided with an engine devoted solely to its driving, and the speed of this can be so controlled as to increase in proportion as the steam pressure falls, thus making it possible under all ordinary conditions to maintain a practically constant steam pressure and to insure immediate response to sudden demands. The fan lends itself admirably for use in connection with heat economizers, and another feature of convenience is to be found in the ability to burn cheap fuels and in abating the smoke nuisance.

Mr. Snow stated that tests of nine large boiler plants equipped with economizers and mechanical draft are reported by Roney to have shown on an average a saving of about 14 per cent. As to forcing, he points out that low combustion and evaporation rates are not essential to high efficiency.

INCANDESCENT LAMPS FOR INCLOSED ARC RESISTANCES.

In answer to a query deposited in the question box as to the practicability of substituting an incandescent lamp in place of wire resistance in direct current inclosed arc lamps, Mr. J. W. Mabbs gave the result of some experiments on this point which he had made. He found that an inclosed arc works much better with lamps substituted for metal resistance, and the light from such lamps can be utilized. He uses six lamps of 10 c.p. in multiple series, each one consuming about 1 amp., from which very good results are obtained. The lamps used are of about 4 watts per c.p., so that if one lamp breaks the other five will carry the current until the broken lamp is renewed. Eight or ten arc lamps have thus been fitted, the glow lamps being placed from 50 to 60 ft. distant. Mr. Kimball stated that in Hartford, Conn., extended experiments have been made in this line and a special form of series lamp adopted, which is installed in stairways, entries and places of that description. The experiment had been very successful, and about fifty arc lamps have been thus fitted.

ELECTRIC SMELTING.

In the absence of Mr. W. S. Horry, Mr. Doherty read a paper contributed by that gentleman on electric smelting. The paper referred to the fact that in the manufacture of carbide of calcium there are molten masses weighing a ton or more at the temperature of probably 3000 degs. C. in immediate proximity to cast iron surfaces that would be melted if a temperature of 1100 degs. C. was reached. The enormous temperatures of electric smelting are, nevertheless, easily under control, and the heat can be indicated very accurately by means of a wattmeter, so that results once obtained in this apparatus can always be duplicated with ease. He spoke of some experiments with sulphide nickel ore found at certain mines in Ontario, from which it was proposed to extract the sulphur to be used as sulphuric acid in paper making. Roasting the ore in a regenerating furnace did not produce the proper results, but when it was ground up and mixed with lime and carbon and subjected to heat in an electric furnace the sulphur was entirely eliminated and the nickel was separated from the iron, thus demonstrating that nickel in the free state of purity can be obtained by this process. In another instance pure copper was separated from a matte of copper, nickel and iron when smelted electrically. The carbide furnace used at Sault Ste. Marie consists of cast iron drums 10 ft. in diameter and 2 ft. long, mounted on a shaft and slowly rotated by a hand worm gear; the electrodes are carbons 2 ft. long and 4 ins. square; there are four pencils in an electrode, and the two electrodes are separated by a space of 8 in., the axis being the axis of the furnaces. As the ore is reduced the resultant metal lowers the resistance of the furnace, when the latter is slowly rotated, by which movement the metal is drawn away from the electrodes and fresh ore is brought between them to be acted upon. The voltage is 100, and about 1500 amps. of current are used.

LIGHTNING ARRESTERS.

Mr. A. J. Wurts delivered an address on the subject of lightning arresters, in which he stated that not long ago the president of a large electric plant wrote to him asking whether he thought it possible to absolutely protect a plant against lightning; he answered that he thought that it could be absolutely protected against all ordinary effects of lightning, although there are, of course, exceptions. Mr. Wurts stated that the deductions obtained from experimenting with a static machine may be applied to lightning discharges, the phenomena observed in the first case corresponding with those accompanying the latter.

Referring to statements made that a lightning arrester should have a low breakdown e.m.f., he said that a lightning arrester has nothing to do with the e.m.f. of a dynamo. The only standard for the resistance of a lightning arrester is the ease with which it will conduct oscillatory discharges to earth, and this has absolutely no reference to ohmic resistance or breakdown e.m.f. He said that what he calls a free path for an oscillatory discharge is one which has a spark gap or several spark gaps; the discharge will smash the air between the gaps and thus form at once a free path for the electrical oscillations.

Referring to the underwriters' requirements that lightning arresters must be connected with a thoroughly good ground connection by metallic strips, the wires having a conductivity of not less than that of No. 6 B. & S. wire, and must be run as nearly in a straight line as possible to the earth connection, Mr. Wurts asked why such a rule as this should be made if there is put in the circuit of the lightning arrester an ohmic resistance many times that of the ground connection?

The question having been asked whether on an overhead three-wire tension distribution additional protection is afforded against lightning by grounding the neutral wire at various points throughout the system, Mr. Wurts replied that in his opinion the grounding of the neutral wire might and probably would protect the generator, but he did not think that the ground would protect apparatus at any considerable distance from the point at which the wire is grounded. He said that the self-inductance of a perfectly straight wire is so great on oscillatory discharges that the discharge will not travel any considerable distance, but will jump to the ground in preference. If the neutral is grounded as it enters a house, it will very materially protect the apparatus in that house. If grounded at frequent intervals, apparatus in the neighborhood of the grounds will be protected. Should the grounding of the neutral assure safety from oscillatory discharges, this would only apply to that wire, but would not relieve the other two wires of the necessity for lightning arresters.

In reply to a question, Mr. Wurts stated that an overhead ground wire is not a good protection from lightning. It may help to protect under certain circumstances, but lightning arresters should not be dispensed with. He thinks that barbed wire, however, has advantages over plain wire, for the reason that points drain electrical discharges much more rapidly than smooth surfaces.

INCANDESCENT LAMPS.

Mr. S. Everett Doane in a paper on the subject of incandescent lamps, called attention to the fact that the old theory which ascribes the blackening of lamps to the evaporation of carbon and a subsequent condensation on the bulb, has been replaced by one which refers the blackening to a chemical effect. He dwelt upon the fact that an incandescent lamp has no particular c.p., being capable of delivering as many definite c.p. as definite voltages are applied. Change of resistance has very little to do with the change of the c.p. of a lamp, for a well constructed incandescent lamp does not change its resistance materially throughout its effective life; the c.p., however, changes considerably, due to a change in the radiating power of the surface of the filament.

Mr. Doane laid down two principles concerning the c.p. of incandescent lamps. First, that the c.p. never remains absolutely constant, but falls continuously, barring the first sharp rise; and, second, that the curve of change in candles is nearly a straight line, and for all practical purposes can be considered as such, neglecting, of course, the rapid rise at the commencement of the life and the sudden slump at the finish. As to the initial rise in c.p., this is usually very rapid, the maximum incandescence being frequently reached after the first one or two hours. Stress was laid upon the point that a purchaser should have a care that he does not test a lamp until after it has burned some time, in order that the peak in the curve shall not be encountered. He does not believe in the method of putting a planimeter on the curve, and averaging the c.p. hours up to the time when it has fallen a given percentage, 80, for instance, as this, he considers, places a premium upon the initial rise in c.p.

The statement was made that incandescent lamps lend themselves quite easily to deception. For example, a little rough handling of the lamp on the pump will blacken the filament, which will increase the c.p. for a period of a couple of hours until the sooty coating has been burned off. Mr. Doane believes it is very difficult for even a lamp expert to see any difference between a 20-c.p. and a 16-c.p. lamp, if both lamps are operating at the same watts per candle.

In summing up, Mr. Doane stated that lamps rise in c.p.; that everything is being done to obviate this and that eventually it will be entirely avoided. Bright lamps and dim lamps are equally objectionable and the most important consideration in determining from a life test the best available lamps for central station use, is that the true initial c.p. of the lamp under test be properly determined.

In the discussion of Mr. Snow's paper Mr. Doherty stated that in a test which he made of a steam pump he found that it used steam at the rate of 150 lbs. per h.p.-hour, and he figured out that in that particular case by pumping electrically this consumption would be reduced to about 26 lbs. per hour. Mr. Doherty considers that mechanical draft must be forced in order to do efficient service. In his station a Hazen boiler is used, a portion of which is cut out, when necessary, and thus a good efficiency maintained—this being 59 per cent with a very bad load. He said that one time he attempted to build a smokeless furnace but obtained a lower efficiency than with a smoky furnace, this fact being due to too great an admixture of air.

Mr. Dow said that he found that better results could be obtained with a thick layer of fuel than with a thin one, and he considers that the ordinary idea that a very thin bed should be used is entirely wrong.

Mr. Cross belives that small stations do not need mechanical draft, economizers or automatic stokers, and he does not think they are worth considering in plants in cities of less than 50,000 inhabitants.

COST OF ELECTRIC POWER.

RENTED POWER FOR ELECTRIC RAILWAYS.

For the purpose of determining just what price was being paid for electric power by the street railway companies throughout the country which do not operate their own plant, but rent or purchase power from outside companies, letters were addressed to all the companies in the United States that were known to purchase power. The replies received are given below and form a very interesting study. Most of the information received was given in confidence, and it is therefore impossible to publish the names of all the companies reporting. The replies received are as follows:

A company operating twenty-four motor cars and nine trail cars on 18 miles of track pays $.011 per k.w. hour.

A company operating five cars on 6 miles of track rents power from an electric light company at $1.80 per car per day of eighteen hours, the street railway company owning the generator and the electric light company paying all expenses of running it. The street railway company states, however, that it has recently been notified that this rate will be raised to $2.10 per car per day, as the present figures do not cover the entire cost.

A company operating four motor cars daily, and on extra occasions six motor cars and occasionally trailers, and owning 6 miles of track, pays $2 per day for each of the four motor cars, and $1.50 per day for each additional motor car and 50 cents per day for each trailer in excess of twelve days in each month. This street railway company states that its contract for power has been in force four years with satisfaction to both parties, and thinks this arrangement cheaper than owning and operating its own plant for so few cars.

A company operating about five cars pays a fixed charge of $12.50 for five cars or less per day, and $2 for each additional car above that number.

A company operating ten motor cars on 6½ miles of track purchases its power from a lighting company on a car-mile basis, paying $.015 per car mile.

A company operating in the South reports as follows: "We rent our power from the city on contract for five years, the rate being $.015 per k.w. We, however, put up the feeders for a distance of 3¼ miles, using the city's poles to string them on. Our meter is at the power house end, and the expense to operate eleven cars, eighteen hours per day, runs from $660 to $680 per month. We have a great many steep grades and our main line is up grade for over 2 miles. We operate eight cars per hour over this grade, and on another line we operate four cars per hour over a grade of 1½ miles in length; on still another line we have a very steep grade, but only about 1500 ft. long; over this line the cars make a round trip in fifty-one minutes, there usually being three cars on the line. We have a number of slight grades on other parts of our line, and taking everything into consideration, we have quite a hard street railway city, but we consider our rate reasonable."

A company operating fourteen motor cars and two trail cars on 7½ miles of track purchases power from an electric light company, paying $3 per car per day. The electric light company is owned by the same interests that control the street railway company.

A company reports as follows: "Our company owns its own generators and a gas company furnishes us with steam power, together with the necessary labor to operate the generators. For two of the generators our company pays $19 per day of nineteen hours; for three others $7 each per day, and for four others, which is the extent of our contract, $6 each per day. Our power bill last year, based on the number of car miles, was $.02125 per car mile, this amount including heat and light for the cars, also light for the stations. No extra charge is made for snow plow service."

A company operating sixty motor cars and twelve trail cars on 20½ miles of track buys power for less than $.03 per k.w. hour.

A company operating four cars about seventeen hours per day and owning 3½ miles of track has a contract with an electric light company by which it pays $50 per month for power. The average ampere load at 500 volts is about sixty.

A company operating fourteen motor cars on 8 miles of track reports that it pays on one of its lines $3 per car per day, which includes maintenance of lines; and on the other branches $2.50 per car per day, which does not include cost of maintenance.

A company reports that it furnishes power to a number of street railway companies, a uniform charge of $.03 per car mile being made to all.

A company pays $10 a day for power for three cars from 6 A. M. to 11 P. M. These cars run about 425 miles in that time. For extra cars it pays $1.50 per half day, or if only one trip is made, $.25 an hour.

A company operating seven motor cars on 7 miles of track reports that it rents power from an electric lighting company and pays $2.75 per day of eighteen hours for each car operated.

A company operating 10½ miles of track places its own dynamos in the power station of an electric light company, the electric light company furnishing the power and attendance and caring for the machines. For this the street railway company pays at the rate of $2 per day of eighteen hours for each of five motor cars, with the additional right of attaching two trailers without cost. For all additional motor cars a charge of $1.85 each per day is made, and for additional trailer cars $1 per day. This amount also includes light for the cars.

A company owning 4½ miles of track pays $200 per month for its power and operates daily five cars and on some occasions as many as nine cars. The company states, however, that the power is rented from a company very closely connected, and that the cost for power is considerably less than it could be purchased from outside parties.

A company owning 3 miles of track pays for its power $6.50 for two cars per day; some parts of the year one S. R. F. 30 motor and one G. E. 800 motor are run, and at other times two S. R. F. 30 motors.

A company owning 7.5 miles of track has a contract with another company for all its power used. This contract calls for a minimum payment of $12 per day for a maximum number of four cars, operating sixteen hours. Eight bench open cars and 16-ft. closed cars are used, each car being equipped with two Thomson-Houston S. R. G. 30 motors, with old-style controller and rheostat.

A company operating several large lines reports that the approximate charge for power is about $2.50 per car per day for a certain number of cars, and this amount less 10 per cent for additional cars. A trailer is allowed to one or two motor cars under certain conditions.

A company operating three motor cars on 1½ miles of track reports that up to a short time ago it paid from $4 to $4.50 per car per day for power.

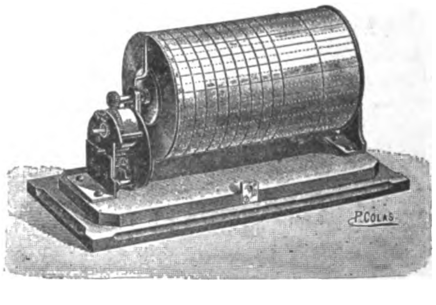
A company owning 4 miles of track pays an electric light company $6 per day of fifteen hours for power for two cars with double 30 h.p. motors each.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

An Electric Water Glass.—According to "L'Elettricità," a hydrographic engineer of Cracow, M. Malachowski, has desigened a simple and satisfactory apparatus for viewing bodies submerged to a depth of 40 to 60 feet. It is composed of a binocular telescope to which is attached a long zinc tube which plunges under the water. On the bottom of this tube is arranged a cylindrical chamber containing a system of mirrors and incandescent lamps, the aperture of the tube being closed with a glass window. Weights attached to the lower end of the tube balance the apparatus in the water.

Automatic Station Log Book.—In stations where the readings of the switchboard instruments, etc., are recorded in a log-book at regular intervals the tendency of most employees is to invent figures whenever they are prevented by any cause from making the entries at the proper moments, and thus to produce a record which is useless and misleading. To secure the registration of the figures at the proper moments and to guard against the filling out of the sheets with arbitrary numbers at the leisure of the man in charge, M. A. Peyramale, engineer of a lighting station at Bordeaux, has devised a simple piece of apparatus which is illustrated in "L'Industrie Electrique." The sheet for the daily log, properly ruled, is mounted on the face of a cylinder which is turned by clockwork. The illustration shows the cylinder with the sheet in place. Covering the cylinder and clockwork is a case with a narrow slot in the top through which the figures may be written in their proper places. The cover is locked in place so that the apparatus may not be tampered with, and the whole forms a neat and convenient method of handling the log sheets. The further advantage of clean sheets is also secured by its use, as the switchboard man only touches the sheet with his pencil or pen.



AUTOMATIC STATION LOG BOOK.

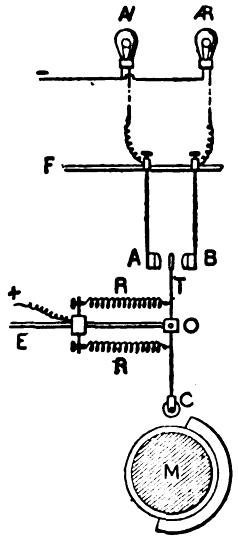
X-Ray Photographs of Alloys.—The X-rays have been applied by Messrs. Haycock and Neville to the study of the structure of metallic alloys, their paper on the subject having been presented to the Cambridge Philosophical Society. When the alloy is composed of two metals of different transparencies radiographs of thin plates show the separation of the two during solidification. Thus an alloy of aluminum and gold shows on solidification a precipitate of the compound $AuAl_2$, which separates out in octahedral crystals.

The Motorwoman.—Our rather sprightly contemporary, "L'Energie Electrique," commenting on the sport of "automobilizing" as practiced in France, says: "The Duchess d'Uzès by applying for a license as driver of an automobile has not made the sport aristocratic, for that social formality was long ago performed, but she has feminized and consecrated it. This noble example, we feel sure, is going to be followed by troops of duchesses, princesses, marquises and other belles dames fleurdelysées.....The leaders of commerce and finance will not fail to automobilize themselves in their turn, and the time will soon be here when the valet will say to us without causing astonishment: 'Madame has gone out to try her new motor in the park.'"

A Simple Electrolytic Meter.—A novel and simple electric meter, the invention of Mr. C. O. Bastian, is described in the (English) "Electrical Review." It consists of a vertical cylindrical glass vessel of approximately uniform bore, containing at the bottom two platinum foil electrodes. The cylinder is filled with dilute sulphuric acid on which a film of oil is floated to prevent evaporation. The whole is enclosed in a cast iron case, having a scale graduated in Board of Trade units (k.w. hours). The graduation is effected directly for each instrument to avoid errors due to the varying bore of the tube. The fluid is electrolyzed by the passage of the current, the gases escaping and its level falling. When it is exhausted it is filled with water, and is then ready for another period of service. The meter is said to work very well, and its simplicity, cheapness and direct reading qualities seem to commend it as an excellent instrument where great accuracy is not necessary.

Temperature of Incandescent Lamps.—In a paper presented to the Académie des Sciences M. P. Janet gives the results of researches upon the temperature of incandescent filaments. The method used consisted of measuring the resistance of the lamp as a function of the e.m.f. across its terminals, and the variation with time of the resistance of the lamp while cooling. From these data the curve of watts radiated in any time and the heat units given off by the lamp may be deduced. Then by weighing the filament the temperature can be deduced from Violle's formula. The experiments were made on four lamps of 10 c.p. at 65 volts. The results showed temperatures of 1720, 1610, 1630 and 1620 degs. (Centigrade) for the various lamps, which are remarkably accordant. The principal difficulty with the method outlined is that of accurately weighing the very light filament, but the author suggests that to avoid this low voltage lamps with thick filaments can be employed for future work.

A Simple Speed Indicator.—Among the auxiliary apparatus on naval and other vessels are helm indicators and revolution counters. The simple apparatus described here, due to M. Cadiou and illustrated in "L'Electricien," is of the latter class, and is so designed that it may be made out of material on hand and applied to almost any steam vessel having an electric light plant aboard. A glance at the illustration renders a description almost unnecessary.



SPEED AND DIRECTION INDICATOR.

The main shaft is shown at M and carries an arc which engages with the roller C. This is at the end of a rod which is held by the opposing springs RR, and carries at its other end the contact point T. The lamps shown are connected with the points A and B, so that one of them flashes for each revolution of the shaft in one direction while the other flashes if the motion is reversed. To time the revolutions all that is needed is a watch. The lamps may, of course, be put anywhere about the vessel that is most convenient.

Rare Oxides in Incandescent Filaments.—"L'Eclairage Electrique" gives a short discussion of the recent researches and theory of M. Bunte concerning the effect of the rare oxides used in incandescent gas burner mantles when used in electric lamp filaments. It appears that the office of the oxides is two fold. The oxide of cerium, which is always present in the mantles in larger or smaller quantities, is to cause, by its catalytic action, a more violent combination of the elements of the gas and the air, and thus to make the mantle the seat of very energetic action. The oxide of thorium, which constitutes the greater part of the mantle, has, according to M. Bunte, no special emissive power, but, on account of the energetic action just described and its own lack of conductivity, is raised to a very high temperature. In support of this theory, it is stated that mantles of pure ceria or thoria do not give more than one-tenth to one-twentieth of the light radiated by one composed of these materials mixed together. Carbon, magnesia, ceria and thoria heated to the same temperature in an electric furnace gave the same emission of light. On these accounts, it is held that the addition of these oxides to the carbon filament in an incandescent lamp will have no effect upon the light emitted by it.

Air Circulation in Telephone Cables.—A very interesting paper on dry air circulation in telephone cables was read by M. A. Barbarat before the Société Internationale des Electriciens, and has been translated by the "Electrician." It appears that when enlargement of the Paris telephone system required the substitution of cheaper and smaller cables than those which had been installed originally an experiment was made with dry paper cables having the ends paraffined to keep out moisture. These cables were successful, but were liable to be injured by the absorption of moisture through any break in the lead covering, especially as the most of them are laid in sewers. To obviate this trouble dry air is kept circulating through the cables. The cable heads are of wood, and, as it is impossible to make these tight enough to resist the air pressure used, the end of the cable is sealed with paraffin and the air led in through a pipe tapped into the cable behind the seal. The air is dried by passing it through six cylinders 1 ft. in diameter and 6 ft. long containing calcium chloride. In cables in sewers or elsewhere where they are liable to be covered with water the pressure is kept at 45 lbs. A puncture is immediately shown by a meter on the air supply pipe. The results obtained from this system are said to be excellent.

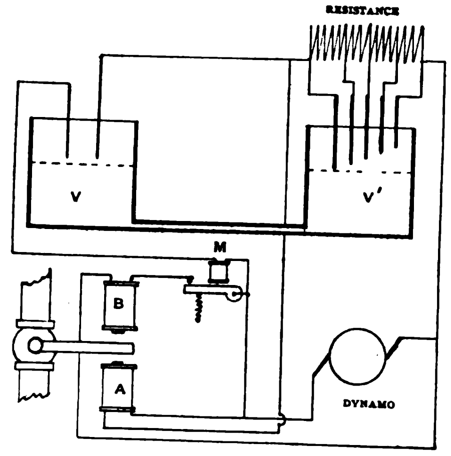
Effects of Electricity Upon Germination.—Sig. Tolomei has presented to the Accademia Reale Lincei a note upon the effect of electricity upon the germination of seeds, which is abstracted in "L'Elettricità." It had been previously noted by the author that seeds under the action of the electric current augment in weight more rapidly than those under normal conditions. His present experiments tend to show a diminution of the period of germination under the same action. An apparatus was used which traced a curve upon a cylinder making one revolution per week, two simultaneous curves showing the swelling of two seeds in water, one of them being subjected to the influence of electricity. The research was carried on with seed in water charged negatively and positively, and also permeated by alternating and continuous currents. In the first case, where the water was negatively charged, there was a diminution of the time of absorption when the sky is clear, that is, when the charge of the atmosphere is positive. When the charge of the seed is positive the reverse takes place. Both alternating and direct currents were shown to shorten the time needed for the seed to reach the state of saturation, but the total amount of water absorbed is the same as in the normal case. The author hints that seeds which require a very long time for absorption ordinarily may have their germination hastened by the electric current or even by simple electrification.

Electrolytic Manufacture of Iodoform.—A process for the electrolytic manufacture of iodoform has been devised by K. Elbs and A. Hertz and described in the "Zeitschrift für Elektrochemie." Iodoform is produced by the reaction of iodine upon warm alcohol in the presence of an alkali or an alkaline carbonate, the formula being:

$$CH^3CH^2OH + 10\,I + H^2O =$$
$$CHI^3 + CO^2 + 7HI.$$

This reaction can be brought about by passing a current of electricity through a solution of iodide of potassium and caustic soda containing alcohol. Under the action of the current potassium and iodine are set free. The hydriodic acid or the iodides formed by secondary reaction are immediately redecomposed, so that the iodine not used up in the production of iodoform is almost entirely regenerated, only a little appearing at the anode as iodate. The best results are obtained when the temperature of the bath is between 60° and 70° Centigrade. Too much alkali diminishes the output of iodoform and favors the formation of iodates. The current density should not exceed 10 amps. per square foot. Good results are obtained with an electrolyte containing 16 to 17 per cent of alcohol, 4 to 5 per cent of sodium carbonate, and 8 to 9 per cent of potassium iodide. Iodic acid forms very slowly and does not interfere with the main reaction for some time. The efficiency of the process is stated to be as high as 97 per cent of the theoretical possibility, which is 1.468 grammes of iodoform per ampere hour. The iodoform produced is crystalline and very lightly tinted with yellow.

Electric Regulator for Marine Engines.—In a heavy sea when a vessel is pitching the screw is often thrown up into broken water, or even clear of the water altogether, thus suddenly throwing the load off the engine and starting it to race. When the screw descends with the backward pitch a severe shock is given to shaft and engines. A recent device for the electrical control of engines under these circumstances is described by Sig. E. Putato in "L'Elettricista." It consists of two vessels of mercury, V and V¹, connected by a tube, and mounted fore and aft in the ship, V¹ being towards the bow. The normal level of the mercury is indicated by the dotted line. When the vessel pitches forward so as to raise the screw the rods connected with the resistance are submerged one after the other, so that the electro-magnet, a, is brought into play, the whole resistance being short-circuited when the screw is lifted clear of the water. The electro-magnet operates a throttling valve in the main steam pipe, which is thrown open by another magnet, b. This is worked through a contact controlled by an auxiliary magnet, m, which is in turn thrown into circuit by the immersion of the contacts in vessel V. By this arrangement the steam is turned on full head as soon as the screw is immersed by the backward pitch. In still water neither set of contacts is immersed in the mercury and no current is consumed. From experiments, which are said to have been very satisfactory, it is stated that the mercury vessels need not be more than 34 inches apart on a 300-foot ship.



ELECTRIC REGULATOR FOR MARINE ENGINES.

Electrodes for Electrolizing Alkaline Chlorides.—In an article in "L'Industrie Electrochemique," M. H. Becker notes the various sorts of electrodes used in the electrolysis of alkaline chlorides and reviews their advantages and defects. Carbon in some form is the material most commonly employed, the electrodes being made of the ground carbon mixed with some binding material rich in carbon and heated under pressure in a closed mould. The resistance of such electrodes to the destructive action of the evolved chlorine and oxygen is greater as they are more compact and less porous, so that the least possible quantity of the binding material should be used and the calcination carried on at high heats. A process has been developed by Messrs. Girard and Street in which the high temperatures of the electric furnaces are used. Certain metallic oxides are also frequently employed, among them peroxide of lead, iron plates covered with a layer of magnetite (Fe_3O_4), or better, plates covered with a layer of ilmenite, an oxide of iron and titanium, having the formula $FeTiO_3$. Among metallic electrodes the most useful are those of platinum-iridium, containing about 10 per cent of iridium, which are used in several chlorate of potash works. Pure platinum electrodes are not so good and those of platinized metal are worse. These electrodes are generally made of wire gauze or thin sheets of the metal stretched across frames. Both ferro-silicon and the phosphide of chromium have been suggested as proper materials for such electrodes. For cathodes carbon, iron or nickel are generally used. Mercury is employed in the Castner and Kellner process, and black oxide of copper in some others.

Carbonization of Filaments by Electric Heat.—There is nothing new in the idea of applying electric heat to the carbonization of incandescent lamp filaments, but for some reason this method seems to have been neglected. Mr. Legh Powell writes at some length in the (English) "Electrical Review" describing some experiments made by him to determine if this method was feasible. He used a brick trough, containing carbon blocks on which the filaments were wound, packed full of powdered carbon. At the bottom of the trough was a layer of plumbago powder sprinkled with paraffine, which by its volatilization displaced the air in the apparatus. The filaments obtained were in every way satisfactory, being of good color and flexibility and uniform resistance. The current required to heat a row of blocks about 10 ft. long started at 18 amps., was increased slowly to 25 amps., was 30 amps. ten hours after the start, 35 amps. in 12 hours and 65 amps. in seventeen hours. At this point current was turned off for six and one-half hours and then started again at 27 amps., increasing to 65 amps. in six hours, at which time it was finally shut off. The advantages which the author foresees for the electric method of cooking filaments are the more perfect control obtainable, which must result in a more uniform product, and the saving of labor in working the process. He thinks that the initial cost of the apparatus would be less for electric heating, while the compactness of the apparatus makes possible heating the filaments in vacuo or under other unusual conditions, and the uniform high temperatures that may be attained might result in filaments of a very hard and dense character.

Reduction of Silicon in the Electric Furnace.—Some time ago M. Moissan showed that silica is reduced by carbon at the high temperature of the electric furnace. In recent researches by M. Lebau for the preparation of glucina by the electric furnace, described in "L'Eclairage Electrique," it has been discovered that it is possible to prepare silicon on an industrial scale from rough emerald. A charge of 220 pounds of powdered emerald and 110 pounds of coke was heated for an hour by means of a current of 1500 amps. The inner layer of the furnace product showed a crystalline fracture and almost the color and appearance of crystallized silicon. Analysis showed that the mass contained about 64 per cent of silicon. Treating the mass with hydrofluoric acid and then with sulphuric acid left a residue consisting of silicon containing about 1 per cent of silicon carbide. Some samples showed as much as 80 per cent of crystals of silicon.

It is interesting to note in this connection that silicon has certain properties which are claimed to make it of great value as a high resistance material for use in electric heating apparatus of all sorts.

Cement for Leather Belting.—A cement recommended by the "Mechanical World" is made by kneading 10 parts of carbon bisulphide and 1 part of spirits of turpentine with gutta-percha until the result is a thick paste. The portions of the leather where the cement is to be applied are to be unrolled and roughened, and the joint kept under pressure until the cement is dry. Good rubber cements for rubber goods or rubber on metal are obtainable by dissolving shellac in ten times its weight of ammonia water. After standing three or four weeks a transparent putty remains which is used cold. The cemented places soften at first, but harden after the evaporation of the ammonia, which may be hastened by heating. This cement is water-tight and gas-proof, and is efficient for hard rubber articles, a mixture of gutta-percha and asphalt also being serviceable for this class of work.

A New Standard of Light.—As the introduction into practical use of various high temperature sources of illumination increases, the difficulty attending the use of the older standards for photometric work also increases, as nearly all of these are of a reddish color. Various ingenious methods have been devised for overcoming the difficulty due to the difference in color between the standard and the light measured. The best method, however, is the use of a standard whose temperature and hence its color approaches that of the light to be measured. Outside of these considerations the conditions necessary for a standard of light are simplicity and definiteness of structure, permitting its easy and accurate reproduction, and some arrangement permitting the accurate measurement of the combustible burned. To meet these conditions M. Ch. Féry has lately suggested in a paper presented to the Académie des Sciences the use of acetylene burning in free air at the end of a thermometer tube cut off square. The inner diameter of the tube used in his experiments was about 1-50 in., and he states that differences of pressure of as much as 10 per cent make very little difference in the intensity of the light. The burner should not be forced to a greater consumption than about ¼ cu. ft. of the gas per hour. Under so small a consumption the difficulty of accurately measuring the amount of acetylene burned would be considerable, but it is an easy matter to accurately measure the height of the flame, a simple linear relation existing between this and the luminous intensity. M. Féry uses a camera giving an image of the flame in actual size on a strip of ground glass ruled in millimeters for this measurement. Between heights of 10 and 25 millimeters the proportion between the height of the flame and its illuminating power is almost exactly constant. Determinations of the exact value of the standard have not yet been made, but it is suggested that a use for it outside of its importance as a photometric standard is that it furnishes a ready means of comparing various kinds of carbides for the richness and illuminating power of the gases they generate.

Discriminating Cut-Out for Alternators.—When a number of alternators are working in parallel supplying the same bus-bars it is desirable to connect in the circuit of each some apparatus that will cut it out if it is motored. The use of any magnetic device to accomplish this end seems difficult when it is considered that the direction of the current is reversing several thousand times a minute, but in the cut-out described by Mr. Leonard Andrews in the (English) "Electrical Engineer" this difficulty is very neatly overcome. The apparatus is diagrammatically shown in Fig. 1. D_1 is the dynamo in whose circuit it is connected. It consists practically of a shunt motor, the stationary part of which is energized by a few turns of heavy conductor carrying the whole current of the dynamo. The moving part, SH, is wound with a fine wire coil connected through a small transformer across the bus-bars, the tendency of rotation under normal conditions being such that the switch shown at the right of the illustration is locked fast. If the current through the dynamo D_1 reverses with reference to the currents in the other parts of the system, that is, if the machine is motored, the movable part of the motor turns in a counter-clockwise direction, releasing the weight attached to the switch and opening the latter. Fig. 2 shows the apparatus as applied on the switchboard of the station at Hastings. It is said to be very reliable, and not apt to cause trouble by opening at the wrong time.

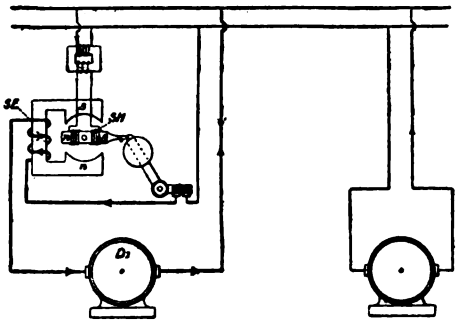


FIG. 1.—DISCRIMINATING CUT-OUT FOR ALTERNATORS.

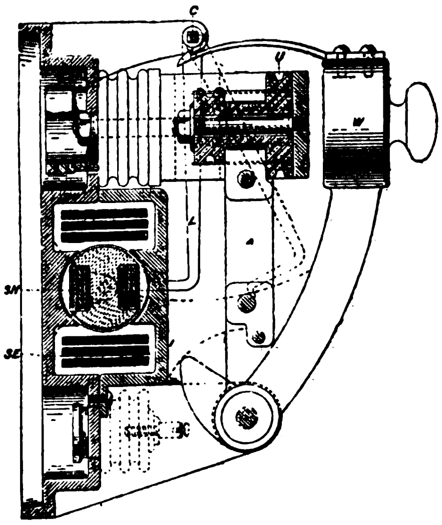

FIG. 2.—DISCRIMINATING CUT-OUT FOR ALTERNATORS.

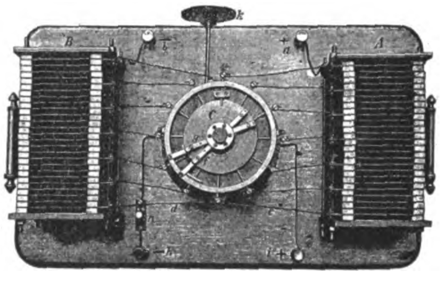
Ammonia-Chloride Accumulators.—Under this title Senor A. Sandaran contributes to "Revista de Obras Publicas" (Madrid) a very long and complete description and data of a remarkable accumulator of his invention. It consists of a solution of sal-ammoniac which is electrolyzed between two electrodes of carbon, a porous diaphragm separating the liquid into two portions. In the fluid surrounding the anode chlorine is liberated and, according to Senor Sandaran, under the action of diffused daylight and sometimes even in the dark, this nascent chlorine decomposes the water of the electrolyte, forming hydrochloric acid, which is immediately dissolved, and oxygen, which escapes. At the cathode ammonia is formed, the unstable radical ammonium, NH^4, being generated by the electrolysis and breaking up into ordinary ammonia, NH^3, and hydrogen, which escapes, the water dissolving the ammonia. On account of the great solubility of the two gases, hydrochloric acid and ammonia, the capacity of a given volume of water for storing them in the dissolved state is very high, and suggests great possibilities in the way of capacity per pound of cell. In the experimental cell, of which a description is given, the charge was at the rate of 0.25 amp., and in another experiment at 1 amp., corresponding respectively to 2.5 and 10 amps. per square foot of plates. The cell was an ordinary battery jar using an ordinary porous cup as the separating diaphragm and two carbon plates in the outer jar and one in the inner jar as electrodes. There was no difficulty about charging at the higher rate. The fluid around the positive electrode became rapidly yellow from the formation of chloric and hypochloric acids. Experiments were also made upon the same cell with the spaces surrounding the electrodes filled with granular carbon. With this its internal resistance was found to be 0.07 ohm and without it 1.25 ohms. In charging the e.m.f is stated to be 1.67 volts at one-twentieth charge, 2 volts at half-charge and 2.2 volts at full charge. In discharge the current is said to be very constant and there is no disengagement of gas. The author states that after twelve hours on open circuit the loss due to admixture of the fluids was small, and that after from 40 to 80 days it was not greater than that in accumulators of the ordinary lead type. A table of comparisons is given showing data of 4 types of lead accumulators in comparison with an ammonia chloride cell. From this the following figures are taken: Capacity of the ammonia cell, 1257 ampere hours; useful capacity, 2388 watt hours; efficiency (in watts), 0.85; weight of plates, 17.6 lbs.; weight of complete cell, 22 lbs.; useful watt hours per pound of cell, 59; weight of cell for a capacity of one h.p. hour, 13 lbs. (an error in the table gives the latter figure at 11 lbs.). If these data are correct it is evident that this cell is by long odds the most powerful for its weight yet produced, but there seems to be reasonable ground to doubt the correctness of such remarkable figures. The presence of the porous diaphragm means either high internal resistance, which is fatal to both efficiency and high discharge rate, or else quick osmose of the liquids and consequent loss of charge. But the principal difficulty with the theory of the cell is that the nascent chlorine will not form hydrochloric acid with the water of the electrolyte if the charge rate is carried to a high point. Still, as the chlorine itself may dissolve in the water and subsequently combine with the ammonia this seems not to be a fatal objection, except that it destroys the author's very elaborate theory of the action of the cell.

For use as balancing cells, where the charge and discharge rates are sometimes excessive and where the capacity for storage for any great length of time is of no account, Senor Sandaran recommends a gravity type, similar to a bluestone battery, having a carbon plate at the bottom and another near the top, the intervening space being filled nearly full of granular carbon. The acid solution being heavier than the other the positive electrode should be the lower one. It is greatly to be hoped that the data stated are correct, but it is to be confessed that they will require abundant confirmation before they meet with general acceptance.

A Laboratory Direct Current Transformer.—Professor Julius Thomsen has presented to the Kgl. Danske Videnskabernes Selskabs an account of an ingenious direct current transformer for laboratory use, whereby a direct current of 110 volts is transformed to one of 7.2 volts, the current strength being correspondingly increased. The figure shows the apparatus in plan. A and B are storage batteries, each containing twenty-four elements of very simple and ingenious construction. The plates are of thin sheet lead about 4 by 5 ins. in size, every fourth plate being provided with an ear for the attachment of a connector. The twenty-four-cell battery is made by laying up the sheets of lead in a frame, a U-shaped piece of soft rubber having a rectangular section ⅜ by ⅝ in. separating every pair of plates. The end plates are held between two iron plates ⅛ in. thick, which are clamped together by bolts as shown in the illustration. A solution of 1 part sulphuric acid and 4 parts of water is used, and the plates are "formed" by a current of about 1 amp. Each of the lead plates plays a double rôle, as one side of it is coated with peroxide by the forming process and the other side reduced to spongy lead, while the central part of the plate forms the connection between the two. As the illustration shows, each fourth plate is connected in regular order to one bar of a commutator, C. Upon this work two brushes carried by the arms f and g, these being in contact with copper rings connected to the posts h and i. The arms f and g are so set that the brushes are always 30 degs. apart, so that one group of four cells is always connected to the posts h and i. The 110-volt mains are connected to the posts a and b, and the commutator is turned at the rate of 15 to 20 r.p.m. by a screw gearing operated from the pulley k. The capacity of the machine is said to be about 16 amps. in the secondary at 7.2 volts, with 110 volts and 1.5 amperes in the primary. A balancing battery of three cells similar to those composing the groups A and B is connected across the terminals of the low-tension side of the machine to steady its output at the moment when the commutator brushes are changing from section to section.



A SIMPLE DIRECT-CURRENT TRANSFORMER.

Osmium and Thoria in Incandescent Lamps.—There has been so much speculation concerning the use of other substances than carbon in the manufacture of incandescent lamp filaments, and so much interest has been aroused by the latest invention of Dr. Auer von Welsbach that Mr. A. M. Gibson, writing in the (London) "Electrical Review," believes definite information on the subject will be welcomed by all interested in lighting. He describes at length the processes described in the Hungarian patent granted to Dr. Auer, which seems to cover the use of incandescing bodies of osmium and thoria.

Osmium is a metal of the platinum group, the heaviest and most refractory substance known. It is easily oxidized, the tetroxide, OsO_4 being a volatile substance and extremely poisonous. Thoria is largely employed in the manufacture of mantles for incandescent gas lights, and is the oxide of the somewhat rare metal thorium.

Osmium has never been melted. At very high temperatures it goes off in fumes, which burn in the air, forming the tetroxide. It is claimed that it does not volatilize in vacuo or when heated in gases free from oxygen. To obtain his osmium filaments Dr. Auer takes a platinum wire about .0008 inch diameter, which is made to glow in an atmosphere of water vapor and a hydrocarbon, small quantities of the osmium tetroxide being introduced from time to time. A deposit of metallic osmium forms on the wire, but this must be formed very slowly and apparently in a number of very thin layers. The difficulty of obtaining a perfectly smooth coating is very great. When the filament comes from the flashing apparatus it is quite fragile, since the coating contains some oxide. On this account the flashing is driven up to the point when the platinum wire volatilizes and the oxide is reduced, leaving a tube of metallic osmium having the appearance of platinum and quite elas- to draw the platinum wire through a solution of a sulphide or tetra-hydroxide of osmium and then flash it in a vacuum. This operation must be repeated at least 100 times to obtain the necessary thickness of the osmium layer. An electrolytic method is also mentioned, but vaguely. Vegetable or animal fibres can also be employed as the base of the osmium filament, and nitro-cellulose may be used very much in the usual way.

With thoria coatings the phenomena are very interesting. As the energy of the flashing current is increased a dazzling white spot of light appears on the filament and spreads more or less slowly along its length, a minute ball being seen at the same time to spring from the thread. This is due to the volatilization of the platinum core, leaving a tube of thoria which can stand still higher intensity of current. It is curious to note that at a current tension that fuses or destroys any other known substance very little heat is emitted by the brilliantly incandescing thoria filament. Continuing the increase of current strength a point is reached at which the tube bursts with a slight explosion. Its thickness needs be but some tenths of a millimeter. A mere film will answer, in which case the colors of the spectrum appear at one stage of the process. The process for making the thoria filament is hardly a commercial one. A thin platinum wire, of about the size of a cocoon fibre, is drawn through elastic cheeks which are moistened with a solution of a salt of thorium that willl "give an oxide when glowed." A nitrate or a selenate will do this. After each drawing the wire is flashed, and the drawing and flashing must be repeated at least fifty times. To reach perfection the solution used must be very dilute, and the drawing and flashing repeated several hundred times. A compound wire of platinum, osmium, ruthenium and rhodium or iridium is best for the base on account of its high fusing point. In practice the platinum core is not volatilized, the expriment described above simply illustrating the enormous heat resistance of pure thoria. Although not so stated in the specification, alternating current will evidently give the best results, direct currents electrolyzing the filament. No mention is made of an electrolytic way of making the thoria coating, though it is known that by this means a dense, firm coating may be made.

The processes described appear to be still in the laboratory stage of development, and the cost of lamps constructed with any of the filaments mentioned would be very great. The inventor has made no public statement of the efficiencies obtained, but it has been reported that results as low as 1.5 watts per candle have been shown.

PERMANENT MAGNETS.

As the result of a number of experiments Precee found that the mean intensity of magnetic flux in various kinds of magnet steel varies from 1.315 to 2.540 per sq. c.m., the latter figure applying to Marchal steel, the next in merit being Clemandot steel, which retained 2265 lines. As a comparison with electro-magnets, good wrought iron will carry 15,000 lines per sq. c.m.

Electricity as It is Sometimes Understood.

To the Editor of American Electrician:

Having read in a note in the June issue of the amusing electrical definitions given by students, I compiled the following statements and answers of the same character which I have come across in students' note books and examination papers:

A coulomb is the 1-1000 part of an ohm.

A short circuit is a wire of great resistance connecting the main terminals.

Hysteresis is the loss of magnetism when the wire has a static charge.

The internal resistance of a secondary cell is determined by the primary.

The internal resistance [of a cell] forces the current from the zinc to the carbon; while external resistance forces from the carbon to zinc over the outside wire.

All resistançe boxes are regarded in their working as Wheatstone bridges.

A farad is one-billionth of the earth's quadrant.

The difference between voltage and e.m.f. is that the voltage is the amount used and e.m.f. is the time it took to use it.

A magnet that has poles throughout its whole length is said to have consequent poles.

German silver is the best known conductor.

The best known conductor is the earth.

The present accepted theory of electricity is that it is a competition of ether stress.

Electrolysis is an instrument for decomposing liquids.

Electrolysis is the process of obtaining an unlimited number of sparks by the use of a pan filled with melted resin on a dish with an insulated handle.

Electrolysis is the condition of a battery, the elements being consumed so fast the chemicals have not had time to produce the amount called for.

Electrolysis is when the currents tend to act in unison.

Specific inductive capacity is the amount of electricity that will pass a point in one second.

Permeability is that quality of material that permits electricity to be conducted through or over it.

The amount of current a piece of metal of a given size will deliver under given conditions.

Permeability is the electricity that remains on a wire that has been charged and then recharged.

Eddy currents can be laminated.

Field magnets are not laminated "because the eddy currents tend to hold the lines of force straight."

Lamination of armature core is "to collect currents and avoid sparking."

Siemens' shuttle armature: "This armature would heat very easily on account of the lamination, of which they did not know anything about."

The following may be of interest to central station managers: "A compound dynamo is to keep the load uniform."

But the most trying to the teacher, who has carefully explained the principle of the dynamo, is to read in an examination paper that current is generated by the friction of the brushes on the commutator.

C. R. FONTAIN.

Washington, D. C.

Electrical Journals

To the Editor of American Electrician:

The list of electrical periodicals which have joined the great majority, prepared by Mr. Caldwell and appearing in your June issue, seems to be very nearly complete, but men now living should, if possible, contribute towards its perfection.

Among the omissions are a few whose titles and location I can give, but, unfortunately, few other details. "The Electrical Era," published in Philadelphia about 1885, was continued for several months; also, a few years later, "The Message," edited by Mr. Howell, in New York City. "Electricity" was barely started in Cincinnati about 1884. I never saw a copy of it, but it was the name which the late Franklin L. Pope had proposed to adopt for "The Electrician," of which he assumed editorial charge in 1884. Upon learning of the existence of "Electricity" he changed his plans, and his paper was called "The Electrician and Electrical Engineer."

I do not think Mr. Pope had any editorial connection with "The Esquimaux," as he and his party consisted of but four men when he went to Lake Tatla, built Bulkley House and explored the headquarters of the Sticken River in the spring of 1866. "Telegraphica," which is included in Mr. Caldwell's communication, was started by Walter P. Phillips, in New York City, and the literary ability which he displayed in its columns led to his engagement with the Associated Press and his subsequent career in the management of the United Press.

New York. RALPH W. POPE.

To the Editor of American Electrician:

In the list of defunct electrical publications, given by Mr. Edward Caldwell in the June number of the American Electrician, there should be enumerated one formerly published at Rochester, N. Y.—"The Station," monthly, of which only two numbers, January and February, 1896, were issued.

Yours respectfully,
D. L. DAVIS.

Salem, Ohio.

Action of Storage Batteries.

To the Editor of American Electrician:

In a note in the June number under the heading "Lead-Zinc Cadmium Accumulators," the following statement is made: "During charge a deposit of zinc and cadmium is thrown down on the negative plate and a certain quantity of hydrogen is disengaged, which is said to enter into combination with the deposited metals, or, more properly, to be absorbed by them."

I believe there is no doubt that with the ordinary lead plates both oxygen and hydrogen are dissolved by the plates during charge. This may be easily shown by warming the plates after charge, the result being a very large loss of potential. Or a lead plate may be charged by placing it in dilute sulphuric acid with zinc, after which it gives a strong deflection with a lead peroxide plate.

The hydrogen may also be removed by placing the plate in chlorine. In April, 1897, I read a paper on this subject before the National Science Section of the Ontario Educational Association, at Toronto, giving a list of experiments with results, proving, I believe, the preceding statements. SIDNEY SILCOX.

Collingwood, Ontario.

NOTES.

The General Electric Engineering Society.—A society has been formed at Schenectady under the name of the General Electric Engineering Society, with a membership comprising the engineers attached to the several technical departments of the General Electric Company.

The "Canadian Electrical News."—Our Canadian contemporary, the "Canadian Electrical News," issued apropos of the eighth annual convention of the Canadian Electrical Association, held in Montreal on June 29th and 30th instant, a specially interesting number for June, the contents of which serve to illustrate the rapid development of electricity in Canada. Besides illustrations and particulars of the electrical features of Montreal (including portraits of the local committee of the Electrical Association Convention), other articles worthy of mention are: "The Mooted Wireless Telegraphy," by D. H. Keely, superintendent Dominion Telegraph System; "The Cataract Power Company's Works," in course of construction (illustrated); description of C. P. R. copper wire telegraph line from Montreal to Vancouver, B. C., with portraits of officials and superintendents of construction; map showing long distance lines and offices of the Bell Telephone Company.

Soldering Acids and Fluxes.—In a paper read at the March meeting of the American Institute of Electrical Engineers, Prof. R. A. Fessenden said that the ordinary soldering acid, which is a solution of chloride of zinc, is harmful to cellulose fabrics, which it turns into a paste. It never evaporates, but always takes up moisture from the air, and will gradually eat its way through quite a thickness of insulation. Whether it is acid or neutral makes no difference, so far as its action on the insulation is concerned, though the neutral solution does not corrode the wire. Rosin has the disadvantage that it is not a fluid and it is clumsy to handle. Prof. Fessenden found that by shaking up powdered rosin in very strong ammonia, an ammonia soap is produced which works well in most cases; the ammonia dissolves the copper oxide and evaporates afterward, leaving the powered rosin, which is an insulator.

The Chicago Convention.

Perhaps the most distinguishing feature of the Chicago convention was its business-like character. The administration of President Insull produced not only an interest in the association and the convention itself, but resulted also in the preparation of one of the most excellent programmes of papers ever presented to that body. While there was no paper of an academic character, and none of deep technical interest, the importance of the topics chosen and the sensible and conservative manner of their discussion mark this convention as one in which the association realized fully the objects of its existence, and directly and indirectly benefited the industry it represents.

One of the papers, that of Mr. Dow on the question of municipal ownership, marks an era in the evolution of the attitude of the electric light man toward this all-important matter. Mr. Dow's argument may be summarized in brief as an exposition of the facts; that a municipality has the right to engage in public lighting if it pleases; that it has not the right to engage in private lighting; that a private corporation engaged in private lighting can, under proper and equitable conditions, furnish the municipality its public lights in addition at a less cost than the municipality itself can make them. From these premises the conclusion that public lighting is best done by a private company and that the establishment of a municipal plant is a fallacious enterprise are irresistible. But it is neither to the argument nor the conclusion that the greatest attention will be directed, but rather to the admission that a municipal corporation has the right to engage in the electric light business. Unfortunately for the ideas of those reformers who advocate municipal ownership in and out of season the admission will not seriously strengthen their cause, as the folly of municipal ownership is made as evident as its propriety. That the entire membership of the association will agree with Mr. Dow in the somewhat altruistic ideas he advanced as to the profit to be demanded by electric contractors is not, of course, to be expected, but there is much food for thought in his suggestions, and more in the fact that there seems to be a tendency to establish the basis for dealings between electric light companies and municipalities on equitable grounds. In Mr. Insull's presidential address much the same variety of ideas were prominent, and it is much to be hoped that these are indications of the trend of opinion in the electric lighting fraternity at large.

The time-honored question of the proper variety of current, direct or alternating, for central station supply, brought forth two excellent papers, the advocate of the alternating current, Mr. Wagner, having naturally rather the better argument. The fundamental idea in this paper was that the system of direct-current supply so carefully and intelligently worked out in the past few years, is equally available for the supply of alternating current, while there is no superiority of the direct over the alternating current in any particular save that of age and establishment. The flexibility of the single-phase system of supply, especially when adapted to the feeder and main method of distribution, and the high station efficiency that can be attained by this method, were strikingly brought out.

In Mr. Ferguson's paper the data of the supply system of a great electric lighting company, while rather staggering as to magnitude of figures, were very interesting. Perhaps the main feature of his paper is the elaborate discussion of the storage battery as a factor in distribution and station economy. A fact that has escaped general notice was pointed out by Mr. Ferguson when he stated that accumulators are valuable in systems whose load curve has an average peak of not more than two hours in width. The battery is rated by the h.p. or k.w. hour, and its cost increases in direct proportion with the time that it is to carry the peak load, while the steam engine and dynamo are rated by their output capacity, and cost no more if they are to work continuously than if they are to operate only at the moments of heaviest load on the station. Consequently, if the battery is to carry the full peak for seven or eight hours a day, its cost will be enormously in excess of steam machinery for the same purpose. This, however, does not state the whole case, nor can this fact well be used as an argument against the accumulator, since the greater cost of the latter may well be compensated by the economy introduced through its action in keeping the generating units fully loaded and working at their maximum economy.

In the discussion of Mr. Rice's paper the fact that the system of charging for current based upon the maximum demand of the customer, in its relation to the output of the station, has become the standard, was apparent. Only a year ago the association discussed this method of apportioning charges, and the idea seems to have made gratifying progress, if not in execution, at least in the manner of its reception. It is becoming evident, to quote President Insull, that central station managers should sell electric current to "the greatest number of consumers at the lowest possible price," and notwithstanding make a profit.

The further extension of electric lighting is largely a matter of the price that the consumer has to pay, and it is only through some system of really equitable charge that the burden of cost is reduced for the profitable long-hour customer and the use of the light popularized.

The report of the committee on standard candle-power of incandescent lamps contained the discouraging information that the 16-c.p. lamp of commerce is not a 16-c.p. lamp, after all. It is to be hoped that when the recommendations of the committee are carried into effect this state of things will be less prevalent. Strangely enough, not a word was said at the convention about high-voltage lamps, but this is hardly to be taken as an indication that that subject has lost its perennial interest.

The Northwestern Electrical Association.

The excursion of the Northwestern Electrical Association on the steamer "Northwest" will be memorable from its social features, and the close association of the delegates was conducive to exchanges of information and comparison of experiences that could not fail to be of value. The papers can scarcely be said to measure up to the usual standard of the association, and the same is true of the discussions. Exception should be made of the paper by Mr. W. B. Snow on "Forced Draft," which presented in an able manner a subject which is of growing importance to central station men. Elsewhere in this number will be found abstracts of all the papers read before the convention.

Carbon Filament Resistance.

At the meeting of the Northwestern Electrical Association the information was brought out that incandescent lamps are in successful commercial use replacing the resistances employed with constant potential arc lamps, the light from the filament being utilized in hallways and elsewhere where its necessarily variable character will not be objectionable. Where the circuit is of 125 volts and inclosed arcs are used, 50-volt 16-c.p. low-efficiency lamps should be suitable for this purpose, six being used in parallel for a 6 amp. arc. In this case the lamps would glow normally at nearly full candle power, and thus give almost 100 c.p. of light, which otherwise would merely be wasted as heat in the usual metallic resistance. This is but another instance of the value of the carbon filament for use as a resistance, but it is in connection with alternating currents that its superiority stands out in strongest relief. Owing to its high specific resistance for a given amount of energy dissipated the lines of force inclosed by the loop of an incandescent lamp are relatively extremely small in number, so that as an alternating current flowing in the filament rises and falls in value, the inductive e.m.f. due to the cuttings is negligible in any practical case. In other words, an incandescent lamp filament is practically a non-conductor resistance, which is a precious advantage in some cases.

Powering Small Craft.

The article elsewhere in this issue on the determination of the power and the diameter and pitch of screw for the propulsion of small boats, is one of the most complete presentations of the subject yet written. An important point brought out is that a definite relation exists between the speed and diameter of a screw, and that a high slip may correspond to a maximum efficiency. That is to say, as the revolutions become higher the diameter should be decreased, though this latter operation increases the slip. These facts have long been known to marine engineers, but from the stress often laid on small slip it is well to call attention to what is sometimes considered an anomaly. Another point referred to is that in ordinary cases a four-bladed screw is suitable, but should it be desirable to use one of two or three blades this will be indicated by the results of the calculations made to determine the screw data. It may thus happen that with an electric motor of high speed a three-bladed propeller will be the more efficient, but the determination of this point can be made on an intelligent basis instead of being left to mere surmise.

Owing to the very considerable weight of storage battery required for power, electrically propelled boats are limited as to speed, and should be carefully designed with respect to lines so as to reduce to a minimum the power required for a given speed. As to size, the weight of battery increases at a less rate than the displacement; for example, if the displacement is doubled the power to propel the larger boat at the same speed is only increased about 1.6 times. On the other hand, the elements of first cost and depreciation tend to keep down the size. The question of speed is the serious matter, since the watt-hours of electrical energy required to go over a given distance, and consequently the weight of battery at same rate of discharge, increases as the square of the speed. That is, to travel over 25 miles in two and one-half hours will require four times the watt-hours necessary to cover the same distance in five hours, or at half the speed. The amateur who wishes to possess an electric boat will usually find that a small craft, accommodating not more than three or four persons, and having a speed of not over 5 miles per hour, will be sufficiently expensive to satisfy his desire.

Seeing by Electricity.

For several months past the daily press has been printing paragraphs from time to time concerning a wonderful invention by a Bohemian schoolmaster laboring under the name of Szczpanik, by means of which, it is claimed, a picture can be transmitted by means of electricity. Judging from the accounts thus far printed, the inventor can be welcomed as a new accession to the ranks of the wizards, for after describing in most glowing terms the possibilities of his invention, he confines the explanation to a few generalities, with the statement that full publication is reserved for 1900, when the apparatus will be exhibited at the Paris Exhibition. As described, the light from the object whose image is to be transmitted is thrown on a selenium screen which gives rise to electric currents that reproduce at the receiving end an image duplicating the one at the sending end. The explanation which the inventor gives is principally confined to a description of an arrangement of reflectors whereby the light as it appears on the screen is broken up into squares, and which causes the image to appear and disappear fifty or more times per second. No reason is given why the image should thus be treated, but the description of the action of the reflectors is highly scientific in phraseology and undoubtedly satisfactorily impresses the lay reader. As to the further steps—how the electric currents are generated by the spots of light, how their quantity is proportioned to the intensity of the light, and how at the receiving end the currents produce the effect of light—this information is reserved for 1900, with the exception that selenium is mentioned as one of the agents used in the process. The fact that the resistance of selenium changes with the intensity of the light to which it is subjected has long been known, and many attempts have been made to utilize this property in the transmission of light effects. The Bohemian schoolmaster has probably worked up his story from this basis, adding wizard effects to dazzle the understanding of the lay reader and render the tale enticing to the wonder loving.

DESIGN, CONSTRUCTION AND TEST OF A 2 1-2 K.W. THREE-PHASE, TWO-PHASE TRANSFORMER.

BY PROF. A. F. MCKISSICK.

A very interesting and instructive article by Prof. Henry S. Carhart on the "Design, Construction and Test of a 1250-watt Transformer" appeared in a weekly electrical journal some months ago. The work having been done by two of Prof. Carhart's students under his direction, with the idea of determining how far theory dictated correct practice, it was with this same idea in view that two of my students, Mr. T. G. Conner and Mr. B. S. Patrick, undertook, under my direction, the design, construction and test of a three-phase, two-phase transformer and the results obtained are due to them.

The method of design was taken from Bedell's "Principles of the Transformer," and is due to Prof. Harris J. Ryan of Cornell University.

In a paper read by Mr. Charles F. Scott in 1894 before the National Electric Lighting Association there was described a method of transforming currents of one phase into currents of a different phase, as follows: "If two e.m.fs. differing in phase 90 deg. be connected in series, the resultant e.m.f. is represented in direction and magnitude by the hypothenuse of a right-angle triangle, of which the two sides are the two component e.m.fs. Thus in Fig. 1, if AO and OB are two e.m.fs. at right angles, and these e.m.fs. be connected in series, the resultant is the line AB, of different phase from either of the components. It is a simple matter to so proportion the components that OB is equal to one-half of AB, as shown in the diagram. In a similar manner it is readily seen that the same e.m.f., OA, may be combined with OC, which differs from it by 90 deg. (but is equal and opposite to OB) in such a way as to give AC equal to AB, but differing in direction. BO and OC added together give BC. The e.m.f., BC, may, therefore, be combined with the e.m.f., AO, at right angles to it, in such a way as to give additional e.m.fs., which in connection with BC give three equal e.m.fs. 120 deg. apart.

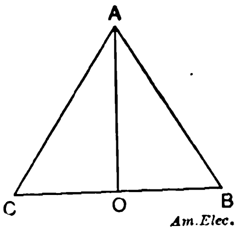

FIG. 1.—E. M. FS. OF PHASING TRANSFORMER.

This is the relation of e.m.fs. in the three-phase system.

"The application of this arrangement to transformers is illustrated in the accompanying Figs. 2 and 3. The primaries of two transformers are connected to a generator giving two-phase current. The secondary e.m.fs., therefore, differ 90 deg. One secondary is made equal to 100 turns, and a loop is brought out at its middle point, giving 50 turns at each side. The second secondary has 87 turns, which is approximately equal to 50 multiplied by the square root of 3. One end of the secondary circuit is connected with the middle point of the secondary of the first transformer, as shown, and the three free terminals will then deliver e.m.fs. differing in phase 120 deg. If the e.m.f. on each primary be 1000 volts, and on one secondary 100 volts, and on the other 87 volts, then the e.m.f. measured between any two secondary terminals will be 100 volts."

Design.—Three-phase current, 220 volts, 133 cycles, to be transformed to two-phase current, 500 volts. Transformer to be 2.5-k.w. capacity, Ferranti type.

The apparatus may be said to consist of two single-phase transformers of equal output practically (1.25 k.w.). The transformer connected to two three-phase mains (BC in Fig. 2) is known as transformer "A," the other as "B."

Transformer "A."--To find the maximum magnetic density (B max.) used in Prof. Ryan's formula, B max. $= 3050 - \dfrac{P_2}{20} = 2990$ where P_2 is output of secondary.

$$\text{Primary turns } (S_1) = \frac{E_1 \times 10^4}{\sqrt{1.11 \times n \times P^2 \times B\ \text{max.}}};$$

n = 133 cycles; therefore, $S_1 = 93.6$.

93.6 is, theoretically, the proper number of turns to use, but this would give a fractional number of turns on the secondary, as the ratio of transformation is 11 : 25. For this reason 88 turns were used on the primary, and consequently 200 turns on secondary, since $S_2 = \dfrac{S_1 \times E_2}{E_1} = 200$.

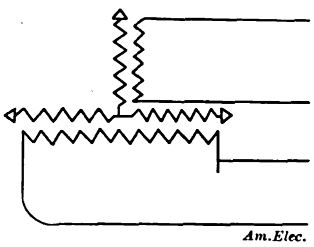

FIG. 2.—TRANSFORMER "A."

To find the cross section of the magnetic circuit in square c.m.s. (A), use the formula:

$$A = \frac{E_1 \times 10^8}{4.45 \times n \times S_1 \times B\ \text{max.}} = 141.3 \text{ sq. c.ms.} = 21.9 \text{ sq. ins.}$$

Assuming 90 per cent of the core is solid iron, we have for total cross-section of core $21.9 \div .9 = 24.3$ sq. ins.

Design of Coils.—Secondary current $= \dfrac{P_2}{E_2} = 2.5$ amps.; primary current $= \dfrac{S_2 \times I_2}{S_1} = 5.7$ amps. Allowing 1200 cir. mils per ampere, then cross-section of secondary $= 2.5 \times 1200 = 3000$ cir. mils, equivalent to No. 15 B. & S. wire. Making the same allowance in primary, its cross-section $= 5.7 \times 1200 = 6480$ cir. mils, or No. 12 B. & S. wire. Diameter No. 15 B. & S. wire (insulated) = .08 in. Secondary copper space $= 200(.08)^2 = 1.28$ sq. ins. Diameter No. 12 B. & S. wire (insulated) = .104 in. Primary copper space $= 88(.104)^2 = .95$ sq. in. Total copper space $= 1.02 \times 1.28 = 2.23$ sq. ins.

A bobbin of micanite 3¾ ins. long, cross-section 4⅜ ins. by 5 ins., was used for winding the primary and secondary coils on. Width of winding space, 3.5 ins.

Number of wires per layer in secondary coil $= \dfrac{3.5}{.08} = 44$. Number of layers $= \dfrac{200}{44} = 4$, with 24 turns on a fifth layer. Number of wires per layer in primary coil $= \dfrac{35}{.104} = 33$. Number of layers $= \dfrac{88}{33} = 2$, with 22 turns on third layer. Primary coil wound on top of secondary.

Losses.—Volume of iron core = 373.35 cu. ins. = 6122 cc. Assuming that a hysteretic coefficient .0024, hysteresis loss $= \dfrac{6122 \times 133 \times .0024 \times 2990^{1.6}}{10^7} = 71$ watts. To calculate the copper losses of secondary coils, we have: Length of inner turn = 19.75 ins.; length of outer turn = 22.95 ins., or an average length of 21.3 ins. Total length of secondary winding, 355 ft.; resistance, 1.14 ohms. Therefore, heat loss $= (2.5)^2 \times 1.14 = 7.12$ watts.

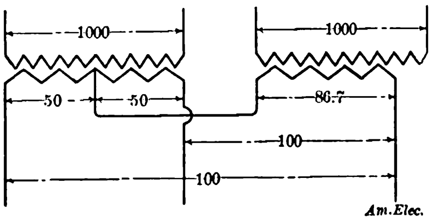

FIG. 3.—TRANSFORMER "B."

The average length of one turn of the primary winding = 24.25 ins.; total length of primary winding = 178 ft.; resistance, = .28 ohms. Heat loss $= (5.7)^2 \times .28 = 9.09$ watts. Losses at full load $= 71 + 7.12 + 9.09 = 87.2$ watts. Efficiency $= \dfrac{1250 - 87.2}{1250} = 93$ per cent.

Design of Transformer "B."—As the secondary of transformer "B" has the same number of turns as the secondary of transformer "A," and as the same e.m.f. is generated in each secondary, we will assume that the magnetic density is the same in each. Therefore they should each have the same cross-section of iron. The bobbins for the coils then should be of the same size and the coils are the same except in number of turns. The secondary of this transformer (B) should have 200 turns, and the primary $\dfrac{88\sqrt{3}}{2}$, or 76 turns.

The two transformers were so similar that only a slight error was made in assuming that the losses in them are the same.

Construction.—The Ferranti type was decided upon because of the ease of construction. Two micanite bobbins were fitted with wooden blocks so that they could be placed in a lathe and wire wound upon them. After the wire was wound, the wooden cores were removed and the iron put in place.

Material Used in Transformers.—Five hundred tweny-four plates of sheet iron were used, 5 ins. wide, .015 in. thick, and varying from 16 to 32 ins. long; two bobbins, cross-section 4⅜ ins. by 5 ins., length, 3.5 ins.; 710 ft. No. 15 B. & S. wire for secondaries; 356 ft. No. 12 B. & S. wire for primaries. The iron used in these transformers was purchased from a dealer and was supposed to be good transformer iron, but subsequent tests proved it to be inferior iron.

Tests.—Two methods were used for measuring the efficiency of the transformer; one, by measuring the input and output, the secondaries being loaded with incandescent lamps, and the other by measuring the iron losses and copper losses for varying loads.

The iron loss was found by measurement to be 241 watts, which differs greatly from the calculated value of 142 watts. This explains the rather low efficiency obtained and also shows that the hysteretic coefficient was .0042, instead of .0024, as assumed.

The copper loss was found by measurement 35 watts at full load, which comes near the calculated value, 32 watts.

The drop in voltage from no load to full load amounted to 4.6 per cent.

Results of Efficiency Tests.— The curves give the values of real and apparent efficiencies for varying loads. In the real efficiency curves the small circles mark the points obtained from the results of the first method, the crosses the results of the second method.

◆

DYNAMO TESTING.

CONVERTED LOAD RESISTANCE.

In previous articles a number of methods of dynamo testing were given, with which an adjustable resistance was necessary. Water resistances will frequently answer every purpose where accuracy and constancy are not essential, but they are a make-shift, and where much testing is to be done, as in the testing rooms of factories, it is best to have a large wire resistance, divided into sections which can be thrown in series or multiple, according to the character of service to be performed. To meet this demand, the writer has found the arrangement described in the following paragraphs very convenient:

Postponing for the moment the actual construction of the resistance itself, the connections will be considered. The resistance is arranged in series, and leads are brought out at equal intervals, as shown in Fig. 1. The wire to be used is preferably a low grade steel wire about No. 14 B. & S. This has a higher resistance than iron wire, and will comfortably carry ten amperes. When a greater load is to be carried, it is met by multiple connection of the sections, as will be shown later.

The leads passing out from the resistance are connected to the middle blocks of double pole, single throw ten ampere switches, of the type shown in Fig. 2. These switches need only be of the roughest kind, as almost any knife switch will carry ten amperes. Indeed, it is not a question of amperes, but of volts, the arcs that are formed at the switches when manipulated being the principal thing to contend with. By proper management these can be almost entirely avoided.

The single-pole switches are arranged to have their jaws connected to common bus-bars, as shown in Fig. 3. A resistance thus arranged may be connected in anv way desired.

For loading arc machines, a high pressure is necessary, and the switches would be thrown as in Fig. 4. If the resistance of each section were about 11 ohms—a convenient value on account of other considerations—each section would add about the equivalent of two arc lamps to the load. In using the rheostat for arc loads, the load may be easily increased or diminished without breaking circuit, by taking care to throw the switch which is to connect for the new load before opening the other. Indeed, it is not necessary to do even this, as all of the switches may be thrown on to the upper bus, with the exception of one at the end, which is thrown on to the lower bar. The load may then be varied by opening the switches on the upper bar, beginning with that next the switch thrown on the lower bar. Care should be taken not to throw the last switch, thus breaking circuit, for a serious arc would result.

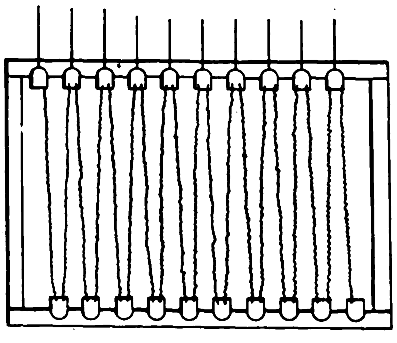

FIG. 1.—FORM OF RESISTANCE.

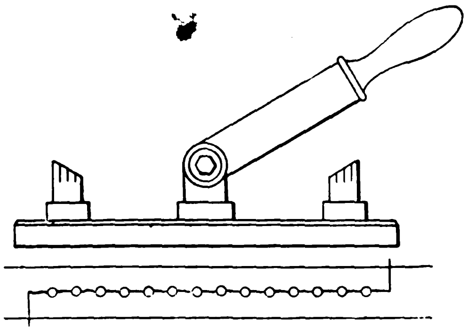

FIG. 2.—TYPE OF SWITCH.

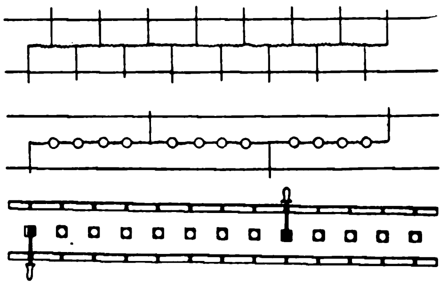
For testing incandescent machines, the switches should be arranged as shown in Fig. 5. Alternate switches are thrown on to the same bar. The sections are thus in multiple with each other. Being of 11 ohms resistance each, the current in them cannot largely exceed ten amperes when subjected to incandescent lighting voltages. For 220-volt testing, every other switch should be thrown alternately on to the bars, thus connecting two sections in series across them; and for 500-volt work, every fifth switch should be thrown, as shown in Fig. 6. In all of these cases, with the exception of the arc machine method, every switch thrown adds an increment of ten amperes to the load. If the single-pole switches are deemed too expensive, the wires coming from the rheostat resistance may terminate with a flexible lead and plug. The two copper bus bars may then simply carry taper holes which fit the plugs. The flexible lead is of sufficient length to allow each plug to be inserted in either bus at will, and it is easy to see that this arrangement will completely replace the switch system described.



FIGS. 3, 4, 5 AND 6.—METHODS OF USING RESISTANCE.

It will be found best to have the leads emerge from symmetrically spaced holes between the bus bars to avoid confusion. Dummy holes should be provided to contain the plugs when not in use, for if they are allowed to swing, a slight disturbance might provoke a brilliant, and perhaps serious, pyrotechnic display, both at the switchboard and at the machines to be tested.

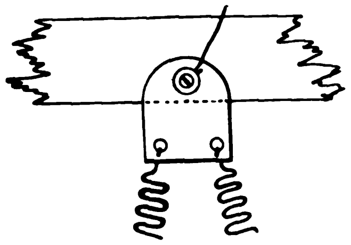


FIG. 7.—DETAIL OF RESISTANCE FRAME.

The construction of the resistance itself is worth a few remarks. A convenient method is to string it on rectangular frames, as shown in Fig. 1. Brass pieces are screwed to the frame at proper intervals, and to them the connections are made, as shown in Fig. 7. The wire is preferably coiled in long spirals, which have sufficient tension to hold the simple hook contact sufficiently tight for the purpose, and this method admits of the ready renewal of the spirals. Six feet is a convenient width for the frames, which may be conveniently hung from the ceiling of the testing room. They should be thus hung in pairs, allowing sufficient space between the pairs to remove a coil if necessary.

For testing alternators, the load which such a resistance would impose, would be too inductive, and it will be found better to use lamps. These may be arranged in parallel banks of ten, as shown in Fig. 8. The leads, L L, pass to a switching system such as has just been described. There should be at least eleven leads and eleven switches.

If the system is well insulated, it may then be thrown on the mains of a 1100-volt machine by simply using the two end switches, but unless some of the lamps are unscrewed from their sockets, this will throw one hundred lamps across the alternator terminals. It is not enough to unscrew the lamps at random; an entire row of ten must be unscrewed if it is desired to reduce the load and this is a disadvantage. It is, however, more common to use a transformer giving 110 volts, and in such a case the switches are thrown alternately on to either bar, each switch controlling a bank of ten lamps. Even when using a transformer, the load will be non-conductive, provided the transformer is fully loaded.

In large testing rooms it is customary to have numerous pedestals on which to test the machines as they come in from the assembling department. They are suitably arranged for convenience in making belted connections to the counter shafts or to calibrated motors, and means are provided to secure the machines firmly to them. It is too frequently the case that a table or box is placed near the machine, and the instruments are arranged upon it, or perhaps on the floor near by. This slipshod arrangement can be replaced by the following convenient and practical device:

From each pedestal should come six wires. Two of these are the output wires, two for a shunt ammeter circuit, when there is one, and two more for a voltmeter circuit. A slate table is provided carrying six sockets for each machine. These sockets are adapted for plug connections. Four of them interrupt the main machine circuit, which can then be completed by a jumper on one side and ammeter connections on the other. The other two sockets form the terminals of the shunt wires coming from the machine, and are usually bridged by an ammeter. The voltmeter wires pass to two insulated binding posts, preferably just under the edge of the table. The load circuit passes on from the testing table to sockets, where it can be conveniently connected to the rheostat by plug connections. The rheostat should be conveniently near the table so that it may be manipulated in accordance with the indications of the instruments.

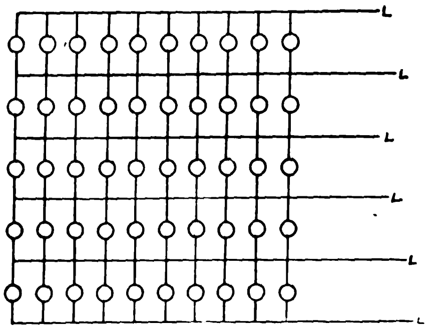

FIG. 8—LAMP RESISTANCE.

Fig. 9, which shows a plan and perspective of this arrangement, will materially assist in making the scheme plain. By this means the electrical manipulation is entirely separate from the mechanical handling of the dynamo, which is a great advantage. Very frequently accidents have happened, such as the coming off of a heavy belt under a sudden load, which have swept a whole table of expensive instruments to destruction. In factory testing the machine is usually given a very hard trial, and those in immediate attendance upon it must give it their entire attention, and those who are recording and reading the instruments must not have their attention distracted. The arrangement described permits these conditions to be realized in a very high degree.

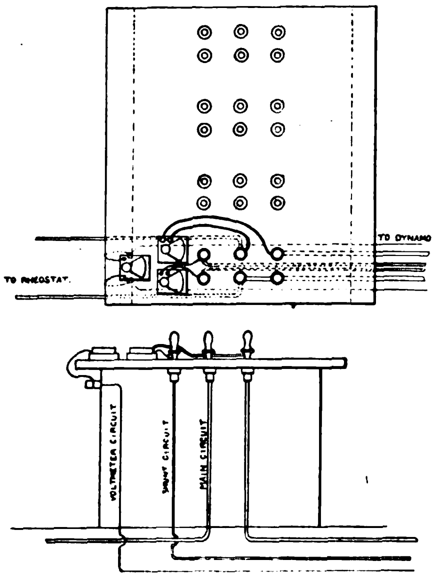

FIG. 9.—TESTING ARRANGEMENT.

◆

CHANGES IN ELECTRIC WIRING.

BY HARRY N. GARDNER.

If one stops to think of the development of electrical industries during the last decade, what a host of changes in the methods of doing work in all departments of the business at once come to mind. One branch of the work in which there have probably been as many changes made as in any other is the system of interior electric wiring for light and power; although perhaps many engineers would not consider the developments that have come to this department worthy of being numbered with the great advancements of the science. A competent wireman, however, cannot repress a smile when he thinks of the manner in which certain work was done but a few years ago; while an examination of that work is sufficient to crowd the dreams of an insurance inspector with nightmares.

It seems almost like the barbaric age of the industry to think of running electric light wires unprotected through the plaster and over the iron or steel frames of large buildings as was done but a few years ago, and "undertakers" wire at that; and yet I believe that such a modern building as the large Auditorium in Chicago has the wiring done in this manner. But before such work is criticised too severely, it must be remembered that many business blocks in all of the large cities were thus wired, and that the service is in many cases still in use, and that little trouble has been experienced from what now seems almost like suicidal methods. No one at all informed upon the subject can help wondering that there has been so few fires caused from imperfect electric wiring; although it is well known that many conflagrations are unjustly attributed to this cause.

It is largely owing to the requirements of the insurance companies, who realized the dangerous possibilities of the new method of lighting and power service, that many of the improvements have been made in the method of interior wiring. While these dangerous possibilities exist, it must be claimed for electric lighting that when wiring is properly done, it offers the safest system of lighting yet devised by man. This assertion is made, notwithstanding the complaints of insurance inspectors, who sometimes, while pointing out defects in wiring to property owners not informed upon the subject, do so in such a manner that the idea is at once conceived that the "juice" is the most dangerous thing that a man can have around his premises.

When it became apparent that the method of running wires, even though they were insulated, unprotected and in contact with timbers and walls, was an improper one, it was found that they could be removed from timbers by the use of porcelain insulators. This was an excellent method as far as it went; but it was still found that it did not help matters in large business blocks where no timbers were used. When some one thought of an insulated interior conduit, he was hailed as the genius of the industry, and there were many instantly ready to credit his product with being the ne plus ultra of the art. There were many things that could be said in favor of the brass armored conduit that jumped at once into favor; although within half a decade its defects became so apparent that some of the very inspectors who a few years ago were demanding its installation in almost all cases are now forbidding its use in any form.

Because inspectors said that "brass armor" was a good thing in some cases, there were plenty of wiremen, who did little thinking for themselves, ready to consider it the essential that "filled the bill" in every particular. Two and a half years ago an isolated plant was being installed in a large brewery. The wireman in charge of the work was one of the above class of workmen. An open system of wiring was followed, and on the whole the work was well done; but whenever any contingency arose that presented difficulty, "brass armor" was always the only remedy to be applied. If an iron pipe had to be crossed, a piece of "brass armor" was slipped over the wire and the difficulty was solved. In one case it was necessary to pass through a two-foot wall of the cold storage, where the wooden sheathing on either side was lined with sawdust which was decidedly moist. No porcelain tubes of the right length were at hand and of course a piece of "brass armor" was cut off and used, notwithstanding the fact that any one who has observed knows that this conduit is not impervious to moisture. The utmost care was taken in all cases to keep the wires removed at least an inch from all wood: but in one case where this conduit was used to protect the wire at a grounded pipe the conduit was broken as it was bent over the pipe, so that the insulated wire necessarily came in contact with the grounded pipe. The inspector who passed upon this work said that it was the best piece of work he had ever seen.

An inspector of another district in another State, who always makes arbitrary rules of his own no matter what the regulations adopted by the underwriters' board may say, would not permit circular loom tubing to be used two and a half years ago, but favored brass armored conduit for almost every purpose. Now the brass armor will not go, but circular loom tubing is all right. Not long since workmen were observed running a row of side lights down a brick wall for a show window. Circular loom tubing was being used, but instead of bringing the tubing out at the outlets, short pieces of wire were tapped on to the circuit at these points, pieces of the tubing were slipped over the wires between the outlets, where the soldered joints were merely taped, and short pieces of tubing were slipped over the short projecting "taps," and the whole left to be plastered over in this manner. A certificate for this work was signed by this inspector, who thirty months before was so in favor of brass armored conduit, and would not permit the use of circular loom tubing, and who then declared: "There is only one right way in which work should be done, and that is the manner in which I want it done."

After the brass armored conduit came the iron armored; and that likewise soon found advocates who were in favor of its use for all kinds of work. Of this system of wiring it can be said that in those places where wires must be run along untimbered walls and ceilings, it is probably the nearest to perfection of any system yet devised, when it is properly installed.

As to the question which has recently caused so much controversy in electrical papers, the relative merits of insulated or plain iron piping for wire conductors, it seems strange that any thinking persons, experienced in the business, should for a moment favor the use of plain gaspipe for this purpose. A few reasons for this opinion are because no pipe as made is perfectly smooth on the inside, and in drawing wires into an uninsulated pipe the rough places are liable to abrade the wires, and a short circuit or grounded wire will result. Again, good engineering practice demands that for all classes of work the factor of safety shall be kept as great as possible, and who will say that this factor is not greater by the use of the lined pipe? It may be said that such a pipe will answer all requirements in 999 cases out of a thousand, but it is that thousandth case that the good engineer is always looking out for. Any observer knows the liability of the insulation of wire to crack with time, especially if kept in a dry place; and if such cracking results in an uninsulated pipe, the liability to cause trouble is increased just that much. It may be said that even if trouble does occur when the wires are incased in an iron pipe, that there can no serious results follow; because if there is any heating the wire is so inclosed in noncombustible material that it can set nothing afire. Suppose, however, that it happens that the wires have come in contact with the iron piping so that a short circuit is formed, the pipe acting as part of the circuit. It frequently happens in the way that joints in the pipe are made, assisted by later oxidation, that some part of the pipe itself offers greater resistance than does the wire, and if any heating results it is outside instead of inside of the pipe.

Even with the use of insulated iron conduit, greater care should frequently be taken in the manner in which it is installed. In many cases the ends of the pipe are not reamed with a "butt" reamer, as should always be done. In cutting off the end of a pipe in the ordinary way there are almost sure to be burrs or fins left, often in such a manner that they project through the insulation and leave a sharp point to cut the wire insulation when it is drawn in. Again, when lead is used for making the joints, it is frequently applied to the ends of the pipe before it is entered in the sleeve, or else it is daubed into the sleeve itself and the ends of the pipe screwed in. Either one of these methods is almost sure to result in the lead being squeezed in through the insulation, so that a metallic contact is made between the pipe and the wire insulation, which partly nullifies the good accomplished by the insulation. The end of the pipe should always be entered for a thread or two into the sleeve, and the lead then carefully applied.

There are many advocates of the iron armored conduit that now hold, as did the advocates of the brass armor a few years ago, that all wiring shoud be done in this manner. Where wiring is to be done for a fireproof building, or one where there are no timbers or where wires are run along brick walls, all good engineers will admit that the system is the best; but for residences or business blocks where wooden floor joists or studding are used, it is doubtful if there has yet been a method of wiring suggested that offers the real safety that does simple porcelain knob and tube work.

Of course, it must be admitted that such work to be safe must be properly installed; but the same can be said about iron armored or any other kind of work. Careless workmen are just as liable to put in iron pipe in an improper manner as they are to screw up knobs or make a tie as it should not be done. One case in mind is work done by a large contracting firm, which tried to convince its customers that all wires should be inclosed in conduit, and who did iron conduit work by running separate pipes for each wire, and that where an alternating current would have to be used.

One objection sometimes made to running wires unprotected between floors on porcelain is that mice will eat off the insulation. Even suppose that does happen, is there as much danger from this as there is when the wires inclosed in an iron pipe come in contact with the pipe? And is there any real danger if the wires are thus exposed? If it is possible for the mice to get at the wire it is proof that it is surrounded by no better conductor than air. Probably the most serious criticism that can be made against porcelain knob and tube work is that there is danger of a wire being weakened in tying, so that, while it is not broken entirely off, its resistance is so increased that if there should be heating in any part of the wire it would come at that point. Even should that happen, it is sure to be at a point where the wire is well supported upon one of the most incombustible of materials.

Every one knows that clear air is as good a non-conductor as can be asked for; and if work of this kind is properly installed, every wire where it passes through timbers is kept from them by a substance as incombustible as iron pipe and a non-conductor instead of a conductor. While it is undoubtedly better to keep wires from coming in contact with wood in any way, there can no real harm come unless in some manner the wire becomes heated, while if two wires come into contact with the iron piping trouble of some kind is pretty sure to result.

The habit of economizing in the use of porcelain as practiced by some contractors is a bad one; but at the same time the new rule of the underwriters, requiring that knobs must be placed not more than four and a half feet apart, appears to be stretching the point about as far the other way. There are many places where knobs should not be placed even a foot apart, and there are many other places where every six or even eight feet is plenty close enough.

Another thing that can be urged in favor of porcelain work wherever it can be used is its cost. It is undoubtedly true that one thing that has kept electric lighting from being used in many cases is the cost of installing the wires; and an effort should be made by all people who have the interest of the industry really at heart to make such work as cheap as is consistent with its proper installation. But all things being equal in the two kinds of work, in a wooden timbered building, the writer believes that porcelain work offers greater safety than any method yet devised.

RESISTIVITY OF GLASS.

The resistance of glass varies widely with temperature. If taken at unity at 68 degs. F., the resistance is .077 at 142 degs. and 87 at 0 degs. At the latter temperature glass has a resistivity of 5000 million million times that of copper.

AMERICAN TELEPHONE PRACTICE.

SELF-RESTORING SWITCHBOARD DROPS.

KEMPSTER B. MILLER.

It is obviously of very great advantage to have switchboards so arranged that it will be unnecessary for the operator to manually restore the drops. When it is considered that every movement on the part of the operator, in establishing a connection between her telephone and that of a subscriber, or between two subscribers' telephones, requires a certain amount of time, and that in the busier portions of the day an operator is worked almost to the extremity of her endurance, it will be clear that the saving of any movement or movements in the establishing of these connections will be a great gain in the rapidity with which the board can be operated. Such saving of the work of the operator not only insures a quicker and therefore a better service, but also reduces the cost of the operation of the exchange by enabling fewer operators to handle the system.

Brief mention has already been made in preceeding articles to the electrically restoring switchboard drops, used to a large extent by the licensees of the American Bell Telephone Company in this country and abroad. The details of such a drop are shown in Figs. 1, 2 and 3. In Fig. 1 a is a tubular electro-magnet, carrying on its rear end an armature c, pivoted at c^1, which armature carries an arm c^3, which projects forward and is provided with a catch c^4 on its extremity. So far the arrangement is almost identical with that of the Warner tubular drop already described in this series. A second tubular electro-magnet d is secured to the front of the plate b, which also supports the magnet a. This second magnet has its poles facing the front of the board. An armature e is pivoted at its lower side by the pivots e^1 and e^2, shown in Fig. 3. The catch c^4 on the rod c^3 is adapted to engage a lug e^3 on the armature and retain it in its vertical position. Pivoted on the bracket f, which is insulated from the magnet by the strip of insulating material f^1, is a light shutter, g. The tendency of the armature e when released is to fall outward, and in so doing it presses against the light shutter g just below its pivotal point, and forces it into a horizontal position.

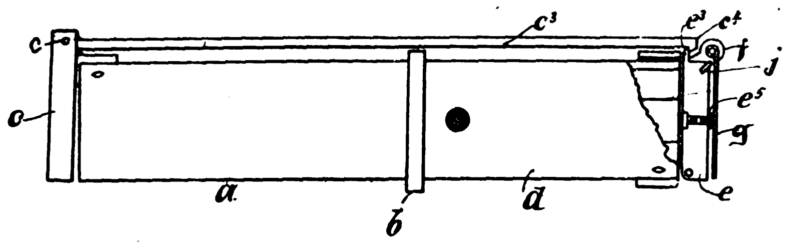

FIG. 1.—DETAIL OF SWITCHBOARD DROP.

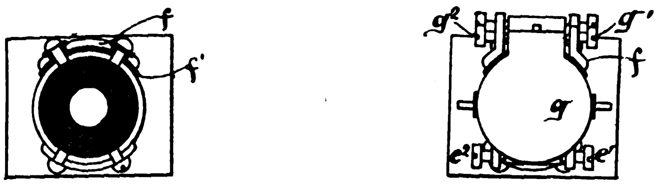

FIGS. 2 AND 3.—DETAILS OF SWITCHBOARD DROP.

The coil of the electro-magnet a is usually termed the actuating coil, and is included in the circuit of the line wire. The coil of the electro-magnet d, termed the restoring coil, is in a local circuit containing a battery which is closed by the insertion of a plug into the spring jack of the line belonging to that drop.

Various arrangements associating drops of this type with the line circuits and with the local circuits at the exchange have been devised and put into practical operation with almost unqualified success. The arrangement in Fig. 4 is typical, and at the same time shows a very interesting improvement designed for saving battery power in the exchange. The ordinary arrangement of subscriber's circuit is shown, and it will be noted that the actuating coil a is bridged across the two sides of the line wire. The coil a, of course, is necessarily wound to about 500 ohms resistance to prevent short-circuiting the voice current. Two sleeves or thimbles, kk^1, are shown on each jack of the line, the inner ones k of which are shown permanently connected together and grounded through a battery k^3. The outer thimbles k^1 are connected together, and are usually connected to the ground directly through the restoring coil d. When with this arrangement a plug is inserted the two thimbles of the jack kk^1 are short-circuited by the sleeve on the plug, and the circuit through the actuating coil is thus closed on the battery k^3. This pulls the armature e back until it engages the catch c^4, and thus allows the shutter to swing into its normal position. Any subsequent currents coming over the line wire will fail to operate the drop, for the coil d will not allow its armature e to fall against the shutter g while the plug is in the jack of that line. This arrangement has been found to be subject to one very considerable objection, viz., the severe use of the battery k^3, owing to the fact that it is on closed circuit through the low resistance coil d as long as the plug is in its socket. In order to overcome this objection the plan shown in Fig. 4 was devised by Scribner. The wire leading from the thimble k^1 to the restoring coil is run to the pivot of the shutter g, as is shown, and the side of the restoring coil which is not grounded is run to the armature e. This connection is very clearly shown in Fig. 4. The shutter g is normally insulated from the armature e by virtue of the small hard rubber bushing e^5 and the insulation f^1 between the bracket f and the magnet d. When, however, the armature e falls forward, a small lug or platinum contact point j on the upper side of the armature strikes against and makes contact with the armature g, thus closing the circuit between them. If no plug is inserted into the jack of the line, the local circuit through the battery k^3 will be open at the jack, and the armature will be allowed to fall forward when released by the catch c^4. As soon, however, as a plug is inserted the local circuit through the battery will be completed, it being closed both at the armature contact point j and at the jack. This will send an impulse of current through the restoring coil, and pull the armature back until caught by the catch c^4. This same movement of the armature opens the circuit at the contact j, and thus no battery power is wasted. A subsequent calling signal upon the line circuit while the plug is in the jack will tend to operate the annunciator, but almost as soon as the shutter e is released the local circuit will be closed at the contact point j, thereby reattracting the armature to its normal con-

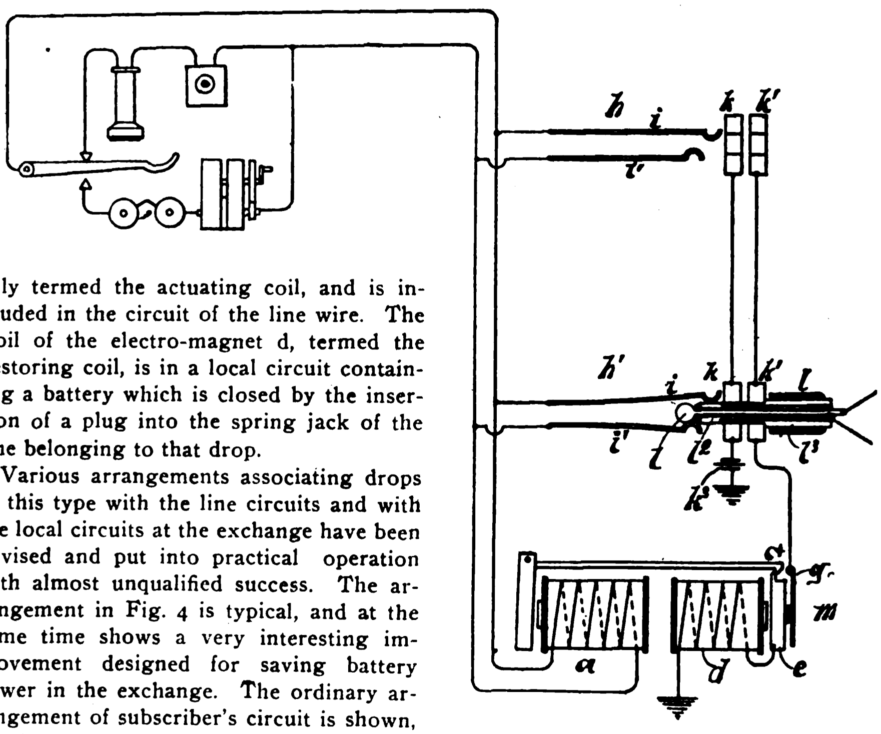

FIG. 4.—SCRIBNER SWITCHBOARD DROP.

dition and preventing it from falling to actuate the shutter.

An entirely different form of self-restoring drop has come into very general use among the companies operating in the United States in opposition to the American Bell Telephone Company. These are what are termed mechanically self-restoring drops, and two forms of them will be described.

LESSONS IN PRACTICAL ELECTRICITY

PHASING TRANSFORMERS

As the subject of phasing transformers involves the consideration of component forces and phase angles, a few introductory paragraphs will be devoted to the consideration of the parallelogram of force.

Suppose (Fig. 1) that a boat is rowed across a river at the rate of four miles per hour, the current of the stream being three miles per hour. If there were no current the boat would go straight across, following the line AB; if, on the other hand, the boat were permitted to drift along the shore, it would follow the line BC, drifting three miles. If, however, the boat is headed directly across the stream, the effect of both the effort in rowing and the current will cause it to have a course represented by the line AC, and in the same time that it would have been rowed four miles or would have drifted three miles, it will have proceeded five miles, landing at the point C. In other words, both forces will act precisely as if they were acting singly, but giving a resultant which in the above case is represented by AC, the component forces being AB and BC.

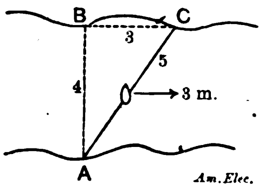

FIG. 1.—TWO FORCES AND RESULTANT.

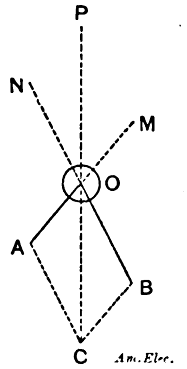

FIG. 2.—PARALLELOGRAM OF FORCE.

Now, referring to Fig 2, suppose that two forces represented in direction and length by AO, BO, are applied to move, for example, a barrel across a floor. Drawing CB parallel to AO and CA parallel to BO, we have a parallelogram, the diagonal of which, CO, will represent in length and direction the resultant of the two forces AO and BO; that is, acting alone, the force AO in a given time would cause the barrel to move through OM; similarly the force BO would cause the barrel to move in the same time through the distance ON, and the resultant or CO cause it to move through the distance OP.

The reason for this construction may be seen by reference to Fig. 3. As in the case of Fig. 1, the force BO may be considered to consist of two components at right angles, BS and SO; similarly, the force AO may be considered to consist of two components, AL and LO. Now, since CO is the diagonal of the parallelogram, a reader versed in geometry will see that AL is equal to BS; he will also see that these two components act in opposite directions, and therefore nullify each other. Consequently, the components free to act are represented by OS and OL; and CO being the diagonal of the parallelogram, LO is equal to CS, and OC is the sum of the forces free to act, or the resultant.

Suppose we have (Fig. 4) two e.m.fs. differing by quarter of a phase, or 90 deg.; one of these, AO, having a value of 86 volts, and the other, OB, a value of 50 volts. Squaring these values, adding and extracting the square root, gives 100 for the value of the hypotheneuse, AB, of the right angle triangle, ABO. That is to say, if we have a transformer whose secondary, bb, gives a voltage of 86, and another transformer whose secondary, aa, gives a voltage of 50, the current in one transformer differing in phase by 90 deg. from that of the other; then if one terminal of one transformer is connected to a terminal of the other, and a circuit led from the two other terminals, we will have a polyphase system consisting of the three circuits, aa, bb, cc, in which the voltages are 50, 86 and 100, respectively. In this case the angle ABO is equal to 60 deg., and the angle OAB is equal to 30 deg. As has been explained before, where we use a triangle such as the above, the differences in phase between the circuits will be represented by the supplement of the angles of the triangle, or 180 deg. minus the latter; therefore the phase differences between the above circuits will be 90 deg., 120 deg. and 150 deg. This, therefore, represents an unsymmetrical polyphased system, and would therefore not be used in practice.

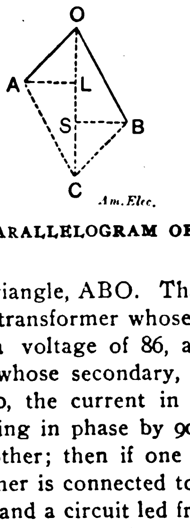

FIG. 3.—PARALLELOGRAM OF FORCE.

Now, taking up phasing transformers, suppose that in Fig. 5 BC refers to a secondary of a transformer having between its terminals an e.m.f. of 500; and AO to the secondary of another transformer having between its terminals an e.m.f. of 1000; furthermore, suppose that the current flowing in one transformer differs in phase by 90 deg. from the current flowing in the other. Now, suppose that one terminal of the secondary of the transformer AO is connected to the middle of the secondary of the terminal BC; then it will be seen from Fig 4 that between the points A and B, and also A and C, the e.m.f. will be 1000 volts. As we have assumed that the difference between the terminals of the transformer, BC, is 1000 volts, if, therefore, from the terminals A, B and C conductors are led, the difference of potential between any two of these conductors will be 1000 volts; moreover, in the triangle ABC, since the three sides are equal, the three including angles are also equal, and the value of each is 60 deg., since the sum of the three angles of a triangle is 180 deg. Consequently, the supplement of the angle in each case will be 120 deg., and we will have a symmetrical three-phase system. As practically applied, the primary terminals of the two-phase transformers BC and AO would be supplied from a two-phase machine at equal voltage, and the unequal voltage of 1000 and 860 would be obtained through one of the secondaries having a less number of turns than the other. It may be added that usually the two transformers are combined in a single structure.

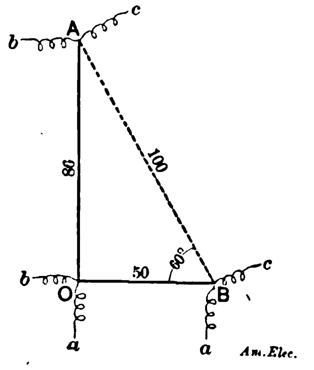

FIG. 4.—DIAGRAM OF PHASING TRANSFORMER.

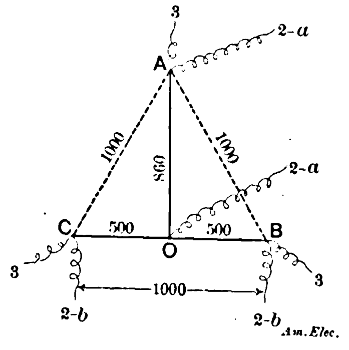

FIG. 5.—TWO-PHASE THREE-PHASE TRANSFORMER.

Fig. 5, it will be seen, represents a method of obtaining three-phased from two-phased currents. Such a phasing transformer is generally located at the generating end of the line, giving three-phased currents for transmission. At the receiving end of the line a similar transformer is located to change the three-phased into two-phased currents, should it be thought desirable to distribute according to the two-phased system.

Fig. 6 is a diagrammatical arrangement of the second transformer, which, it will be seen, is in all respects the same as the one at the generating end. In this case the three-phased lines are connected with the primary of the transformer, which will give a voltage of 860 in the section AO and 1000 in each of the sections AC, CB and BA, the section AO being connected to the middle of the section BC. As it would be desired to have the same voltage on the two two-phased lines, and not 860 volts on one and 1000 volts on the other, the two-phased secondaries will have an unequal number of turns.

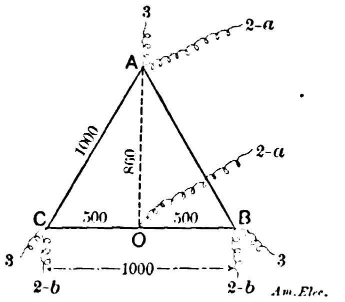

FIG. 6.—THREE-PHASE TWO-PHASE TRANSFORMER.

It will thus be seen that while the functions of the two transformers are different, their windings will be precisely the same if the receiving voltage is to be the same as the generating voltage. If, however, these two voltages are to differ, this is provided for by a change in the number of transformer turns, but with their proportions and connections remaining precisely the same.

In an article on another page by Prof. McKissick, other diagrams of phasing transformers are given, and also directions for the construction of one.

Letters on Practical Subjects

Telephone Induction Coils.

To the Editor of American Electrician:

It might be interesting to some of your readers to know, especially those who have had something to say on telephone induction coil resistance, that the coils used by the largest telephone company in the country measure about .4 ohm for the primary, and 19.5 ohms for the secondary of one style, and 14.5 ohms for another style. The secondary resistance is very low in comparison with those used in early days, but the coils referred to seem to work as well on a long line as on a short one. C. HOLMES.

New York.

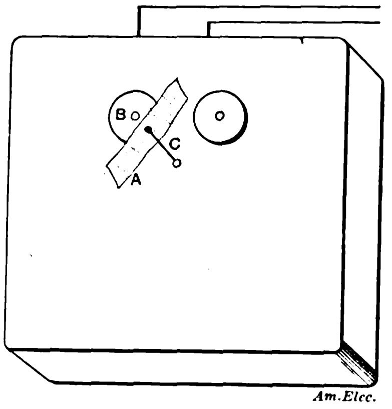
A Simple Telephone Annunciator.

To the Editor of American Electrician:

Following is a simple way of telling if there has been a call on the telephone while one is out, which takes the place of an annunciator and costs nothing to put in place:

A small piece of writing paper, A, is placed between the hammer of the magneto and a gong B. The hammer will hold the paper against the bell until there is a call, when it will drop out. On some 'phones the hammer does not touch a gong when at rest, but on nearly all it is in contact or nearly so. JAMES L. BROWN.

The Dalles, Ore.



A SIMPLE TELEPHONE ANNUNCIATOR.

Compounding and Equalizing Curves.

To the Editor of American Electrician:

Some time ago I noted a request in these columns for compounding curves, and send herewith a set of compounding test curves taken from three direct-connected dynamos. Following are the data of the machines as specified:

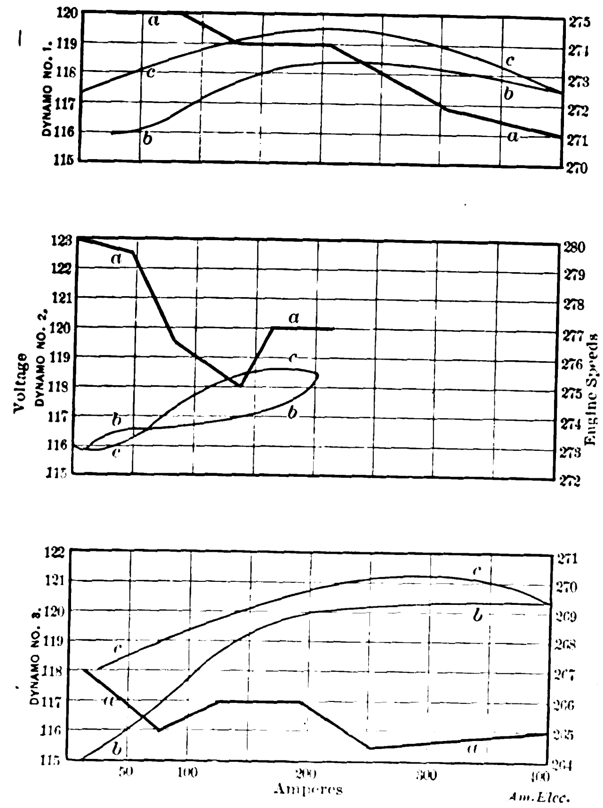


FIG. 1.—COMPOUNDING CURVES.

No. 1.	Speed 265 r. p. m.	Capacity 50 KW
No. 2.	" 275 "	" 25 KW
No. 3.	" 265 "	" 50 KW

As will be seen, the curves were plotted **under commercial conditions and not with reference to constant speed. An approximate curve for constant speed may, however, be simply determined from the data of the given curves.**

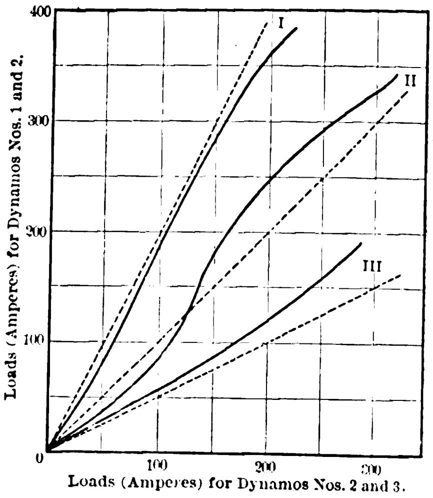

FIG. 2.—EQUALIZING CURVES.

The same dynamos were tested for equalization, and the results are plotted in Fig. 2.

The dotted lines represent the currents which would be given by the machines if run singly. The irregular curves were plotted from the readings of ammeters, one of which was placed in the circuit of each machine. M. N. BORDEN.

New York.

Water Rheostat for Controlling a Lathe.

To the Editor of American Electrician:

The foreman of a street car repair shop, having occasion to set up a motor for running an iron cutting lathe, found that the rheostat furnished with the motor was only wound for 110 volts, and that he was unable to keep the speed of lathe within limits therewith. To overcome the difficulty, an oil barrel was set up convenient to the motor, and two pieces of brass steam pipe, 1½ in., were placed in the barrel and kept apart by slipping them through holes bored in two bits of board. The boards were cut to fit across the inside of the barrel, and were nailed fast after they were in place with the pipes in them.

The pipes were connected up to the motor wiring, and placed in series with the starting rheostat and the lathe. When all was ready, the barrel was filled with water, and the resistance was found to be so great that no appreciable current passed through. A little acid stirred into the water soon cured this, and the solution was "tuned up" until the resistance was just great enough to balance the heavy voltage of a railway current.

The same appliance is a very handy thing to have when a few arc lights are needed

about a power house, to be run from the 500-volt circuit. Even for permanent circuits of ten arcs in series, a water rheostat, with the plates adjustable as to distance apart by the action of a solenoid in the circuit, would appear to make a good automatic regulator, and it will take care of a less number of lamps when one or two of the series are cut out by turning the switch in the "jumper" by which each lamp is arranged to be short-circuited at will.

Philadelphia, Pa. J. R. PERKINS.

Some Electrical Sport.

To the Editor of American Electrician:

It seems to be the proper thing now-a-days to keep some "Electrical Sport" agoing, and I will try my hand at that business for a change. But first I want to tell how a carpenter furnished electrical sport without meaning to do so. It was soon after the Pulitzer Building, in New York City, had been completed. It was desired to cut a door through one of the partitions between two of the offices, and a carpenter was at work at the job.

While engaged in stripping out the terra-cotta bricks, of which the partition was composed, he came across the three heavy insulated wires which composed the electric light distribution to that group of offices. The carpenter poked the three wires out of his way several times, but they kept falling back again. Finally the man got mad, gathered up the three wires in his left hand, and struck them with his hatchet. I was watching the man as he stood there on the staging, 5 ft. from the ground, and when he struck at the wires, I yelled at him, and started toward him, but was too late.

He struck another blow, and that time he hit the wires fair—all three of them. There was a flash and a bang up there by the carpenter, and another fireworks display in the corridor at the fuse box. The wires came off and down upon the floor, and most of the carpenter came with them, but his mustache, eye-brows and a good bit of his hair did not come with him. They went off into space, with a good chunk out of the edge of his hatchet and the fuse in the corridor. It is safe to say that the carpenter will never again try wire cutting with a hatchet when the "juice" is on. As for the sport it was sport for the observers, if not for the carpenter.

JAMES FRANCIS.

Brooklyn, N. Y.

ELECTRICAL CATECHISM

220. What is meant by $\mathfrak{B}$ and $\mathfrak{H}$ as applied to magnetism?

$\mathfrak{B}$ means the intensity of magnetization through iron or other magnetic substance. $\mathfrak{H}$ refers to the magnetizing force, or what is equal, the strength of the magnetic field when there is no iron present. For example, suppose that a wooden ring 10 ins. in diameter is wound with 1000 turns of wire through which a current of 10 amps. is sent. The strength of the magnetic field inside the ring equals 1.25 times the number of turns of wire times the amperes of current in the wire, divided by the length of the ring, measured in centimeters, or

$$\frac{1.25 \times 1000 \times 10}{10 \times 3.14 \times 2.54} = 156 \text{ lines per square centimeter.}$$

If the wire had been wound around a ring of wrought iron, the same magnetizing force would have caused a stronger magnetization of about 14,200 lines per square centimeter, or 93,000 lines per square inch. This would be called $\mathfrak{B}$.

221. How can one calculate the number of turns of wire necessary to magnetize a circuit?

There are a number of methods, all based on the law that the magnetization equals the magnetizing force divided by the reluctance of the magnetic circuit. A convenient method is given in the paper on "Designing Dynamos and Motors," in "American Electrician," February, 1898, page 59.

222. Is it necessary to have iron in a magnetic circuit?

Not always. In some cases it is better to have none, as in the case of certain instruments for measuring alternating currents, such as the Siemens electrodynamometer, the Weston A. C. voltmeter or the Thomson recording wattmeter.

223. What is there in common between measuring instruments and electric motors?

Nearly every instrument for measuring current, pressure or energy is really a motor in which the armature can rotate through only part of a revolution. A brief discussion of certain instruments may therefore properly introduce the study of the motor.

224. What is the electrodynamometer?

It is an instrument for measuring amperes, volts or watts. The Siemens electrodynamometer consists of two coils at right angles to each other, one coil being stationary while the other is free to rotate. Fig. 1 shows a common form, in which the stationary coil is inside, the movable coil being in the form of a rectangle outside the other and hung from a thread inside the spiral spring. Electrical connection with the movable coil is made through mercury cups into which the ends of the coil dip. When currents are sent through the two coils the magnetic stresses tend to move the two coils so as to become parallel, and the movable coil then begins to rotate to a position at right angles to that shown in the figure. The movable coil is then brought back to its original position by rotating the torsion head to which one end of the spring is attached. The amount of twist given the spring by the torsion head in order to bring the coil back to zero is a measure of the current in the two coils.

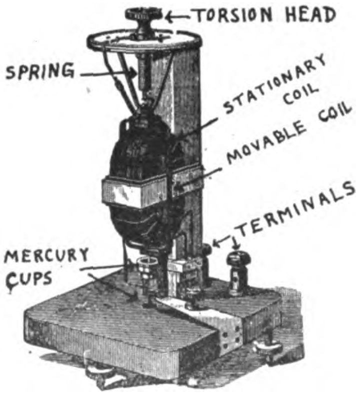

FIG. 1.—SIEMENS' ELECTRODYNAMOMETER.

225. How can the electrodynamometer be used as a voltmeter?

By having both coils made of a large number of turns of fine wire the instrument is sensitive to small currents. Then by connecting a high resistance in series with the instrument it may be connected across the terminals of the circuit whose pressure is to be measured. The electrodynamometer really measures the current passing through it, but by Ohm's law this is proportional to the pressure or e.m.f. at its terminals, and the force is therefore a measure of the e.m.f.

226. How can the electrodynamometer be used for measuring watts?

The magnetic force of each coil is proportional to the current through it, and the force tending to rotate the movable coil equals the product of the magnetic forces of the two coils. If, therefore, one coil is suitable for carrying the main current, and the other consists of many turns of fine wire with high resistance suitable for connecting across the circuit, the force between the two coils will be proportional to the product of current by volts, and therefore measures the watts.

227. What are the advantages of the electrodynamometer?

It is suitable for measuring currents either direct or alternating, and its calibration is independent of the frequency or form of the alternating current. Having no iron or permanent magnets, its reliability and permanency depend upon the spring, which experience shows does not change from year to year.

228. What are its disadvantages?

The instrument must be kept carefully leveled, and must be kept free from outside magnetic influences. It is not direct reading, but the torsion head must be adjusted so that the pointer comes back to zero each time before a reading can be made. It therefore requires some time and careful handling, and is of little use when the current fluctuates rapidly.

229. Are there other instruments based on the electrodynamic effect of the current?

Besides the Siemens electrodynamometer, there are other forms by Kohlrausch, Weber, Thomson and others, which are also zero instruments that must be adjusted for each reading. Some others, such as the Weston alternating current voltmeter, are direct reading, the coils being so shaped that the movable coil can rotate through a wide angle while a pointer attached to it travels across a scale and shows the voltage or e.m.f. at the terminals of the instrument. In the Bristol recording voltmeter the two coils are parallel and repel one another, the movable coil carrying a pointer that moves across a scale.

QUERIES AND ANSWERS

Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied. The privilege of this department only extends to subscribers, and queries must be accompanied by name and address to secure attention.

I have an alternating current lamp, the carbons of which jump violently up and down when current is turned on. What is the remedy? L. D. S.

A dash pot added will prevent the action described.

Is a storage battery injured by intermittent charging, as from a dynamo run by a windmill?—W. W. G.

No. But a dynamo may be designed to give practically a constant charging voltage over a wide range of speed.

Why is it that the induction coil used in the Bell system is composed of two separate primaries and secondaries? J. R. M.

Most probably only for convenience, since in special work it is sometimes desirable to split one coil or the other.

Can current from a 110-volt circuit be used for sparking a gas engine? C. D. A.

Yes; for the battery substitute a connection with the circuit, having in series a lamp, or two or more lamps in series-parallel.

Knowing the circular units, how may the diameter of a wire be determined? C. H. K.

Extract the square root of the circular mils, which will give the diameter in mils; dividing this by 1000 will give the diameter in decimal of an inch.

I have a synchronous motor in circuit with some induction motors. How shall I proceed with the former to reduce the power factor to unity? E. T. B.

Experiment by increasing the strength of the field of the synchronous motor. Motors are usually carefully designed for this purpose.

I want to design a condenser of 80 microfarads capacity for a voltage of 100. Kindly give the surface required, dielectric, size of box, etc. C. E. V. W.

Such a condenser would require not less than 2800 sheets of tin foil 1 ft. square, the sheets being separated by two layers of paraffined paper. We doubt if a single condenser of this size has ever been made.

What changes should be made in the windings of a transformer to change the voltage of the secondary a definite amount? J. R. P.

To lower the secondary voltage, increase the primary turns in the ratio of the present to the required primary voltage; or decrease the secondary turns in the ratio of the required to the present secondary voltage.

Does Ohm's law apply fully to alternating currents? J. S.

Yes, but in applying it allowance must be made for the counter e.m.fs. introduced into an alternating current circuit by inductance and capacity, and the accompanying difference of phase between the current and e.m.f.

What is the power in each branch of a three-phase line? E. T. B.

Calculate it, if balanced, as if the branch were a simple alternating current circuit; that is, the power is the product of the voltage, current and the power factor. If unbalanced, the calculation of the power in any of the three circuits with reference to the current flowing would appear to be very complicated.

How can I reduce an alternating current of 100 volts to one of 50 volts and 4 amperes? R. L.

Wind No. 20 or larger wire about a core or cylindrical ring of soft iron wire 1 in. in diameter, the number of turns to be determined experimentally.

How are the joints of a lead-covered cable made? A. E. G.

The copper joint is made as usual and insulated; a lead sleeve is then slipped over the joint and its ends wiped.

I have an alternating current fan motor running on a circuit of 20 cycles, and wish to run it on a circuit of 60 cycles. What change is necessary? L. W.

To preserve the present efficiency, it will be necessary to rewind the machine. Otherwise a non-inductive resistance may be placed in circuit of a value sufficient to take up half the voltage; or a choking coil may be used, its size to be determined experimentally, owing to the shifting of phase.

We have a 50-h.p., 220-volt, shunt-wound motor, receiving current from a generator 2 miles distant, and, owing to high line resistance the machine does not give sufficient power. We have a small generator of same voltage within 600 ft. of the motor, and I should like to know if there would be any advantage to use it to separately excite the field. H. S. R.

Owing to the small fraction of energy taken by the field there would be no material advantage. Connect the small machine to the line.

What is the simplest way of counting the number of vibrations of an induction coil interrupter? A. S.

Connect a telephone across the primary break and ask a friend with a musical ear to fix the fundamental note; knowing this, the corresponding number of vibrations may be obtained by reference to any book on sound. Or the telephone may be connected over a few turns of the primary or secondary, which will reduce the noise in the telephone, but still give the pitch.

1. Does a change in the resistance of a secondary coil affect in any way the primary current? 2. Would not the energy expended by the primary be the same if the secondary coil and connections were removed?—S. S.

1. Yes, if the change in the secondary resistance reduces the secondary current. 2. No; the energy expended in the primary coil is the product of the volts, amperes and cosine of angle of lag, and both of the latter are dependent on the current in the secondary.

What is the effect of operating a transformer made for 1600 alternations on a circuit of the same voltage 7200 alternations? E. T. B.

Since the rate of cutting is reduced the number of lines must be increased, and therefore also the magnetizing current; the copper loss is thus greater, and also the iron loss, since the loss per alternation increases faster as the lines are increased than it decreases from less cuttings. The heating also increases, which lowers the capacity of the transformer.

How may the watts be calculated necessary to raise water a certain number of degrees in temperature? E. T. B.

A horse-power is 550 foot-pounds per second, and also 746 joules per second, or 746 watts; therefore, a watt is .737, and a kilowatt 737, foot-pounds per second. A heat unit is equivalent to 778 foot-pounds; therefore, a kilowatt will raise a pound of water .94 deg. Fahr. in one second, or 56.4 degs. in one minute; or it will raise 18 lbs. of water from the freezing to the boiling point in one hour.

Has any economical method been devised for converting heat into electricity?—H. L.

No, and there is no probability of any such device equalling the efficiency of the steam engine and dynamo combined. As in the steam engine, only a part of the heat delivered is available for transformation, represented by the ratio of range of temperature to the upper temperature expressed on the absolute scale; besides, the intrinsic efficiency or percentage of available heat utilized is much smaller in thermo-electric devices than in the steam engine, and the same is true of the activity or capacity for a given weight.

Knowing the circular units of one size of wire in the B. & S. gage, how may the circular units of the other sizes be determined? C. H. K.

Three numbers are to be memorized. First, that the circular units of a No. 10 wire are 10,380; second, the factor .793, multiplying by which gives the next size below of any wire; and, third, the factor .629, multiplying by which gives the second size below. Furthermore, it should be remembered that in the B. & S. gage sizes are doubled every three numbers. For example, if we wish to know the circular mils of No. 3 wire, first find the circular mils of No. 12, which will be 10,380x.629=6590; therefore, No. 9 wire will have 13,180 c.m.; No. 6 wire, 26,360 c.m., and No. 3 wire, 52,720 c.m. The actual circular mils, according to a wire table, are 52,630.

Please give data for a dynamo to be used with a gas engine to furnish the spark. C. D. A.

Belt any small dynamo, such as a fan motor, to the engine; on the commutator place two rings, connected to diametrically opposite segments and insulated from all others. Lead the current from the rings to one winding on a core of soft iron wire, a second winding connecting with the spark gap. The number of turns in the primary winding will depend upon the voltage of the dynamo, and the number in the secondary on the sparking arrangement; if a "wiping" spark, the turns may be equal, and of, say, No. 22 wire; if a jumping spark, there will be needed many turns of fine wire on the secondary; or in this latter case an ordinary induction coil may be used with its primary connected to the machine and no rings employed.

NEW Apparatus AND Appliances.

WIRELESS TELEGRAPHY.

The central attraction of the late New York Electrical Exhibition was conceded by all to be the demonstration by Mr. W. J. Clarke, of wireless telegraphy, and through the courtesy of the manufacturers, the United States Electrical Supply Company, 120 Liberty Street, New York, we are enabled to illustrate herewith the apparatus used.

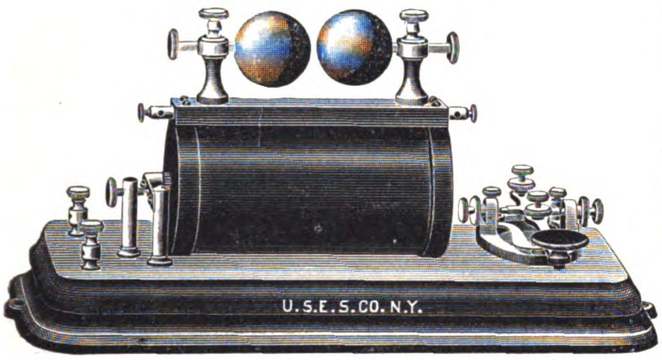

FIG. 1.—TRANSMITTER.

The form of transmitter is shown in Fig. 1. A storage battery feeds the primary of an induction coil. At tne exhibition the current from the battery first passed through an automatic circuit breaker, which made and broke the circuit in the same manner as a telegraph operator would when manipulating his Morse key in the act of calling "N. Y.," the telegraph call for New York City.

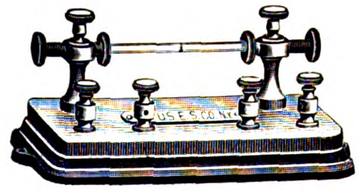

FIG. 3.—BRANLY TUBE.

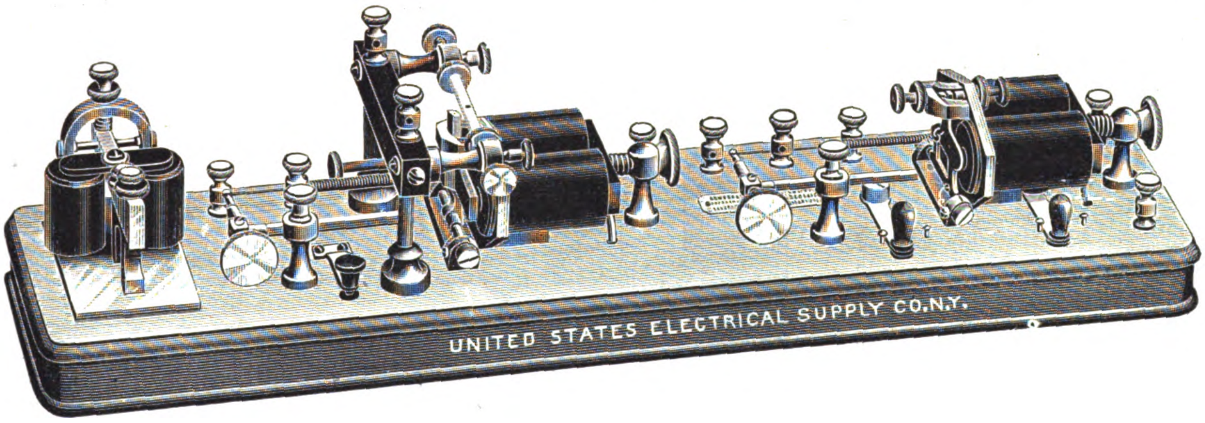


UNITED STATES ELECTRICAL SUPPLY CO.N.Y.

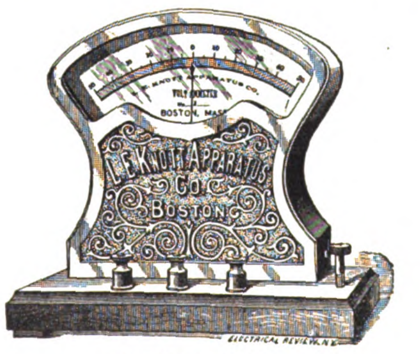
FIG. 2.—RECEIVER.

Over the induction coil is shown the Clarke oscillator, which consists of two solid brass balls about 4 ins. in diameter, mounted so that the distance between them is readily adjustable. The secondary terminals of the coil are connected to two binding posts on the heads of this oscillator. The distance between the balls being properly adjusted and the current turned on from the battery, the sound of the secondary sparks passing between the balls can quite easily be deciphered as the dots and dashes of the signal "N. Y." One terminal of the oscillator is connected to earth and the other to a brass rod about 10 ft. in length placed on top of the show case.

The receiver, Fig. 3, consists of a Branly-Clarke coherer relay and Clarke receiving instrument (the former shown separately in Fig. 3). At the exhibition a large 6-in. vibrating bell was connected up in the local circuit in addition to the telegraph sounder shown, and continually rang out the Morse signals "N. Y.," and by holding down the hammer of the bell the sounder could be distinctly heard repeating the same call.

LOW PRICED VOLT-AMMETER.

The increased use of storage batteries has created a demand for a practical low-priced volt-ammeter, and the cut here presented shows such an instrument devised with special reference to this work. It has a double winding with double graduations. As shown in the cut, one set of binding posts connect with the ampere coil and the other set with the volt coil. This instrument has an aluminum case, jewel bearings, and in every particular is claimed to be a substantial and practical instrument. The manufacturers are the L. E. Knott Apparatus Company, Boston, Mass.



VOLT AMMETER

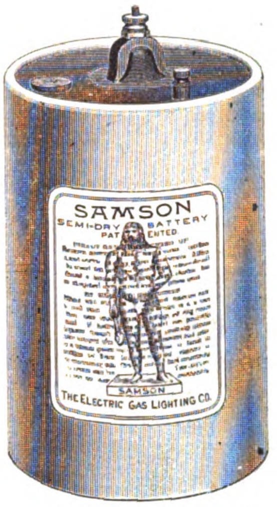
VOLT-AMMETER.

PORTABLE BATTERIES.

The accompanying illustration shows an open-circuit cell adapted for portable purposes where large current and long life are required. The elements are large and strong to enable the cell to perform the heavy work for which it is designed, and are contained in a porcelain jar 4⅝x7⅝ ins., which is sealed at the top to prevent the spilling of solution. The latter is made by filling the jar with water, which dissolves the dry salts placed therein.



PORTABLE BATTERY.

The makers state that this battery is used largely for gasoline launch work, portable gasoline agricultural machines, the operation of portable electrical devices, and for marine service. The cell is called the Samson semi-dry, and is claimed by its manufacturers, the Electric Gas Lighting Company, 193 Devonshire Street, Boston, Mass., to be much stronger and longer lived than their No. 2 Samson cell.

SKINNER AUTOMATIC SELF-OILING ENGINE.

The engine shown in the accompanying illustration is claimed by the makers to mark in several respects an important advance in steam engineering. One of the most important of these features is the self-oiling arrangement, which is shown in detail in the sketch.

Hinged to a stand bolted to the top of bed, is a feeder or oil tube overhanging the guides, and through sight-feed glasses placed therein oil is conveyed to the guides, cross-head and cross-head pin. To two stands placed near main bearings is hinged a feeder of arched shape, through which oil is conveyed to sight-feed glasses in the pillow blocks cap over shaft, and through which the main bearings and crank pin are oiled. Regulating screws are located in feeders over each glass, and when once adjusted require no further attention.

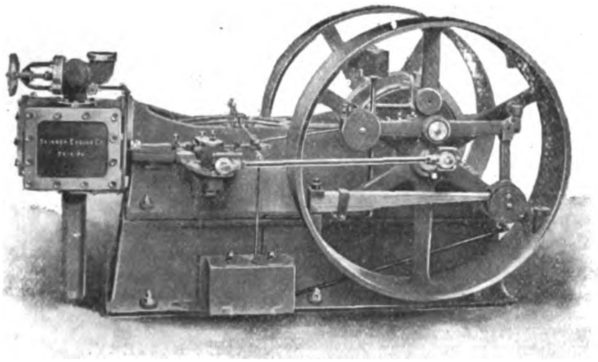


FIG. I.—SKINNER AUTOMATIC SELF-OILING ENGINE.

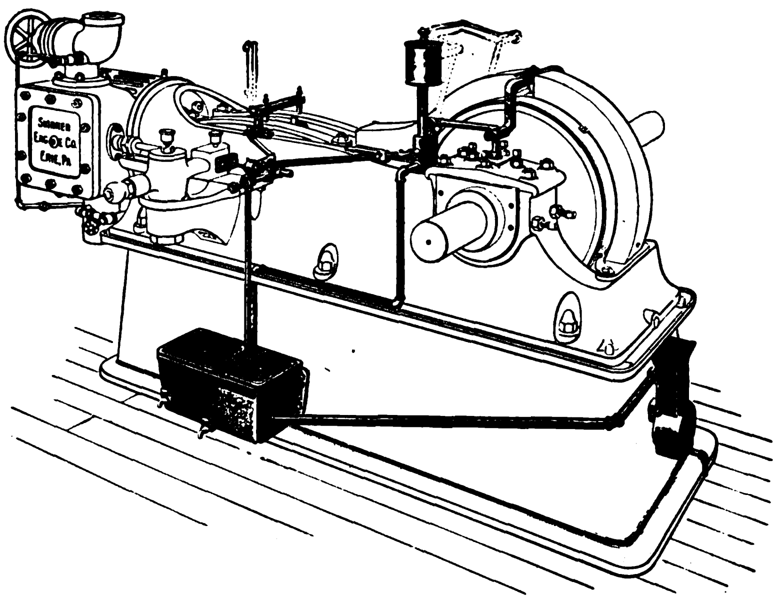

FIG. 2.—DETAILS OF SELF-OILING ARRANGEMENT.

When the engine is shut down, raising these jointed feeders to the position shown by dotted lines shuts off the oil supply, and when in this position ready access to any part of the engine for examination. adjustment or removal of any part, is afforded. By the loosening of a set-screw at each joint, each feeder and joint can be entirely removed from the engine.

A reservoir placed above the bed supplies the feeders with oil under a constant pressure, and is provided with an overflow which returns excess oil to the supply tank shown attached to side of sub-base. Oil is forced to the reservoir by a pump of peculiar construction operated from the valve slide. It has a positive motion valve and is noiseless. The valve and seat can be removed and replaced in position without stopping the engine or interrupting the flow of oil to the feeders; when removed oil is automatically shut off from the pump, and when replaced the pump immediately starts.

An oil and water separator is placed on the end of the sub-base below the engine, into which the drip (consisting of oil and the water from the stuffing boxes) flows, and in which separation of oil from the water is effected, the water escaping through a small pipe to the bottom of the separator, and the oil being drawn from a pipe at the top. This device, it is stated, has withstood the test of equal parts of oil and hot water combined by violent agitation, and passed through the separator at the full capacity of the funnel. There is an oil purifier in connection with the supply tank, into which oil flows from the separator and from which it passes to the supply tank freed from all foreign matter.

All parts of the system and the pipes connecting the different parts outside of the bed are in full view and reach of the attendant. Neither strainer nor filtering material (such as waste or sponge) is employed, nor anything that will obstruct free circulation of oil through the entire system.

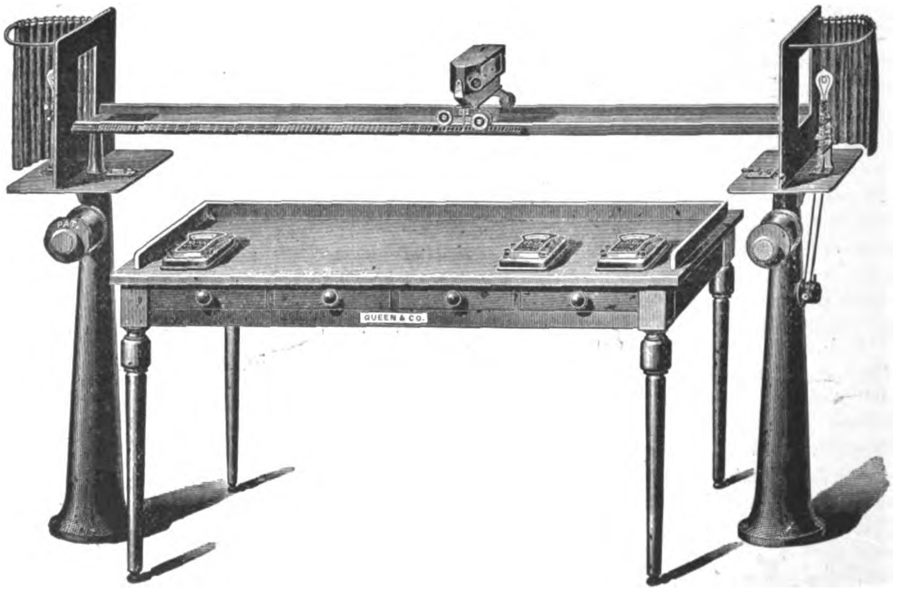
The valve is balanced and operated by a governor consisting of but three parts—eccentric arm, weight and spring, which are mounted in a wheel on frictionless roller bearing, requiring no lubrication.

The makers state that the governor will maintain the same regulation with steam pressure ranging from 30 to 100 lbs. The speed of engine can be changed 40 per cent by simply bolting on or taking off weights, and maintain the same regulation, without any other adjustment of the governor. The manufacturers guarantee that this governor will maintain a regulation within ½ of 1 per cent, and that the whole load may be thrown on and off the engine instantly, and the instantaneous change will not be over 1 per cent above or below, and will resume normal speed in six revolutions of the shaft.

The engine above described is made by the Skinner Engine Company, Erie, Pa.

NEW ELECTRIC LIGHT PHOTOMETER.

Queen & Company, Philadelphia, have placed on the market a new photometer, illustrated herewith. As will be noticed, it is a departure from the usual design. Cast iron pedestals support the metal photometer bar and carry stages for the support of the lights, screens, etc. The rheostat shown on the left hand pedestal is for the control of the potential on the standard, which is an incandescent lamp supplied with a certificate of standardization. It has about 800 or 1000 steps and permits of perfect adjustment. A similar rheostat on the right regulates the current on the test lamp. The graduated bar is inclined at an angle of 45 degs., in which position the graduations are lighted by the lamp under test.

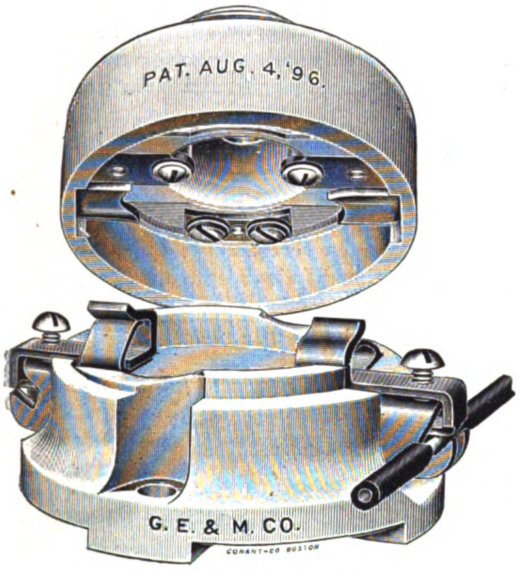


ELECTRIC LIGHT PHOTOMETER.

The screen, which may be of either the Bunsen or Lummer-Brodhun type, is mounted on a truck and may be rolled along the bar wherever desired. A milled head permits of close adjustment when balance is nearly attained. The instrument, it will be noted, is complete in every respect, and is the result of several years' experience with photometric apparatus.

CEILING ROSETTE.

The rosette shown herewith does not require the use of a screwdriver when it is to be re-fused, it only being required to give the cap a quarter turn. The line wire is held by clamps instead of screw points, thus not marring the softest wire. A long fuse may be used with this type of rosette, which is made by the Gilmore Electric Company, 625 First Street, South Boston, Mass.



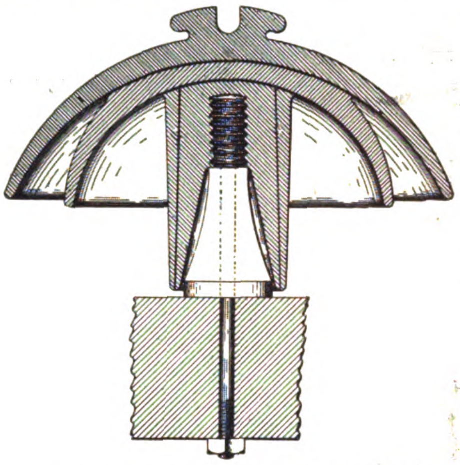
CEILING ROSETTE.

HIGH VOLTAGE LINE INSULATOR.

The accompanying engraving is reproduced from a patent granted June 7 of the present year to Fred. M. Locke, Victor, N.Y., and illustrates the principle of the insulator manufactured by the patentee for high voltage work.

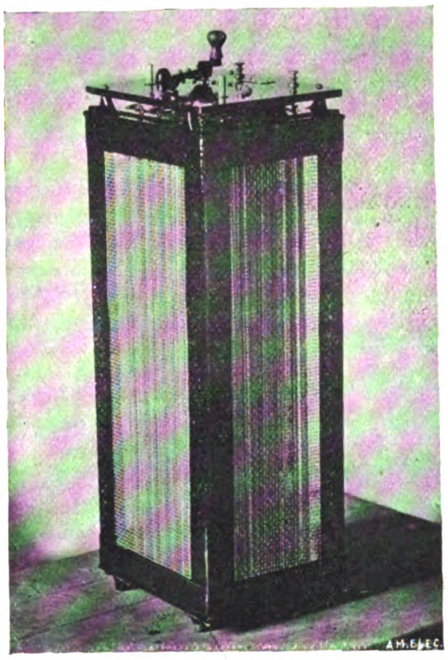
In the specification of the patent the inventor states that in passing a current of electricity of high voltage over a wire he has found that the static discharge from the surface of the insulator supporting the wire, or the arcing of the current around the insulator, burns the insulator pin off on a plane with the bottom of the petticoat extending the lowest. He has also found that by providing the insulator with a long central petticoat, which incloses the pin down to a point adjacent to the cross-arm, and by making it small in diameter in proportion to the adjacent petticoats of the insulator above it, this central piece is the most valuable insulating surface of the whole insulator on account of the fact that the area of the surface is so small that but little moisture at most can congregate there.

The object of the inventor therefore consists in so constructing an insulator as to prevent this leakage of the current over the insulator to the support, and thereby obviate the burning off of the pin, and to that end his invention consists in constructing an insulator having its inner petticoat extending down to a point adjacent to the cross-arms upon which the pin is mounted, to serve as a protecting sleeve for the pin and increase the arcing distance of the current around the insulator.



HIGH VOLTAGE LINE INSULATOR.

The insulator as shown consists of an outer shell, an inner shell and a central petticoat so elongated as to form a protecting sleeve for the insulating pin. This central piece may be constructed in two parts, as shown, and the pin itself be surrounded by a porcelain case, as also shown. The different parts of the insulator are secured together by coating them with a layer of glaze and then baking.



MOTOR SPEED REGULATOR.

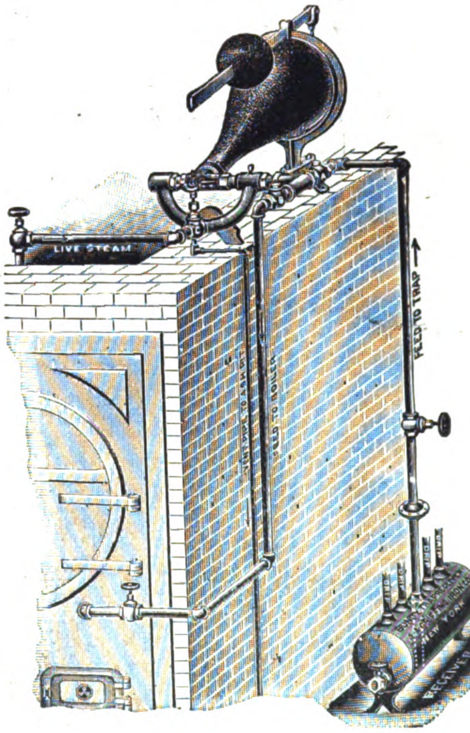
IMPERIAL MOTOR SPEED REGULATORS.

The accompanying cut represents a 5 h.p. Imperial motor speed regulator, manufactured by the Ohio Electric Specialty Manufacturing Company, of Troy, Ohio. This rheostat is built to stand a continuous flow of current supplying a motor under full load, and is used both as a motor-starter and speed-regulator. The regulator is fireproof and dissipates heat at a low temperature by providing for ample ventilation in all parts. Marbleized slate is used on the face of the regulator and the entire apparatus is neatly finished.

All contacts have ample capacity and close gradation of resistance between steps is given. These regulations are specially adapted for use with motors driving ventilating fans, pumps, manufacturing ice-cream, or any purpose for which regulation of motor speed is desired.

RETURN STEAM TRAP.

The economy of a steam trap that will return all drainage to the boiler is evident, and those who admire ingenious mechanism will find an additional interest in the steam trap illustrated herewith from the manner in which it enables this end to be attained.



RETURN STEAM TRAP.

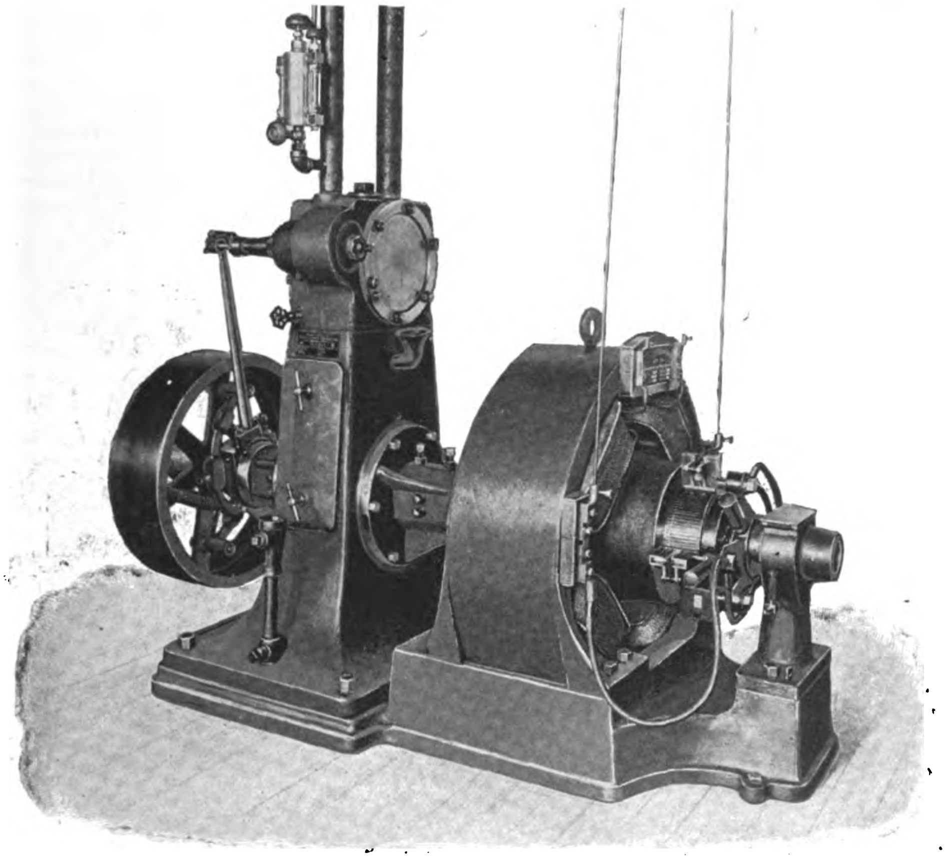
As shown the trap is fitted on a boiler to return condensation from radiators, coils, kettles or other appliances. The condensed water ascends the vertical pipe and passes through a check valve, A, into the pear-shaped bowl, the latter being kept open to the atmosphere through an air vent below, C, the pipe from which is shown leading to the ash pit.

When the bowl becomes nearly full the weight of water overbalances the weight of the ball shown, and the bowl tips toward the right. This motion raises the disc of a valve, C, which allows steam from the boiler to enter the bowl, the check, A, being closed by the consequent pressure. The pressure in the trap being now equal to the boiler pressure, the water contained in the bowl flows through a check, B, into the boiler. When the trap is emptied the ball weight raises the bowl, the valve, C, is thereby closed, the air valve under C opened, and the water of condensation again flows into the trap through A, the check, B, being closed by the boiler pressure.

The steam trap described, known as the Bundy return steam trap, is made by the A. A. Griffiing Iron Company, Jersey City, N. J.

A YACHT LIGHTING PLANT.

The electric lighting outfit shown herewith has recently been installed on the yacht "Ballymea," and consists of a Case engine and a Riker dynamo.



YACHT LIGHTING PLANT.

The dynamo is of cast steel with toothed armature, the armature core being keyed to a spider secured to the shaft. The construction of this spider facilitates radiation and insures a cool running armature and machine. Form wound armature coils are used, giving an electrically and mechanically balanced armature. The commutator bars are of tempered copper, and the insulation of the commutator and also of the armature is of mica. The field coils are wound upon thimbles with brass ends, and are insulated with mica.

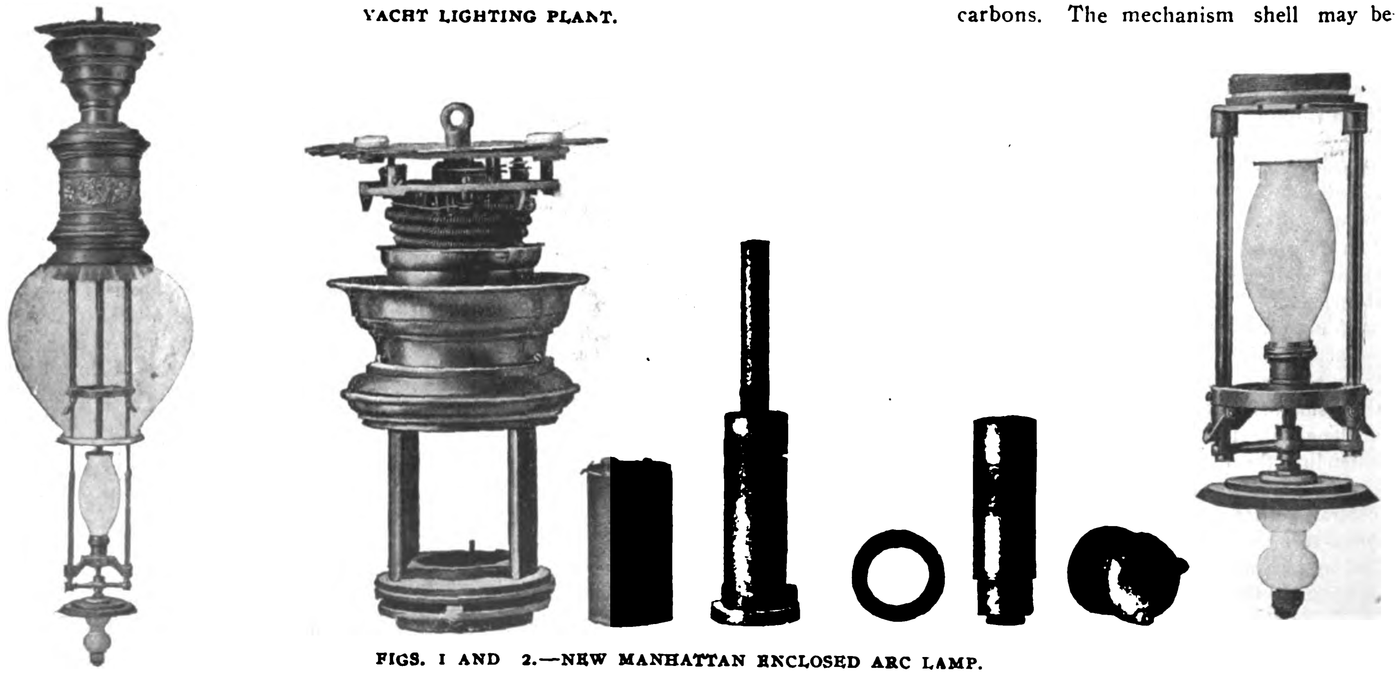
The brushes, which are of carbon, are held in position by a brush holder, which feeds the brush automatically and always in the same line. The machine is so designed that the brushes do not require shifting from no load to full load. The bearings are fitted with phosphor bronze bushings and oil rings. The latter dip into an oil well in each bearing pedestal and efficiently lubricate the shaft. All the moving parts are low and perfectly balanced, thus avoiding vibration. The Riker Company has also used the Case engine with the crank shaft extended on both sides of the machine and armatures on either end, the unit being used on three-wire circuits. The Case engine mentioned above is manufactured by the New Britain Machine Co., New Britain, Conn.

NEW MANHATTAN ENCLOSED ARC LAMP.

The new style of Manhattan arc lamp illustrated herewith is designed to burn in multiple on direct-current circuits of from 90 to 250 volts, in series on circuits of from 200 to 600 volts, and on alternating-current circuits of any frequency and from 90 to 130 volts.

In this new type the length has been decreased from 36 ins. to 29 ins., and numerous improvements have been introduced. In retrimming it is no longer necessary to remove several parts which have to be held in the hand, and the bulb is lowered down through the bottom of the water globe on double tube coping rods, as shown in Fig. 1, the inner bulb and carbon thus being brought into full view below the lamp. To lower the trimming device it is only necessary to press the knob on the bottom of the lamp. The current is fed to the upper electric carbon directly through the sheath, thus obviating the use of a separate brush box as formerly; contact between the sheath and the inner tube is made through metal balls, which are magnetically attracted against the sides of the inner tube, thus insuring good contact.

A new cap is used with the present lamp which materially lengthens the life of the carbons. The mechanism shell may be lowered while the lamp hangs in position by a very simple manual operation, thus



FIGS. 1 AND 2.—NEW MANHATTAN ENCLOSED ARC LAMP.

enabling the current adjustment to be changed at will. The adjustment of the rheostat for voltage may be made by loosening set screws and lowering the split canopy at the top.

The number of parts has been considerably reduced, all mechanism below the armature being dispensed with, and the only moving part in the lamp is the armature. The clutch consists of four balls which ride between the inclined surface of the inside of the armature and openings in the central brass tube. The armature and clutch may be removed from the lamp while it hangs in position by unscrewing one nut.

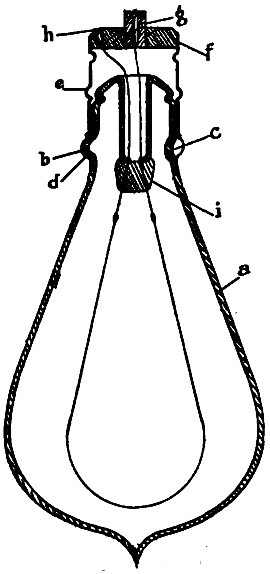
The controlling magnet is ventilated, thus providing against a burn-out under abnormal conditions that would cause trouble with the old form of magnet. A current of air is also kept constantly passing between the magnet and central tube.

The steady burning of the old lamp depended absolutely upon perfection of the air chamber, which caused variation in burning of different lamps, and it was impossible to make lamps altogether interchangeable. In the new lamp there is no such chamber, and a loose fit is maintained between all of the parts. In addition to the air chamber in which the armature works in the old lamp a further chamber was provided around the clutch, making it necessary to take the shell off in a most inconvenient manner, and great care had to be used in replacing insulation at this point, which made the old lamp most difficult to assemble. This has also been remedied in the new lamp. Instead of requiring a driving fit, all of the parts are now loose fits, and may be removed with the fingers, and the number of operations to assemble the lamp have been reduced from twenty to six. The various parts of the lamp are shown in Fig. 2. The manufacturers are the Manhattan General Construction Co., 11 Broadway, New York.

A NEW INCANDESCENT LAMP.

An incandescent lamp made with a base that does away with the use of plaster of paris, and which is interchangeable, is an innovation in lamp manufacture recently put on the market. Referring to the accompanying illustration, it will be seen that the bulb has on its upper portion an annular projection, b, containing a notch, c. Around this projection slips a split brass collar, d, which has an indentation to fit the projection, b, and also a small projection which fits in the notch, c, and prevents the collar from turning. Around this collar, which has an outward springing tendency, is slipped the base e, which may be of any one of the standard styles. The upper portion of this base is closed by a porcelain disc, f, with a brass tip, g, in the center, to which one of the terminals is soldered, the other terminal being soldered to the base, e, at h. The leading-in wires are fused into a glass projection, i, in the usual manner. A drop of solder mechanically joins the collar, d, with the base, e, and prevents the latter from turning.

This method, as will be seen, does away with the use of plaster of paris, making a mechanically strong lamp and one that will not soak up or hold moisture which, by electrolytic action, eats away the inleading wires and short circuits the lamp in the base. These lamps have interchangeable bases and are especially adapted to street lighting, sign work, for use in damp places and in places where lamps are roughly handled. The above lamp, which is known as the "20th Century" lamp, is manufactured at the Twentieth Century Lamp Works, 1031 Walnut Street, Philadelphia.



A NEW INCANDESCENT LAMP.

NEW BOOKS.

ANDERSON'S PHYSICAL EDUCATION. By William Gilbert Anderson, M. D., New York: A. D. Dana. 102 pages, illustrated. Price, 50 cents.

This pamphlet is a treatise on physical training by means of special apparatus for use in the house, the writer being Professor of Gymnastics in Yale. The movements for exercising different portions of the body are described in detail, numerous illustrations making their learning an easy matter.

APPLIED MECHANICS. A Treatise for the Use of Students Who Have Time to Work Experimental, Numerical and Graphical Exercises, Illustrating the Subject. By John Perry. 678 pages, 371 illustrations. Price, $2.50.

As a thorough practical treatise on applied mechanics from the standpoint of the engineer, this book can be recommended without reservation. One of its valuable characteristics is the manner in which the student is taken into the confidence of the author, being everywhere guided by helpful advice, and having pointed out to him the practical limitations and bearings of the knowledge imparted. The numerous examples all relate to calculations met with in practical work, and principles are illustrated by reference to actual machines and practice. The work is therefore of special value to the engineer, both as a book of reference and as a means of finding out the real significance of the knowledge he previously obtained as a student from the usual school text-book on mechanics.

THE ARITHMETIC OF THE STEAM ENGINE. By E. Sherman Gould. New York: D. Van Nostrand Company. 104 pages, 6 illustrations. Price, $1.

The object of this volume is to impart a knowledge of the fundamental principles of the steam engine, and to illustrate practical calculations based upon them. The examples are on the calculation of heat, engine efficiency, horse power, etc. Tables are given of hyperbolic logarithms and of the properties of saturated steam. A useful feature is a list of standard books on steam and mechanical engineering.

THE LOCAL DISTRIBUTION OF POWER IN WORK SHOPS, ETC. By Ernest Kilburn Scott, A. I. E. E. London: Biggs & Company. 148 pages, 23 illustrations. Price, 2s.

Much tabulated matter of value is contained in this volume on the subject of interior power distribution, including data on the power required for driving various kinds of machines. Part I. takes up the subject of the advantages of electric driving, and the power required by various machines. Part II. is on the advantages and disadvantages of alternating current from the standpoint of power distribution. Part III. consists of notes on the various points of a power installation, with examples of recent practice.

THE PRINCIPLES OF ALTERNATING CURRENT WORKING. By Alfred Hay, B. Sc. London: Biggs & Company. 289 pages, 119 illustrations. Price, 5s.

The outcome of a course of lectures originally delivered to a class of evening students, this book presupposes on the part of the reader but little electrical or mathematical knowledge. The author being apparently a teacher, he naturally drops into academic methods, summing up, for example, in definitions which are of no earthly use if the reader has understood the preceding explanations. Nevertheless, the book is perhaps the most satisfactory simple exposition of alternating current phenomena yet written in English.

FIRST PRINCIPLES OF ELECTRICITY AND MAGNETISM, By C. H. W. Biggs. London: Biggs & Company. 497 pages, 343 illustrations. Price, 3s. 6d.

This book, about half of the contents of which appeared originally in the columns of our English contemporary, *Electrical Engineer*, is written for beginners in practical electrical work, and as an easily read treatise, it will be found useful in obtaining an elementary knowledge of the fundamental principles of electrical science. It has an advantage over the usual book having a similar object in that its information has, as far as possible, a direct practical bearing. Text-book methods are avoided, and weight is given to subjects in accordance, not with their theoretical interest, but with the importance they assume in practical work.

TRADE PUBLICATIONS.

ELECTRICAL ROCK DRILLS. — The Marvin Electric Drill Company, Canastota, N. Y., have published a 32-page pamphlet, describing and illustrating the Marvin electric percussion drill, many forms of which are shown in half-tone engravings.

SWITCHES, PANEL BOARDS, Etc.—J. Jones & Son, 64 Cortlandt Street, New York, in their catalogue No. 6, illustrate numerous forms of switchboards, panel boards and panel board boxes, knife switches of all types and capacities, and a full line of switchboard fittings.

WIRT DYNAMO BRUSHES AND RHEOSTATS.—With this title, Charles Wirt, 1028 Filbert Street, Philadelphia, has issued a catalogue of Wirt dynamo brushes, rheostats and Queen-Wirt electrical measuring instruments. Several pages on the use of brushes will be of interest to dynamo tenders.

SWITCHBOARDS AND SWITCHES.—The Technic Electrical Works, 214 New Street, Philadelphia, Pa., have issued a pocket price list of isolated plant switchboards and knife switchboards. Panels of from one to six circuits are listed, and switches of from 100 to 500 amps., both single and double pole.

TRANSFORMERS.—The Lakon Company, Elkhart, Ind., has issued a unique publication, in which a tale of a dog that grins introduces us gradually to the subject of transformers in general, and the Lakon transformer in particular. The story of the dog is carried on in illustrations after it has been dropped in words.

INSULATION MANUAL.—The Mica Insulator Company, New York and Chicago, has issued an "Electricians' Sheet Insulation Manual," in which the various forms of insulation made by it are described, a sample of the insulation being secured to the page facing the description.

PRISMATIC ELECTRIC SIGNS. — The Prismatic Electric Sign Company, Williamsport, Pa., in a well printed pamphlet describes and illustrates types of prismatic signs which, by means of electric illumination, can be made to produce the most brilliant effects.

LINE AND CONSTRUCTION TOOLS.—The Western Electric Co., of Chicago, in a 24-page pamphlet, gives a complete list of construction and linemen's tools, including illustrations of all the more important or latest types of such tools. This pamphlet is known as "Tool Catalogue No. 3," and may be obtained upon application.

STEAM SPECIALTIES.—The 1898 catalogue of the Lunkenheimer Company, Cincinnati, Ohio, is handsomely bound and contains 208 pages of matter, and perhaps twice that number of cuts. Each type of steam fitting is clearly described, and where desirable, directions for setting up and use are given.

TUBULAR BOILERS.—The Murray Iron Works Company, Burlington, Iowa, in a catalogue of high pressure tubular boilers, prints some extremely fine half-tone illustrations of boilers which, we learn from the imprint, come from the engraving department of our contemporary, the "American Machinist."

PELTON WATER WHEEL.—A new edition, recently issued, of the catalogue of the Pelton Water Wheel Company, San Francisco, Cal., includes a vast amount of data referring to the utilization of high heads of water. An interesting feature consists of concise descriptions of electric light and power plants employing the Pelton wheel.

IRON-ARMORED CONDUITS.—The Safety Conduit Company, Rankin Station, Pa., has issued a pamphlet devoted to the "Loricated" electric conduit for interior construction. This conduit consists of a smooth tube of mild iron or steel, having a tough insulating coating that will not crack or come off in bending, and will resist acids and alkalies.

GASOLINE ENGINES.—The Otto Gas Engine Works, Thirty-third and Walnut Streets, Philadelphia, have issued a large-page catalogue, with illuminated cover, in which the Otto gasoline engine is thoroughly described and illustrated. Among the applications illustrated are for driving dynamoes, horseless vehicles, marine purposes, &c.

BRISTOL RECORDING INSTRUMENTS.—The Bristol Company, Waterbury, Conn., has issued a "partial" list of recording instruments for pressure, temperature and electricity, which nevertheless includes 117 different varieties and ranges. More than half the list is devoted to recording voltmeters, ammeters and wattmeters, for both direct and alternating currents.

TELEPHONES.—The ninth edition of the catalogue of DeVeau & Co., 27 Rose Street, New York, contains several novelties. Among these is an "egg" telephone for suspending from a wall, ceiling or bracket. When not in use the transmitter and receiver fit together, and have somewhat the appearance of a suspended egg. This is claimed to be the smallest telephone outfit on the market.

OILS AND BOILER COMPOUNDS.—In a neat pamphlet with a cover of unique design the Dearborn Drug and Chemical Works, 29 Rialto Building, Chicago, gives some advice on the selection of oils for different work which the engineer will find of value. Another pamphlet, uniform with the above, treats of boiler compounds in a similar manner.

INCLOSED ARC LAMPS.—The Jandus Electric Company, Cleveland, Ohio, in a pamphlet handsomely bound and printed, besides giving descriptions of the Jandus arc lamp, includes some curves, accompanied by explanatory matter, showing the distribution of light from this type of lamp. Those interested in either inclosed arc lamps or fine printing will find much to please them in this pamphlet.

HUNT RAILWAYS.—Two recent publications of the C. W. Hunt Company, 45 Broadway, New York, are entitled "Hunt Automatic Railway" and "Hunt Cable Railway." The former railway is for transferring coal from the wharf to the bin, and is operated entirely by gravity. The cable railway is for handling coal and merchandise under all conditions. Both pamphlets are handsomely gotten up and profusely illustrated.

STURTEVANT ENGINES.—In a well-printed and handsomely illustrated and bound catalogue of 48 pages, the B. F. Sturtevant Company, Boston, Mass., shows an exclusive line of engines for electric light plants and general high-grade work, and a number of Sturtevant direct-connected electrical generating sets. The latter are of both the inclosed and open type, the latter following the latest marine engineering practice.

MACHINE TOOL MOTORS.—The Bullock Electric Manufacturing Company, Cincinnati, O., is sending out a neat card showing on one side a Bullock motor, direct connected to a 72-in. Gray planer, the other side containing a concise statement of the advantages of electric motors for machine tool driving, neatly printed in two colors. The card forms an attractive and effective educational inclosure for letters.

WALKER BULLETINS.—Walker bulletins 1072-1078 are devoted to static transformers; Walker car motors for street lines, elevated or suburban traffic; railway switchboards, the Walker underground conduit; switchboards for lighting plants, and the Walker pivotal trolley, with Grover trolley head. The bulletin on the Walker underground conduit gives an excellent idea of the system now being so extensively applied in New York City.

ELECTRIC LIGHT SUPPLIES.—A cloth-bound volume of 555 pages, just issued by the Western Electric Company, covers, to quote from the preface, "only such material as is specially adapted to electric light works." As the type is smaller than any used in this journal, the vast development in electric lighting is significantly illustrated by this remark. The volume contains more than 2000 illustrations, and each article listed is accompanied by a telegraphic code word.

LIGHT VS. ILLUMINATION. — Under this title the Holophane Glass Company, 1 Broadway, New York, has issued a 64-page pamphlet on light and illumination, with particular reference to the holophane system of globes, invented by Prof. Blondel, professor in the Ecole des Ponts et Chaussees, Paris. This pamphlet takes rank as a technical treatise on the subject of illumination, and will be found interesting reading by all central station men.

ELECTRIC HEATERS.—The American Electrical Heater Company, 197 River street, Detroit, Mich., has just issued a new catalogue of electrical heating devices, and among the features we note the very attractive trade mark which this company has adopted. Among the devices recently placed upon the market by this concern is a new electric curling iron heater in the form of a column which, being heavily nickeled and mounted on a marblized base, presents a very handsome appearance. The many other new features described make the catalogue a valuable one.

HOW CAN I BECOME AN ELECTRICAL ENGINEER?—With this title the Electrical Engineer Institute of Correspondence Instruction, 120 Liberty Street, New York, has issued a well-printed pamphlet of 64 pages, illustrated with more than thirty half-tone portraits of the great masters of electrical science, from Gilbert to Steinmetz, and of great electrical inventors, from Morse to those of the present day. The text points out the superior advantages of the electrical engineering profession, and how one may become proficient in it.

CROCKER - WHEELER BULLETINS.—Bulletins 1-5 of the Crocker-Wheeler Company have the following subjects: Bulletin 1, bulletins, figures, photographs and patents; bulletin 2, fans; bulletin 3, dynamotors and motor-dynamos; bulletin 4, motors and dynamos; bulletin 5, small size of very slow motors for direct attachment to machinery. The last three bulletins aggregate 106 large pages, and form a technical treatise on the subjects considered, two bearing the signature of Dr. O. O. Wheeler and the third that of Gano S. Dunn, electrical engineer of the company.

LIGHTNING ARRESTERS.—The General Electric Press, Schenectady, sends forth another extremely artistic specimen of the printer's art in a 32-page pamphlet on lightning arresters, the cover and title page of which are beautiful in design. The introduction is a short examination of the qualifications necessary to a perfect lightning arrester, with a short disquisition on the special advantages of the magnetic blow-out. This is followed by concise descriptions of the various types of General Electric arc and incandescent station arresters, including the more recently developed lightning arrester for direct current circuits up to 850 volts, and the short-gap arrester, especially designed for alternating current circuits.

BUSINESS NEWS.

THE WALKER COMPANY, Cleveland, Ohio, is now supplying the Brooklyn Elevated Railway with 400 motors of 80-h.p. each, and is making a specialty of large motors for heavy interurban traffic.

SWITCH PATENT.—In the suit of the Perkins Electric Switch Mfg. Company vs. the Gibbs Elec. Mfg. Company, before Justice Townsend, the Gibbs patents were sustained and the bill against them was dismissed.

THE WESTERN ELECTRIC COMPANY, Chicago, desires to advise the central stations using alternating current apparatus that it will be pleased to quote prices on the Lakon transformers and Lakon cut-outs for transformers.

THE WARREN-MEDBERY COMPANY, of Sandy Hill, N. Y., is now manufacturing a full line of Medbery switches and switchboards in all their various styles, and will shortly be able to supply the market with its widely known Medbery insulation.

DR. F. A. C. PERRINE has obtained two years' leave of absence from Leland Stanford, Jr., University in order to accept during that time the position of consulting electrical engineer for a company which will transmit electric power from Blue Lakes City to San Francisco.

THE CENTRAL TELEPHONE & ELECTRIC COMPANY, of St. Louis, which succeeded to the D. A. Kusel Telephone Manufacturing Company and the Missouri Telephone Manufacturing Company, reports that it has doubled its business in the last six months, and is now about to increase its plant and secure larger quarters.

JAGABI PORTABLE TESTING SET.—James G. Biddle, 910 Drexel Building, Philadelphia, has recently filled an order for ten Jagabi testing sets for the United States Government. A pamphlet description of this very efficient testing outfit has recently been issued, a copy of which may be obtained by application to the above address.

THE JANDUS INCLOSED ARC LAMP manufactured by the Jandus Electric Co., Cleveland, Ohio, has found warm friends in central station men. Economical in current consumption, noiseless in operation, steady in burning and furnishing an ideal illumination, it succeeds in winning business from people who before had declined to use the electric light.

THE CENTRAL ELECTRIC COMPANY, Chicago, reports a brisk trade on the Westinghouse alternating current fan motors, of which it is carrying large quantities in stock. The company also reports a number of new specialties in its house goods department, prominent among which is a new and simple device for electrically lighting the incandescent gas or Welsbach burner.

ELECTRIC SMELTING.—The Burton Electric Smelting Company, 144 Lincoln Street, Boston, Mass., has issued a 32-page pamphlet, giving a full exposition of the Burton processes of electric liquid metal smelting, of heating and working metals by electricity and electrical amalgamation. The several processes are described in detail, and numerous cuts show the various applications.

THE TWENTIETH CENTURY LAMP WORKS of Philadelphia have acquired the rights to manufacture lamps under the Fowler patents. A special feature of this type of lamp is its interchangeable base, no plaster of paris being used—an undoubted advantage to supply houses in renewing their stock. These lamps are equipped with a cellulose filament, and are claimed to be electrically unsurpassed.

PROF. J. J. FLATHER has been appointed Professor of Electrical Engineering in the University of Minnesota. Prof. Flather for the past seven years has been Professor of Mechanical Engineering at Purdue University, Lafayette, Ind., where he built up one of the best courses in mechanical engineering in the country, being particularly strong along the lines of steam engineering and machine design.

THE ELECTRIC GAS LIGHTING COMPANY, of Boston, Mass., has recently built a 260 drop return-call annunciator of the Ross style, for the Indianapolis District Telegraph Company, to be installed in Hotel English, Indianapolis. This is one of a number of large instruments built by this company this spring for hotels in different parts of the country. The company states that its output of annunciators has been exceedingly large the past few months, necessitating running its factory nights to keep up with its orders.

THE SPRAGUE ELECTRIC COMPANY, at its works, New York City, 527 West Thirty-fourth Street, is running day and night upon contracts for interior conduit and Lundell power motors for the Government. The interior conduit manufactured by the Sprague Company is the standard of the United States Government, and it is used not only upon a large number of warships and cruisers, but upon many of the improvised cruisers recently called into service for scouts, torpedo boats and coast defense ships.

GAS ENGINES.—Among recent shipments of gasoline engines for electric lighting purposes made by the Frontier Iron Works, Detroit, Mich., are one 60-h.p. tandem to Sanborn, Ia.; one 50-h.p tandem for Silver City, Ia., and one 50-h.p. tandem for Norway, Mich. The company reports that this engine has shown remarkable results on electric lighting work, the regulation being practically as good as that of a steam engine, and they are now prepared to make all sizes, from 10 h.p. to 100 h.p.

AN IMPORTANT COMBINATION in the rheostat business has just been consummated by the consolidation of the Cutler-Hammer Mfg. Company of Chicago, and the American Rheostat Company of Milwaukee. The business will be carried on under the name of the Cutler-Hammer Mfg. Company, at 70-80 West Jackson Street, Chicago. The capital stock of the combined company has been increased to $75,000, and a large proportion of this increase has been invested in new machinery. The officers of the new company are as follows: F. R. Bacon, president; F. L. Pierce, vice-president; J. G. Hickcox, secretary and treasurer; H. H. Cutler, electrical engineer and general manager.

PIONEER LAMPS.—Kaufman Brothers, of Pittsburg, Pa., have placed an order for over 400 Pioneer inclosed arcs for their new building with the Electric Arc Light Company, 120 Liberty Street, New York. A unique feature of this installation will be the complete lighting of the store with arcs and gas chandeliers. This is the first store in the country to be entirely equipped in this manner. The Pioneer lamp was selected after a three months' competitive test with other makes of inclosed lamps on the market.

THE GOUBERT MANUFACTURING COMPANY, New York, has secured from the Metropolitan Street Railway Company of that city the contract for feed-water heaters for the mammoth power station being erected at Ninety-sixth Street and East River. The first installment consists of 30,000 h.p. in six heaters, horizontal type, and rated at 5000 h.p each. They are to be placed between the low pressure cylinders and the condensers. It is said to be the largest single order for feed-water heaters ever placed in this or any other country.

THE JOSEPH DIXON CRUCIBLE CO., Jersey City, N. J., has secured the following flattering testimonial of the merit of their graphite from an official of the Pennsylvania Railroad Co.: "I had a gas engine at Sharon, Pa., running a pump, and the man that had charge of it allowed the lubricator to run dry and cut the piston, piston rings and cylinder. I had some of Dixon's finely pulverized graphite, and I commenced to feed it into the cylinder through the suction pipe with the air and gas, with immediate relief. After about two weeks the engine was running smoother and using less gas than ever before."

LAMP SHADES AND HOLDERS AND TUBE CLEANERS.—The Faries Mfg. Co., of Decatur, Ill., has recently established an office at 136 Liberty street, New York, under the management of Mr. A. W. Koenig, where a full line of Faries goods may be seen. Among these are a universal adjustable lamp holder, which is made in about thirty different designs of portable and stationary desk and table lamps, side wall fixtures, chandeliers, pendant hall lamps and dental lamps; aluminum and steel lamp shades and reflectors in three styles; fire and water tube boiler cleaners. A comprehensive catalogue may be obtained upon application.

THE OMAHA EXPOSITION OF 1898 surpasses in interest the Centennial Exposition which occurred in Philadelphia in 1876, and is next to the World's Fair at Chicago in importance to the whole country. All of the States in the Trans-Mississippi region are interested, and a visit to Omaha during a continuance of the Exposition, from June to October, inclusive, is recommended to all. Buy your excursion tickets over the Chicago, Milwaukee & St. Paul Railway. An illustrated folder, descriptive of the Exposition, will be sent you on receipt of two-cent stamp for postage. Address George H. Heafford, General Passenger Agent, Chicago, Ill.

A LARGE MILL ELECTRIC PLANT.—The Lyman Mills, which is the largest mill corporation of Holyoke, Mass., employing about 1500 hands, is a progressive concern, and their recent adoption of electric power for the operation of their machinery will undoubtedly have a marked influence upon many other firms in their vicinity. The Westinghouse Electric and Manufacturing Company has installed for the mills a 250-k.w., 440-volt, two-phase, 3600 alternating generator, direct connected to an Allis-Corliss engine running at 120 r.p.m. Six Westinghouse type "C" motors, varying in size from 30 to 75 h.p., are used for the operation of spinning frames, mules, looms, the machine shops, etc.

THE HAZELTON BOILER CO., New York, have orders from the following concerns: Goodyear's India Rubber Glove Manufacturing Co., Naugatuck, Conn., two boilers (third and fourth orders); the New York Mutual Gas Light Co., New York City, two boilers (eighth and ninth orders); the People's Gas Improvement Co., Trenton, N. J., two boilers; the South Middlesex Street Railway Co., South Framingham, Mass, one boiler (third order); A. H. & C. B. Alling, woolen manufacturers, Derby, Conn., one boiler; the Greenfields Electric Light and Power Co., Greenfield, Mass., one boiler (second order); the Brooklyn Union Gas Co., Brooklyn, N. Y., two boilers (eighth and ninth orders), and three boilers for M. Guggenheim's Sons, for their smelting works at Monterey, Mexico. Nearly all of the above boilers will be equipped with the very complete brick lined steel jacket, with square furnace and square grate surface, lately introduced to public use by the Hazelton Boiler Co.

TWO HANDSOME TRAINS—The two splendid trains known as the "Pioneer Limited," which the Barney & Smith Car Company of Dayton, Ohio, has constructed for the Chicago, Milwaukee & St. Paul Ry. Company are now in service between Chicago, Milwaukee, St. Paul and Minneapolis, and it is undoubtedly true that these trains are among the finest products of the car builder's art ever yet exhibited. These duplicate trains consist of the usual mail, express and baggage cars (the latter furnished with bicycle racks and carrying a Westinghouse engine and dynamo to furnish power for the electric lighting of the entire train), buffet, smoking and library cars, standard sleepers, compartment sleepers, dining cars, parlor cars, day coaches and reclining chair cars. The entrance to each car is by way of massive "flush" vestibules, finished in San Domingo mahogany, the elegance of which is but a taste of the splendid display within. All of the cars are electric lighted, steam heated, and the metal finishings are in handsome old bronze made to special design. The method of electric lighting is unique. For emergency, and in addition to the regular dynamo under each car, is located an auxiliary battery sufficient to light a dozen or more lamps in each car. The exterior of these trains is unusually beautiful, all of the cars being painted a deep rich yellow in different shades and finished in gold. The fastest and most powerful locomotives in America are used to haul these superb trains over the Chicago, Milwaukee & St. Paul Railroad, which owns one of the finest roadbeds in the world. . . .

ELECTRIC LIGHT CONVENTION NOTES.

MR. GEORGE CUTTER, of Chicago, interested many in the "Cutter Specialties."

MR. JOHN T. M'ROY, of New York, was present in the interest of the McRoy conduit.

MR. A. W. MORRELL spent a few hours at the convention in the interest of the Miller-Knoblock Company, of South Bend, Ind.

MR. CHARLES E. GREGORY was present, representing the Elliptical Carbon Company, of Chicago and Cleveland.

THE SAWYER-MAN ELECTRIC COMPANY, of Allegheny, Pa., was represented by Mr. Clarence A. Ross, its Western agent.

I-T-E CIRCUIT BREAKERS had their merits brought to the favorable attention of many of the delegates by Mr. H. B. Cutter.

MR. P. C. BURNS, president of the American Electric Telephone Company, was at the convention, where he was warmly greeted.

MESSRS. J. H. M'GILL AND J. G. POMEROY, of Pomeroy & McGill, Chicago, improved the opportunities presented by the convention.

MR. A. R. HUSSEY discussed with several members the advantages of the telephones manufactured by the Allen-Hussey Company, of Chicago.

MR. M. C. JOHNSON looked after the affairs of the Electrical Trading Company, Chicago, dealers in second-hand transformers, etc.

A. L. IDE & SON, Springfield, Ill., manufacturers of the well-known Ideal engine, had their interests well taken care of by their Chicago representative, Mr. Enos Bookwalter.

MR. HENRY SHAFER, of the Stromberg-Carlson Telephone Manufacturing Company, Chicago, was present at several sessions of the convention.

MR. W. E. DOOLITTLE, representing the Sterling Electric Company, of Chicago, made many friends at the convention.

THE CHICAGO INSULATED WIRE COMPANY, Chicago, was represented by Mr. W. M. Smith.

THE CHICAGO FUSE WIRE MANUFACTURING COMPANY, Chicago, sent as its representative Mr. W. R. Goodman.

THE GEORGE M. MAYER MODEL AND MACHINE WORKS, of Chicago, was represented by Mr. Mayer.

MR. T. S. LANE AND MR. R. RALPH LANE represented the Electrical Exchange of Chicago.

MR. W. P. SULLIVAN looked after the interests of the Menominee Electrical & Mechanical Company, of Menominee, Mich.

MR. PHILLIP CASS, of Cass & Aaron, Chicago, looked after the interests of his company at the convention in his usual energetic manner.

MR. JOHN VALENTINE, president of the Valentine-Clark Company, Chicago, dealers in poles, was present at the sessions of the convention.

THE CHARLES E. GREGORY COMPANY, Chicago, had its interests looked after by Messrs. A. Louis Kuehmsted and W. A. Raymond.

MR. A. C. GARRISON, president of the Columbia Incandescent Lamp Company, St. Louis, represented his company's interests at the convention.

MR. C. D. JENNEY was present in the interest of the Jenney Electric Manufacturing Company, Indianapolis, Ind., and was warmly welcomed by many of his old friends.

JAMES C. WORMLEY & CO., Chicago, exhibited a number of very neat designs of portable and bicycle electric lamps working from dry batteries.

THE FARR TELEPHONE AND CONSTRUCTION SUPPLY COMPANY, Chicago, had its interests looked after by Mr. C. W. Farr.

A. O. SCHOONMAKER, of New York, manufacturer of mica and mica products, was represented by Mr. John Child, who exhibited a magnificent sheet of transparent mica.

THE PHOENIX CARBON COMPANY, St. Louis, was ably represented by Col. H. C. Booker, whose genial presence always lends a feature of attractiveness to these gatherings.

MR. THOMAS FERRIS, the Wisconsin representative of the General Electric Company, was present at the convention, where, as usual, he made many friends and was much in demand.

AN INTERESTED ATTENDANT at the convention was Mr. Seiichi Hirota, the London representative of Takata & Company, of Tokio, who are among the largest dealers in electrical and steam machinery in Japan.

THE DODGE MANUFACTURING COMPANY, of Mishawauka, Ind., manufacturers of pulleys and power transmission machinery, was represented by Mr. H. E. Hurlburt, of its Chicago office.

THE LAKON COMPANY, of Elkhart, Ind., was represented by its president, Mr. John C. Boss, who reported a large and steady demand for the well-known transformers manufactured by his company.

THE GARTON-DANIELS ELECTRIC COMPANY, Keokuk, Ia., makers of the well-known lightning arrester bearing its name, was represented at the convention by Mr. W. R. Garton, of Chicago.

THE CABINET MANUFACTURING COMPANY, Steubenville, Ohio, which has recently been doing a great deal of work in the telephone line, was represented by Mr. J. W. Hull.

THE AMERICAN CIRCULAR LOOM COMPANY, Boston, Mass., distributed a highly appreciated souvenir in the shape of a box containing a pipe with tobacco and matches.

MR. W. B. HUGHES, of the Central Manufacturing Company, Chattanooga, Tenn., interested many of the delegates in the yellow pine cross arms, oak brackets and electrical mouldings manufactured by this company.

MR. H. E. PROCUNIER, the president of the Moon Manufacturing Company, Chicago, was frequently seen in the convention hall, and interested many in the annunciators manufactured by his company.

THE JANDUS ELECTRIC COMPANY, Cleveland, Ohio, may be sure that few of the delegates present failed to become acquainted with the merits of their well known line of inclosed arc lamps, which were ably explained by Mr. H. T. Edgar.

THE DEARBORN DRUG & CHEMICAL WORKS, of Chicago, manufacturers of boiler compounds, were ably represented by Mr. C. S. Kehler, who distributed a unique and amusing souvenir in the shape of a red, white and blue cap.

THE DIAMOND ELECTRIC COMPANY, of Peoria, Ill., interested many at the convention in their new alternating current integrating wattmeters, of which they had two on exhibition.

MESSRS. L. A. CHASE & COMPANY, of Boston, distributed some interesting circular matter illustrating and describing the Chase "Knock-out" outlet and junction boxes, as well as their other specialties.

MR. CONVERSE D. MARSH, president of the Bryan-Marsh Lamp Company, interested many delegates in the merits of their Imperial lamps. Mr. Marsh was ably supported by Messrs. S. Everrett Doane and Joseph M. Hill.

MESSRS. F. M. BACON AND J. GILBERT HICKOX, of Milwaukee, formerly of the American Rheostat Company, which has just been consolidated with the Cutler-Hammer Manufacturing Company, Chicago, were present.

MR. JOHN S. MAURER represented interests of the Crouse-Tremaine Carbon Company and the Fostoria Incandescent Lamp Company, Fostoria, Ohio. Mr. B. M. Myers, the Chicago representative of the latter company, was also present at the convention.

THE CENTRAL ELECTRIC COMPANY, of Chicago, was represented by its president, Mr. George A. McKinlock, and Messrs. Charles E. Brown, Charles G. Burton, W. P. Upham and C. W. Cobb, who presented many at the convention with a handsome souvenir consisting of an aluminum ash tray.

THE CRANE COMPANY, Chicago, manufacturers of steam fittings, was represented by its mechanical engineer, Col. G. A. Hurd, whose interests are now equally divided between steam supplies and a volunteer regiment of engineers, which he is raising in Chicago and its vicinity.

MR. F. C. ARMSTRONG, formerly of the Canadian Electric Company, and recently made the London representative of Dick, Kerr & Company, received congratulations from his many friends upon his appointment to the new position, which those who know him are confident that he will adorn.

MR. GEORGE F. PORTER, the genial secretary of the association, found time to attend not only to his manifold official duties, but also to put in a word in the interest of Kerite wires and cables. Mr. W. R. Brixey's interests were also looked after by Mr. E. L. Barr.

THE D. & W. FUSE COMPANY, Providence, R. I., had a number of its fuses mounted with switches, lightning arresters, etc., in the main parlor of the hotel. Their good points were ably presented to those interested by Mr. L. W. Downes and Mr. A. W. Hutchins.

MR. JAMES WOLF, better known to the trade as "Jimmy," represented the New York Insulated Wire Company, New York, and his well deserved popularity secured for him the enthusiastic reception which has greeted his appearance at so many conventions.

THE MANHATTAN GENERAL CONSTRUCTION COMPANY, of New York, had on exhibition two of its latest models of inclosed arc lamps. Mr. S. Marsh Young, vice-president and general manager of the company, explained to the delegates the features of his new lamps.

THE ELECTRIC APPLIANCE COMPANY, of Chicago, was represented by its president, Mr. W. W. Lowe, and Secretary Thomas I. Stacey. The hustling abilities of these well-known gentlemen have won for their company an enviable position in the electrical field and a success of which they may well feel proud.

THE OKONITE COMPANY, of New York, was represented by Capt. W. L. Candee. Capt. Candee did not suffer interest in Okonite to flag during the days he spent in Chicago, and assisted the memories of a few lucky friends with a souvenir, consisting of a very beautiful porcelain miniature, handsomely framed.

MR. JAMES CUMMINGS represented the various interests in which he plays a prominent part, chief among them being the new Cummings Electric Tube Company, of Detroit, which manufactures an underground current of high tension. He also looked after the interests of the Cummings Conduit Company, of Detroit, and the Armorite Company, of Pittsburgh.

THE WAGNER ELECTRIC MANUFACTURING COMPANY, St. Louis, Mo., had on exhibition a switchboard panel furnished with an illuminated dial voltmeter, ammeter and wattmeter with series transformers. Mr. H. A. Wagner, of course, attended the convention, representing the Missouri Edison Company. The Wagner Company's interests were looked after by Messrs. Abadie, Layman, Pillsbury and Johannesen.

MR. G. O. ROCKWOOD, of the Rockwood Manufacturing Company, Indianapolis, Ind., exhibited at the convention some interesting models of the well-known paper pulleys manufactured by his company, which is also engaged in making friction gears and polishing wheels. Mr. Rockwood has just returned one order for over 2000 pulleys.

EUGENE MUNSELL & CO. and the Mica Insulator Company, of New York and Chicago, were represented at the convention by Mr. Charles E. Coleman, their Western manager. The companies' blotters were distributed freely at the writing rooms and various headquarters of the different companies represented at the Auditorium during the convention.

MR. H. H. CUTLER, president of the Cutler-Hammer Rheostat Company, of Chicago, was present to keep up the interest in rheostats, motor controllers, starting switches, speed regulators and the other well-known auxiliaries manufactured by his company. Mr. Cutler said that his factory is working on full time, and that every indication points to a prosperous season.

THE SPRAGUE ELECTRIC COMPANY, New York, was represented by its president, Mr. E. H. Johnson, and Mr. C. A. Benton. Mr. Johnson is a familiar figure at electric light conventions, having been one of the early presidents of the association and a charter member. A number of fan motors exhibited by this company did excellent service in the corridors of the Auditorium.

THE WESTERN ELECTRIC COMPANY, Chicago and New York, exhibited a number of fan motors and "Sunbeam" incandescent and arc lamps. Mr. C. D. Crandall, manager of the Chicago office; Mr. A. L. Tucker, manager of the supply department; Col. George L. Beetle, Thomas J. Grier, L. K. Comstock, J. W. Ebert and Charles Wilkinson were in attendance.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING COMPANY, Pittsburgh, exhibited a number of high voltage and other types of Sawyer-Man lamps. The company was well represented by Messrs. F. H. Taylor, general sales manager; Maurice Coster, manager of the Chicago office; A. J. Wurts, A. S. Morris, H. A. Ebert, Henry Floy and a number of members of its Chicago force.

J. HOLT GATES & CO. were represented at the convention by J. Holt Gates, George B. Foster and C. H. Philbrook. This firm handles the apparatus of the Walker Company, of Cleveland, Ohio; of the Wagner Electrical Manufacturing Company, of St. Louis, Mo., and the Card Electrical Company, of Mansfield, Ohio. They report the sale last month of 1900 k.w. of generators, besides numerous switchboards, street railway equipment and other electrical details.

THE STERLING ARC LAMP COMPANY, New York, exhibited a number of its inclosed arc lamps under the supervision of Mr. R. J. Randolph, its general manager. These lamps, of a new and very simple design, were shown in operation and as adapted for constant potential and series systems, both direct current and alternating. To insure the remembrance of his visitors Mr. Randolph provided each of them with a combined pencil and cigar cutter, one of the neatest souvenirs given at the convention.

THE WALKER COMPANY, of Cleveland, Ohio, was represented at the convention by J. Holt Gates, George B. Foster, C. H. Philbrook and F. H. Talbot, of the Chicago office. Many of the delegates were interested in the new alternating system of the Walker Company, as well as its new Solenoid Blow-out Controller; also the "L" type of street railway motor of 150-h.p., twenty of which are being supplied the Metropolitan Elevated RR. of Chicago. Many of the visitors called at the new station of the Chicago City Railway, which is designed for fifteen 880 k.w. Walker rope driven generators.

THE ELECTRIC STORAGE BATTERY COMPANY, Philadelphia, made no exhibit at the convention hall, but previous to the date of the meeting had extended an invitation to those attending to visit the station of the Chicago Edison Company and there inspect the large battery recently installed. Most of those in attendance accepted the invitation, and were repaid by the interesting sight of the operation of the largest storage battery in the world—22,400 amp. hours at normal discharge. The representatives of the company present were Messrs. Herbert Lloyd, general manager; J. Appleton, chief engineer, and F. J. Clark, of the Chicago office.

THE GENERAL ELECTRIC COMPANY did not make an exhibit, but took several parties of delegates to visit the various great stations in Chicago equipped with its apparatus. Through the courtesy of President Insull, of the Chicago Edison Company, and Mr. W. E. Baker, of the Metropolitan West Side Elevated Railroad Company, the stations of both these companies were thrown open to these parties, and much interest was manifested. Attention was particularly directed to the converter sub-station system which Mr. Insull has inaugurated in Chicago. The representatives of the company present comprised the entire selling staff at its Chicago office, and several representatives from the offices in other cities. Among them were Messrs. B. E. Sunny, F. H. Boyer, Theodore P. Bailey, J. Scribner, W. S. Arnold, W. J. Ferris, G. J. Caldwell, J. W. Buell, J. W. Johnson, R. C. Noe, O. E. Turner, A. J. Gifford, S. H. Atkin, H. T. Windsor, S. F. Dibble, W. H. Colman and J. J. O'Brien, of the Chicago office; P. A. Clisdell, of the Minneapolis office; George D. Rosenthal, of the St. Louis office; J. H. Livsey, of the Detroit office; W. F. Hays, W. J. Hanley and I. R. Prentiss, of the Cincinnati office; F. M. Kimball, of the Boston office; H. H. Crowel, of the Syracuse office; W. S. Andrews, of the Schenectady works; J. Dalzell, of the Lynn works; A. D. Page, of the Harrison works, and John McGhie, of the New York office.

THE FOLLOWING COMPANIES were also represented at the convention: Messrs. K. McLennan & Co., of Chicago; Cravath Manufacturing Company, Chicago, by J. R. Cravath; Washburn-Moen Manufacturing Company, Worcester, Mass., by Mr. Channing T. Gage, of the St. Paul office; New York & Ohio Company, Warren, Ohio, by Mr. W. D. Packard; Davis Electrical Works, Springfield, Mass., by Mr. Charles F. Munder; Indiana Rubber & Insulated Wire Company, Jonesboro, Ind., by Mr. R. E. Lucas; Munson Belting Company, Chicago, by Col. J. H. Shay; Simplex Electrical Company, Boston, Mass., by Mr. H. R. Hixson, of the Chicago office; Bradford Belting Company, Cincinnati, Ohio, by Mr. O. M. Hubbard; H. B. Camp Company, Aultman, Ohio, by Mr. A. L. Daniels; Zamel Arc Light Meter Company, of Chicago, by Messrs. A. G. Zamel and Charles C. Schumacher; Charles A. Schieren & Co., of New York; by Mr. A. W. Watriss; Warren Electric & Specialty Company, Warren, Ohio, by Messrs. W. S. Hull and E. W. Gillmer; Perkins Electric Switch Manufacturing Company, Hartford, Conn., by Messrs. C. G. Perkins and Edward K. Patton; Royal Electric Company, Peoria, Ill., by Mr. G. G. Luthy; American Battery Company, Chicago, by Mr. George T. Burroughs; India Rubber & Gutta Percha Insulating Company, New York, by Dr. William M. Habirshaw; Standard Underground Cable Company, Pittsburgh, Pa., by Mr. J. R. Wiley; American Electric Heating Corporation, Boston, by Mr. James I. Ayer; American Carbon Company, Noblesville, Ind., by Messrs. Edmund Dickey, A. T. Webb and A. J. Blum; Southwark Foundry & Machine Company, Philadelphia, by Mr. Edward M. Hagar, its Chicago representative; Bryant Electric Company, Bridgeport, Conn., by Mr. Edward R. Grier, its Western manager; Illinois Electric Company, of Chicago, by Mr. H. E. Adams; Phoenix Carbon Manufacturing Company, St. Louis,

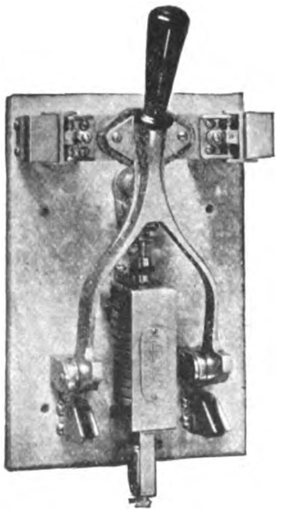
CIRCUIT . . BREAKER . INSURANCE

Can you afford to place your insurance in a company of which you know nothing, or in a company of which the little you know is not likely to increase your confidence? Buying a circuit breaker is like buying insurance. Fire Insurance is a needless expense if you are sure you will have no fire. It's the same with a circuit breaker, if you are sure you will have no grounds, no short circuits, no damage from your wires being struck by lightning, you don't need a circuit breaker. But you cannot be sure, therefore a circuit breaker is a necessity.

I-T-E CIRCUIT BREAKERS



Single Pole only for Alternating Current. Front or Back Connections 5 to 200 Amperes; 2000 Volts or less.

give you a feeling of confidence. They cost little and are absolutely reliable. They are in use in lighting and power stations all over the country. We will be glad to send you a catalogue and full information.

The CUTTER ELECTRICAL & MFG. CO.,
1112 Sansom St., Philadelphia, Pa.
120 Liberty Street, New York.

Mo., by Col. S. G. Booker; Smith-Hill Elevator Company, Quincy, Ill., by Messrs. C. G. Comstock, Thomas Holl and H. S. Wells; M. C. Bullock Manufacturing Company, Chicago, Ill., by Mr. John Svenson; Atlas Engine Works, Chicago, Ill., by Mr. A. M. Morse; T. H. Carbon Company, of Boston, Mass., by Mr. D. F. Urquhardt; Solar Carbon & Manufacturing Company, Pittsburgh, Pa., by Mr. H. E. Webb; Chicago Sectional Underground Electric Company, by C. H. ◆

NORTHWESTERN CONVENTION NOTES.

MR. C. S. KNIGHT, of the Fort Wayne Electric Corporation, Fort Wayne, Ind., secured many new friends among the delegates for the apparatus of his company.

THE NEW VITRIFIED CONDUIT of the H. B. Camp Company, Aultman, O., was brought to the attention of many delegates interested in underground work, by Mr. A. L. Daniels.

CAPT. W. L. CANDEE AND MR. G. T. MANSON, of New York, enjoyed the trip and put in many a good word for Okonite wire.

THE SPRAGUE ELECTRIC COMPANY, New York, had its interests looked after by its Chicago representative, Mr. E. B. Kittle.

THE JANDUS AND BUCKEYE LAMP interests were well taken care of by Mr. H. F. Edgar of Boston, Mass.

THE BRYAN-MARSH COMPANY, New York, was represented by its president, Mr. C. D. Marsh; Supt. S. E. Doane, and Mr. J. M. Hill, of the Western office.

MR. W. D. PACKARD, of the New York & Ohio Company, Warren, O., made many new friends among the delegates for the well-known Packard lamps.

THE COLUMBIA LAMP COMPANY, St. Louis, Mo.—Although Secretary Garrison was unable to take the trip, the company's interests were well taken care of by Mr. Geo. Rex, of the Chicago office.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING COMPANY was well represented by Mr. Arthur Warren, of the Department of Publicity and Promotion, and by Mr. A. J. Wurts, the well-known inventor of the Wurts lightning arrester, manufactured by the Westinghouse Company.

MR. E. H. ABADIE, of the Wagner Electric Manufacturing Company, St. Louis, Mo., made the round trip in the interests of his company. Mr. H. A. Wagner had many friends among the delegates who regretted that he was compelled to leave the party at Milwaukee.

MR. GEO. A. McKINLOCK, president of the Central Electric Company, Chicago, left the ship at Houghton. The interests of his company, however, were well taken care of during the entire trip by Mr. W. P. Upham.

THE DEARBORN DRUG & CHEMICAL WORKS, Chicago, was represented by Mr. Robt. F. Carr, vice-president and general manager, and Mr. C. S. Keeler. This company has met with well-deserved success, owing to the gratifying results secured by those who have adopted its methods of treating boiler scale.

MR. THOS. I. STACEY, of the Electric Appliance Co., Chicago, and Mr. B. B. Downes, the company's Minneapolis representative, contributed in no small degree to the success and enjoyment of the trip.

MR. F. N. PHILLIPS, president of the American Electrical Works, Providence, R. I., and the company's Chicago manager, Mr. F. E. Donohoe, enjoyed the trip immensely.

THE WESTERN ELECTRIC COMPANY, Chicago, had one of its new inclosed arc lamps, without outer globe, hung in the main saloon. Mr. C. D. Wilkinson and Mr. L. K. Comstock explained its advantages to many interested delegates.

New Wabash
Fast Train East.

"The Continental Limited," a new fast train on the Wabash, now leaves Chicago daily at 12:02 noon, and arrives at Buffal › 5:00 A. M., New York 3:30 P. M. and Boston 5:50 P. M next day, with through car service. Ticket office, 97 Adams Street.

The Belknap Motor Co.

OF PORTLAND, ME.,

is very busy at the present time. They are just installing one 40 k.w. direct connected generator and engine in the new building of the Y. M. C. A., Portland, Me. They are also putting in a direct connected electric passenger elevator at the Falmouth Hotel, Portland, Me., in place of an hydraulic formerly in use. They have just completed an electric direct connected freight elevator for the Portland Packing Co., taking out an hydraulic. A hand elevator at E. D. Pettingell's Pickle Works, Portland, has just been taken out and a new direct connected electric has been put in its place by this company. They are also completing a new electric freight elevator for L. B. Griffin, produce dealer, Portland, Me., and have just received order for a direct connected electric elevator for the Hotel Jocelyn, Prout's Neck, Me.

Their direct connected elevator business has become very large; they have installed more elevators in Portland and vicinity in the last two years than all other companies combined. An electric conveyor for discharging vessels has just been installed by them for the Maine S. S. Co., and they have a contract from the same company for a second one. They had previously installed one for the International S. S. Co. at Eastport, Me.

The Chapman Voltage Regulator, manufactured by the Belknap Motor Company, is getting to be one of the most important parts of their business. The Mt. Morris Elec. Co. of N. Y. City, ordered two several months ago, and so well satisfied were they with the results accomplished by their use that they placed their order for seven more, all of which have been shipped to them.

The People's Elec. Co. of Orange, N. J., put in one several months ago, and liked it so well that they have placed their order for a second, which is about ready for shipment.

Frank Jones Elec. Lt. Co. of Portsmouth, N. H., has placed order with them for three of the No. 1 type, which are to be finely finished and erected on pink Tennessee marble, which will be in keeping with the balance of the plant.

A TECHNICAL EDUCATION
50 CENTS A WEEK

THE new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary text-books.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 43 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

THE "CLARK" WIRE

In a Letter from the Inspector of the Boston Fire Underwriters' Union, he states:

"A Thoroughly Reliable and Desirable Wire in Every Respect."

For Switchboard, Railway and Motor use, we make all sizes of Stranded and Flexible Wire and Cables with Clark's Insulation.

The Clark Wire has been before the public and in use for the past nine years, and has met with universal favor. Thousands of miles of this wire have been sold, and are in use throughout the United States and foreign countries, and the demand for it is constantly increasing, because it always gives perfect satisfaction.

The Rubber used in insulating our Wires and Cables is especially chemically prepared and will not deteriorate, oxidize or crack and will remain flexible in extreme cold weather, and is not affected by heat.

We guarantee our Insulation wherever used, Ærial, Underground or Submarine, and our net prices are as low, if not lower, than any other first-class Insulated Wire.

We shall be pleased to mail catalogues with terms and discounts for quantities.

SITUATIONS WANTED.

SITUATION WANTED as a lineman by a first-class workman in all branches. Can give best of reference. Address LINEMAN, care AMERICAN ELECTRICIAN, Havemeyer Building, New York.

POSITION WANTED as assistant electrician in plant or shop. Advertiser is a young man, unmarried, 20 years old; has studied electricity at college and has had practical experience. Satisfactory references from last employer. Address M. F. G., care of AMERICAN ELECTRICIAN, Havemeyer Building, New York City.

SITUATION WANTED as superintendent of railway or lighting plant. Eight years' practical experience, technical education, and first class references. Have done electrical work, steam engineering, car and line work, track building, schedule making, and draughting. Can operate plant at least possible expense. Address "A. B.", care of AMERICAN ELECTRICIAN Co., Havemeyer Building, New York City.

WANTED.—By a competent young man a position with a telephone company or manufacturer. Practical experience in exchange and line construction. Thorough knowledge of instruments. Can furnish references as to character and ability. Address "COMPETENT," care of THE AMERICAN ELECTRICIAN, Havemeyer Building, New York City.

POSITION WANTED.—I wish to act as an assistant to an electrician in the manufacture of dynamos and motors in the vicinity of New York or Philadelphia. Having gone through the W. E. & Mfg. Co.'s works as a student, besides one year's experience in a small shop, I am familiar with the practical side as well as theoretical. Am at present with the Westinghouse Co., but want to get in a small shop. Best of references. Write me. "FAITHFUL," care of AMERICAN ELECTRICIAN Co., New York, N. Y.

FOR SALE.

FOR SALE.—One 60-h. p. New York Safety High Speed Engine; also one 32-k. w. Brush 2,000 Volts Alternator; both in first-class running condition. Reason of selling: Larger machinery was required and installed. ELMHURST ELECTRIC LIGHT & POWER Co., Elmhurst, Ills.

LOCOMOTIVE DUMMY FOR SALE. Built by the Baldwin Locomotive Works; in good condition; 4 feet 8½ inches gauge; weight on driving wheels 24,000 pounds; cylinders, 9x12; driving wheels, 30 inches outside diameter. Will be sold cheap. Dummy can be seen and specifications of same can be obtained from PASSAIC LIGHTING COMPANY, Passaic, N. J.

TRANSFORMERS

Bargains in Transformers of all sizes and manufacture. Satisfaction guaranteed.

All kinds of Electrical Supplies at ruling market prices.

STORAGE BATTERIES IN THE CUSHMAN BUILDING.

THE modern office building is absolutely dependent upon an efficient heat, light and power service. In the congested business districts of our metropolitan cities, the conditions under which such structures are a possibility demand not only the highest perfection in architectural construction, but also require a correspondingly complete and elaborate mechanical and electrical service, without which their existence would be impossible.

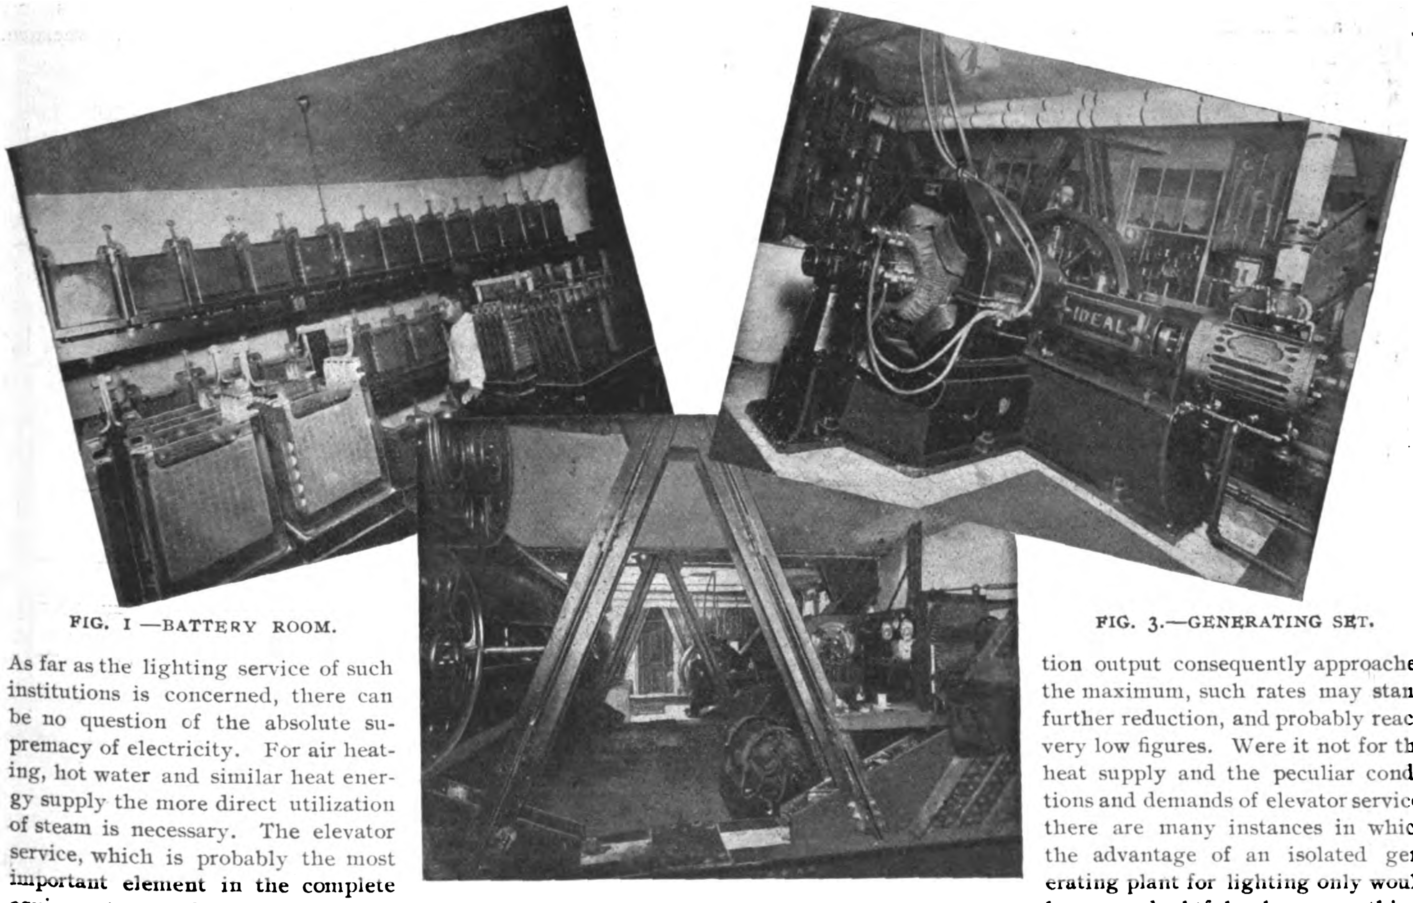

FIG. I —BATTERY ROOM.

FIG. 2.—GENERAL VIEW OF PLANT.

FIG. 3.—GENERATING SET.

As far as the lighting service of such institutions is concerned, there can be no question of the absolute supremacy of electricity. For air heating, hot water and similar heat energy supply the more direct utilization of steam is necessary. The elevator service, which is probably the most important element in the complete equipment, may depend upon either steam, hydraulic or electric power.

It is scarcely necessary to here discuss the relative merits of these methods. Ample experience has already demonstrated the value of the electric elevator, and many of its peculiar features are most strikingly illustrated in this novel installation which is the subject of this article. For ventilating purposes electric power is displacing in many instances all steam machinery for this purpose. It will therefore be seen that neither steam nor electricity can meet the demands alone, and it is only by a most careful combination that efficient results can be obtained.

Whether all or part of this heat, light and power service can be most economically and satisfactorily obtained from a private isolated generating plant or from a central station supply system is a question the solution of which is entirely dependent on the specific conditions in each particular case. Much has been said regarding the relative advantages of electric current supply from isolated plants or central stations. Yet the experience seems to indicate that, taking such service as a whole, the selling price of electricity supply from central stations must be very materially reduced before any very notable change will result in the installation of isolated electric generating plants. Electric supply central stations, operating large units combined to produce the maximum economy, can unquestionably generate electrical energy at a smaller cost per unit than it could be produced in the very much smaller isolated plant. The actual selling price to the consumer, however, is dependent on so many other considerations that it is only in the case of very large services that the rate can be reduced to figures which are at all enticing when compared with good isolated plant practice. Certainly as the demand on a certain station increases and the station output consequently approaches the maximum, such rates may stand further reduction, and probably reach very low figures. Were it not for the heat supply and the peculiar conditions and demands of elevator service, there are many instances in which the advantage of an isolated generating plant for lighting only would be very doubtful when everything, including space, interest, labor, depreciation and repair are considered. Central station electric service, where the elevator work may be ignored, or is a small item, undoubtedly presents many decidedly advantageous features.

As compared with the central station service, it may be noted that an isolated steam plant used for steam-hydraulic elevator service can, in many cases, with but a comparatively small additional outlay, and perhaps no additional labor expense, supply electric generating units. Here the steam-hydraulic elevator service constitutes the power and heating plant proper, of which the lighting element is but an auxiliary. The advantage and superiority of the electric elevator being acknowledged, a steam-electric generating plant which supplies light and power from one efficient set of generating units and heat from the exhaust steam energy used therein must certainly prove to be the best arrangement of isolated heat, light and power plant that will be most likely to combat central station encroachment.

FIG. 5.—PLAN OF INSTALLATION.

The difficulties associated with the installation of a high pressure steam plant in buildings of the kind under consideration frequently overbalance the actual economy of operation of the isolated steam plant, and result in the adoption of central station electric service and perhaps a low pressure isolated steam heating service. Where, as in New York City, central station steam service can be obtained, it may even be advisable to adopt steam and electric central station supply, adopting an elevator service (either steam-hydraulic or electric) which best meets the conditions and can be most economically operated. On first consideration it would seem almost improbable that central station steam service, transformed at the customer's premises to electrical energy which is used for light and elevator service, while the exhaust is used for heating, would prove an economical and satisfactory combination. Yet a recently completed office building in this city has been equipped in this manner, and the apparent results have thus far been excellent.

The structure served in this novel manner is known as the Cushman Building, and is located at the northeast corner of Broadway and Maiden Lane. The lot occupied by the building measures 25 ft. x 50 ft. It is 13 stories in height, including the ground floor with basement, and sub-basement beneath. Each floor has five office rooms, with three stores on the ground floor. The foundation consists of five caissons topped by grillage beams, traversely across which five very heavy truss girders are placed—one every 12 ft. along the 50 ft. Maiden Lane side. The building proper rises above these girders in the standard iron skeleton construction. The adoption of the truss foundation beams was due to the desire to save this sub-basement space for vault purposes, but it is now occupied by the various machinery, and serves as the engine, elevator and storage battery room. The available space for machinery can readily be imagined when it is known that the originally small plot has not only been decreased by the foundation walls, but is cut up into four small divisions by the traversely placed trusses, each division measuring 12 ft. x 24 ft. The difficulty of moving machinery into this space, which is only 10 feet in height, can also be appreciated. The disposition of the machinery has, however, been so compactly arranged that the engine room, with its tiled flooring and enameled brick machinery foundation piers, has a "well put together air" about it.

The service to be supplied consists of about 500 incandescent lamps, two passenger elevators, heating and ventilating apparatus. The machinery arrangement for this service is shown in the diagram, Fig. 5 giving a plan of the engine room. A steam service from the New York Safety Steam Power Company's plant enters the building on the Maiden Lane side. The 3-in. service pipe connects with the standard meter of the steam company, and passes from thence to the engine. The piping arrangement also permits a supply of live steam to the heating system through a reducing valve, when necessary. The single steam electric generating unit consists of a direct connected Ideal horizontal engine and an Eddy multipolar dynamo operating at 300 r.p.m. This unit is shown in Fig. 3. The engine cylinder measures 7 ins. x 10 ins., and gives an output of about 25 h.p. at 80 lbs., which is the pressure of the steam supplied from the street service pipe. The dynamo is of the standard four-pole type, developing 20 k.w. at 230 volts. The exhaust from the engine passes through a 4-in. exhaust pipe, properly connected with the heating system and an exhaust head on the roof. All water of condensation, drip, etc., are handled by an automatically governed pump, which arrangement is made necessary by the fact that the engine room is below the sewer line. Hot water is supplied from a heating tank in which live or exhaust steam can be used.

The successful operation of the plant is really dependent upon the storage battery equipment, which, working in conjunction with the 20-k.w. dynamo, makes it possible to supply the varying elevator demands. This storage battery equipment occupies one of the previously mentioned end sections, and is separated from the engine room by a glass windowed partition wall. This part of the plant consists of 118 type 9F cells, furnished by the Electric Storage Battery Company, of Philadelphia. Each cell has four positive and five negative plates, measuring 10½ ins. x 10½ ins. The positive plates are of the Manchester type. These storage cells are mounted on wooden supporting tiers, each glass battery jar being placed on glass insulators. The cells are all permanently connected in a single series and have an output of 320 amp.-hours at a normal discharge rate of 40 amps.

This combined electric generating and storage equipment supplies about 500 16-c.p. incandescent lamps, located throughout the building; two Sprague screw and multiple sheave electric elevators, together with several pump and ventilating motors.

The operation of both lights and elevators from the same connected generating dynamo and storage battery at 230 volts gives excellent service, notwithstanding the exceedingly heavy starting currents required for the elevators.

Leads from the dynamo, battery elevators and the lighting mains are brought to the switchboard, which is located in one of the sections, as shown in the illustration. The main switchboard consists of two marbleized slate panels, centrally placed side by side between the two elevator regulator panels, which are set at a slight angle therewith. See Fig. 4. The left half of the main board is devoted to dynamo power and lighting circuit controlling switches and appliances, and the right panel is equipped with the storage battery switches, circuit breaker and booster regulators.

The arrangement of the switchboard permits of operating the elevators or lights separately on either the battery or dynamo. Separate ammeters and voltmeters are provided for each section of the switchboard, and a break down switch, controlling the bus bars, from which both light and power leads are taken, permits of operating the plant from a street service instead of the dynamo in case of necessity. All the lighting and power switches are arranged on the upper part of the left section. The storage battery section of the board is arranged so that the batteries are interposed between the lighting and elevator service, the potential of the lighting bus to which the dynamo is connected being "boosted" up while they are being charged.

The booster for this purpose is of General Electric manufacture, and is set immediately in front of the switchboard. It is of the separate and direct connected motor driven dynamo type. The motor and dy-

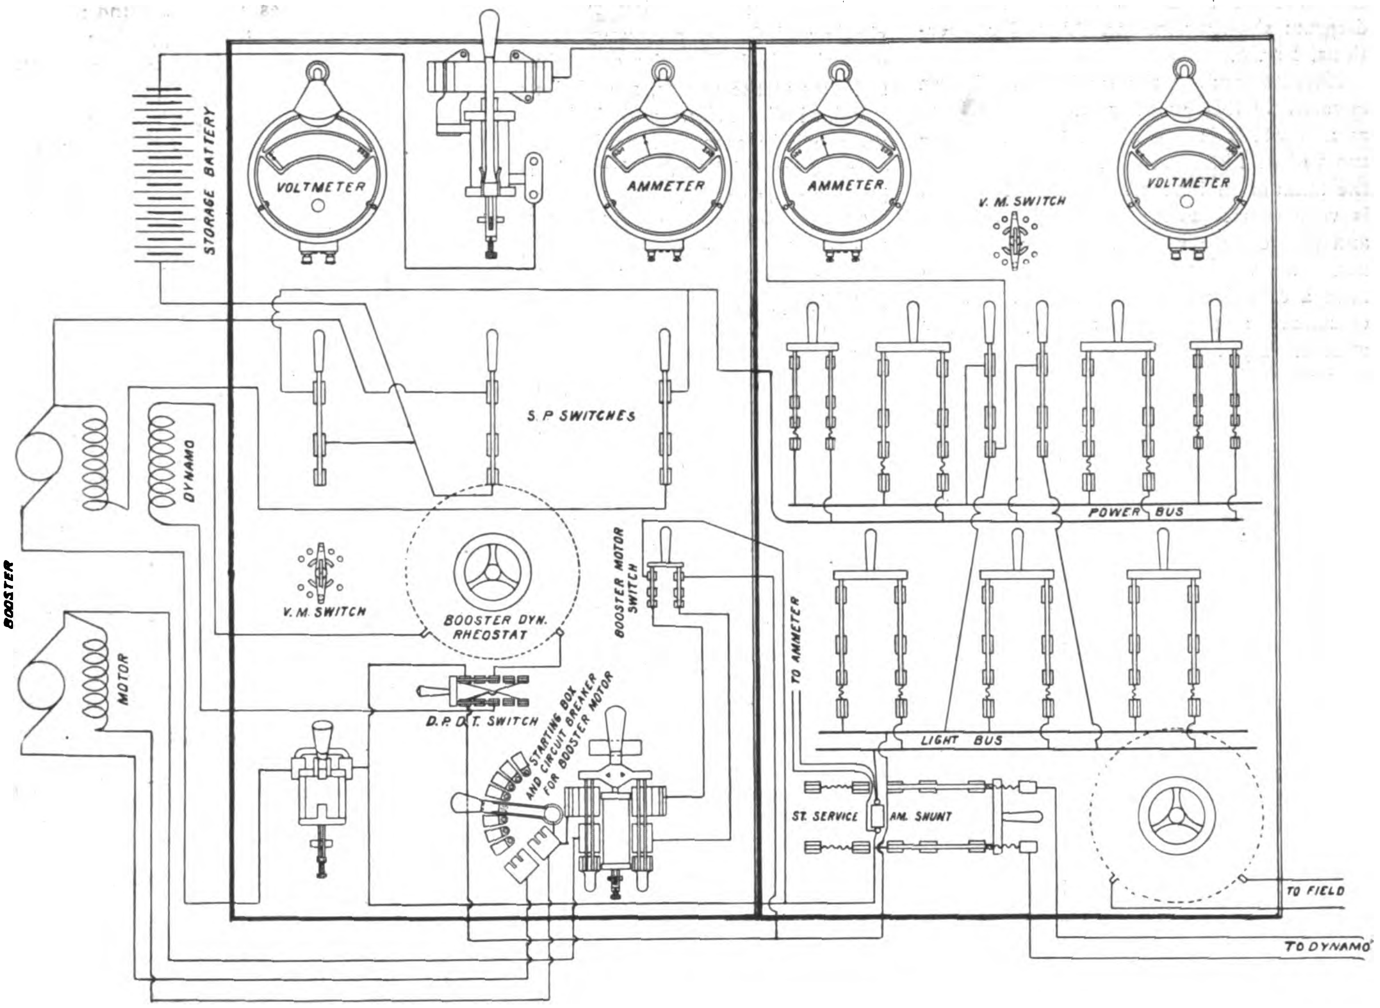

FIG. 6.—DIAGRAM OF SWITCHBOARD CONNECTIONS.

namo are both multipolar, operating at about 800 r.p.m. Current for the shunt motor is supplied from the battery at 230 volts. The booster dynamo proper has a differential shunt and series winding, the latter being in series with the armature in charging from the dynamo, while the shunt field is connected in shunt across the bus. At times, after the battery has been fully charged, its potential is too high to operate the lamps. Suitable switches are therefore provided so that the connections of the shunt booster field may be reversed and its potential used to "buck" against the battery and lower the voltage supplied to the lamp bus when the engine and dynamo have been stopped. The detail connections and various possible arrangements of the different apparatus is shown in the diagram showing the switchboard connections, Fig. 6.

Notwithstanding the small ground area covered by this building and the fact that as a whole it is one of the "bijou" structures of its kind, yet owing to its location the amount of business transacted therein is very great. For this reason an ample and first class elevator service was essential. The two passenger elevators provided have a capacity of 2200 lbs. each, and the cars travel at the rate of about 300 ft. per minute. The hoisting machines are of the Sprague multiple sheave screw and sliding nut type, and were supplied by the Sprague Electric Company. Each machine is equipped with a 35-h.p. motor. They are 28 ft. in length and are arranged double deck—one on top of the other. In but few similar installations can such a striking exhibition of the superior features and absolute flexibility of the electric elevator be found. In fact, not only is the observer in doubt as to how the machines were placed, but he is also impressed with the undoubted fact that no steam-hydraulic elevator machinery could perform the same high class service in the space devoted to these electric machines.

The screw and sliding nut type of Sprague electric elevators is so well known that a description is unnecessary here. As the motors take current in hoisting only it is quite obvious that these machines cannot be load counterbalanced, or, as it is commonly termed, over counterbalanced, and therefore require larger starting currents than in the case of over counterbalanced machines. While this peculiarity of these elevator machines would, if street service or dynamo service alone were used, be objectionable when both lights and elevators are operated from the same bus, yet with the combination as here existing the variation in the lamp service with power and lights connected together is practically inappreciable when the battery and dynamo are serving as a unit. The satisfactory and economical operation of the plant and the fact that steam service used in this indirect manner has proven itself more desirable than either more direct steam machinery or electric street service is due to the fact that the electric elevator only takes current corresponding to its load, and the peculiar ability of the storage battery to average this varying demand.

All wires throughout the building, including the engine room, are run in "Armorite" (wood lined iron conduit.) Feeder circuits run from the switchboard to centers of distribution on the first, fifth and eighth floors. From these centers vertical mains run up and down, connecting with slate distributing panels on each floor, to which the several branch circuits are connected. Iron outlet boxes are used and the combination fixture wires are direct connected. The feeders are No. 6 B. & S.; the branch wires No. 14. Notwithstanding the small wire sizes used for the two wire mains and feeders, the loss from the switchboard to lamps is only 2 per cent. A single separate power main is also run to the top floor with a connecting outlet box on each floor. The wire used is the ordinary Simplex rubber covered single and duplex conductor, and the accessories, including the small fused knife switches at the panels, are of the ordinary standard dimensions and design. In fact no specially arranged devices have been deemed essential to satisfactorily serve 230 instead of 110 volts.

The water pumping service of the building consists of a small direct connected electric pump, operated by a 1-h.p. Lundell motor. Ventilating apparatus for so small a building with two sides exposed is entirely unnecessary, but a large direct connected fan ventilator is being installed in the engine room.

As far as the operation of the plant is concerned, it is quite obvious that since its completion several months ago the elevator service has been the main item. Owing to the small lighting load during the summer it has been unnecessary to run the dynamo continuously during the day, as is intended when the current demand warrants. At the present time the dynamo is operated from 8 A. M. to 1 P. M. feeding the battery, and in conjunction with it, supplying both light and power. From 1 to 4 P. M. the dynamo is shut down, and the battery used alone. From then until 6 P. M. the dynamo and battery are again operated together.

As the elevators descend without any current consumption and are operated so that one is ascending while the other descends, the current supply for this purpose is limited to the demands of the hoisting machine only. The character and magnitude of the demand can readily be appreciated from the fact that 125 amps. are required to start and 80 amps. to run each fully loaded car in ascending.

The adoption of this novel combination of—as it may well be called—central station and isolated plant service seems to be based entirely upon economical reasons. The operation of the plant up to date, with reasonable allowance for the increased winter heating and lighting load is claimed by the engineers, Messrs. Osterberg & Sutton, to indicate the correctness of their selection. A comparison of the following figures apparently shows a saving in favor of the steam-electric service as here adopted. They are furnished by the engineers who received the various proposals for each particular service for comparison.

Two electric central station supply companies would furnish street service current at 10c. per k.w.-hour, with a guaranteed minimum consumption of $250.00 per month. This rate included light and power service, with electric elevator machinery. Taking the minimum guarantee price as the probable value of the current consumption and allowing twenty-five service days per month, the cost per day would be $10, which, at the above rate (10c. per k.w.-hour) would mean a consumption, per day of ten hours, of 100 k.w. for that time. This figure is claimed to be lower than the actual average demand for all seasons will prove to be, and while it includes light and power the heating and hot water supply of the building still required separate consideration.

The installation of a steam-hydraulic elevator service was considered, and a proposal from the steam supply company gave the following flat rates, which were based on the probable steam consumption in such machinery at the rate of $60 per h.p. per year of ten-hour service days. For the elevator service, $1400 per year, and for heating service, $500 per year was asked. This proposition on the other hand did not consider lighting. Electricity for the lighting service of this 500 16-c.p. installation would be rated at figures coming close to the regular retail rates (1c. per 16-c.p. lamp hour).

Taking, therefore, the electric central station service minimum guarantee rate and adding the $500 for steam heating service, the cost per year would have been $3500.

In case steam-hydraulic elevator service had been adopted the cost for this service and heating would be $1900 per year, with an additional amount of probably $600 or more per year for lighting and pumping, making a total of $2500.

In both of the above proposed central station services lamp renewals are included, but the labor and repair account would hardly be much less than with the present system. The superintendent of the building now serves as engineer, and has an assistant, and the additional items of repair and maintenance are the dynamo, engine and battery equipment. The plant has been in actual service for over two months with almost every office and all stores occupied. The bills for steam at the rate above mentioned, measured by meter, was for May, $70, and for June, $80. Allowing for the heavier lighting load during other months and the partial use of live steam for heating, if the exhaust should be insufficient, $100 per month would be a safe, in fact a large, figure to allow for the average monthly rate, making $1200 per year. In fact it is claimed that, allowing a fair amount for other items, a saving of over $500 in the cost of the heat, light and power service has been effected.

This novel installation will be watched with great interest. Osterberg & Sutton were the consulting and supervising engineers for the complete installation. The electrical work was installed by P. M. Mowrey & Company.

THE "SOO" WATER POWER.

Lake Superior has an area of about 30,000 square miles. Its mean outflow over the Sault Rapids section is about 90,000 cubic ft. per second. Its mean elevation is 601.5 ft. and the elevation of the Sault River below the rapids 582 ft. In the past there have been some attempts to develop this natural power. Some have failed and others have been partly successful. It has been left to the organization of the Lake Superior Power Company, the present owners of the water power privileges on both sides of the Sault Rapids, to compass the magnitude of the opportunity by a project which is worthy of it. The company consists for the most part of Eastern capitalists and manufacturers. The present officers of the company are: Mr. E. V. Douglas, of Philadelphia president; Mr. F. H. Clergue, of Bangor, Maine, vice-president; Mr. W. P. Douglas, of Philadelphia, treasurer. The company's headquarters are at 1420 Chestnut Street, Philadelphia, Pa. To Mr. Clergue belongs the credit of securing the operating privileges of the water power on both sides of the rapids, and under his guidance the company developed the power on the Canadian side, completing the hydraulic canal with the necessary construction capable of yielding 20,000 h.p. and a 40-grinder pulp mill. Over $1,000,000 has been expended in less than three years on the Sault water power. Within recent times additional right of way has been secured on the American side, but the prevailing unfavorable conditions for new industrial enterprises acted as an effective damper until the advent of a new commercial commodity made it possible to enter upon the construction of the greater Sault water power on the American side.

FIG. 1.—MAP OF CANAL.

The Union Carbide Company, a concern which controls the manufacture of calcium carbide over a large portion of the United States, have made arrangements with the Lake Superior Power Company for an enormous carbide plant to be located at the Sault and requiring for a starter 20,000 electrical h.p. This the American Lake Superior Power Company have contracted to deliver at a not distant date. The remaining power to be developed, or at least a portion of it, will probably be devoted to the electrical reduction and concentration of the various silver and nickel ores, which the country north of the Sault is rich in.

The hydraulic part of this project is to divert a certain volume of water over the most direct and economical route between the upper and lower levels in sufficient measure to yield 40,000 mechanical h.p. at the turbine shafts. The Lake Superior Company came into possession of a right of way for canal location, which was selected some ten years ago by a now defunct organization. This location has been since regarded as a water power canal, if the old excavation and incomplete timber revetment entitles it to this distinction. In a measure this location is the logical one, for the intake from the upper level is fixed by conditions created by the existence of a Government ship canal. For this reason the canal must continue easterly to some point below the rapids. The old company located the canal easterly from Ashmun Bay, south of the southwest ship canal pier, for a distance of several miles to a point below the rapids, and this location represented a right of way from 150 to 400 ft. wide, which had to be acquired by the present company in order to secure the franchise and carry out the project.

FIG. 3.—POWER HOUSE FOUNDATION.

The location decided upon for the pending development follows the old one for about 6000 ft. and then curves northerly and debouches in the river shore a short distance below the nearest point on the rapids where private improvements can be made. The map, Fig. 1, shows the location to good advantage. The entire length of the proposed canal will be about 10,200 ft. The preliminary survey as to the physical character of the material resulted in the following data: For about 3000 ft. at the beginning of the west end of the location Potsdam sandstone comes to the surface, and for the remaining reaches the formation is sand, gravel, clay and boulders in undefined and irregular deposits, the sand largely predominating. The material of over two-thirds of the location cannot resist a transporting current of a mean velocity exceeding 3 ft. per second, and such a flow would require a sectional area in canal prism of about 12,000 square ft., or a width of about 450 to 500 ft. The lands adjacent to the old power canal have become settled and have been built upon, and the real or imaginary value fixed upon them by their owners prohibits any thought of acquiring much of it for right of way. The velocity of flow, therefore, had to be increased to something that could be safely maintained in the rock cut. It was fixed at 7½ ft. per second.

The canal capacity based on a development of 40,000 h.p. at the turbine shaft yielding 80 per cent efficiency, requires about 57,000 hydraulic h.p., or to be precise, an energy of 31,428,550 foot pounds. Computing the volume of water to produce this h.p. from the velocity, the effective head is found to be 16.5 ft., and a volume of water of about 4200 cubic ft. is necessary. The prism in the rock section is rectangular in design and is 200 by 22. The earth section prism is trapezoidal in form, with slopes at 45 degs. The dimensions are 174 ft. at the base, 218 ft. at the top, and 22 ft. deep. The slopes and base are to be substantially revetted with timbers, as shown in Fig. 2. The intake is 2400 ft. long, leading through a shallow bay to a navigable channel in the St. Mary's River. The prism is gradually widened at this place to 500 ft. at its mouth, the velocity being correspondingly lower. At the terminal of the canal below the rapids it widens out to 1400 ft. to meet the forebay, which is closed by the power house. For convenience in construction the canal is subdivided into the intake section, canal sections 1, 2 and 3, forebay and power house. The intake section extends from the navigation channel easterly to the river shore, traversing Ashmun Bay, a shallow sheet of water lying south of the Government ship canal pier above the rapids. The eastern portion is to be cofferdammed and a rectangular canal prism 200 ft. wide and 220 ft. below Lake Superior level is to be excavated dry. The western portion is to be gradually widened to a 500-ft. entrance and to be dredged to a depth of 18 ft. The sides of the dredged portion are to be retained by log timber cribs topped with stone-paved earth embankments. The terminal will be provided with bulkhead wharves 600 ft. long. Canal section 1 extends from the river shore 2800 ft. easterly. It is all in rock and a canal prism 200 by 22 is to be excavated, the sides being channeled. Section 2 extends for 3000 ft. easterly and is all of sand, gravel and clay. The canal prism through this section is trapezoidal, of the dimensions previously given. The revetment will consists of log timber sills, resting on bearing piles, the whole to be closely floored with deck planking. The slopes above the water surface will be stone paved. The third section extends by a 3-degree curve northerly for a distance of 3000 ft., terminating at the forebay. The construction is similar to that of section 2. The forebay consists of the gradual expansion of the conduit by similar curves east and west through a length of 1400 ft. and to a width of from 300 to 350 ft. The excavation of the forebay is to be the depth of section 3, the material being largely clay. The sloping banks are to be timber revetted, as in the other earth section. The power house foundation, see Fig 3, is to be about 1350 by 125 ft. wide. It will consist of a timber grillage laid upon stiff blue clay, resting against strain piles and surrounded by triple-lap sheet piling, filled and enveloped with Portland cement and concrete. The power house will consist of eighty-five units all similar in construction. The substructure is the wheel pit, composed of an arched forebay wall 13 ft. thick and 19 ft. high, and two wheel pits, 15½ ft. from center to center and 3 ft. thick. The wheel pit will be 92 ft. long and 19 ft. high and arched above and below. It will serve the double purpose of sustaining the superstructure of the penstock and mill walls and carrying off the tail water. The pit construction is entirely of Portland cement and concrete blocks keyed into each other by tongues and grooves. The penstocks are erected upon the pit and consist of two partitions, a roof and bulkhead. The partitions are of I-beam uprights with channel sills and caps. The frames are filled and faced with Portland cement grouting. The roof consists of steel frame trusses and the bulkhead is a steel plate cylinder secured to the floor and partitions.

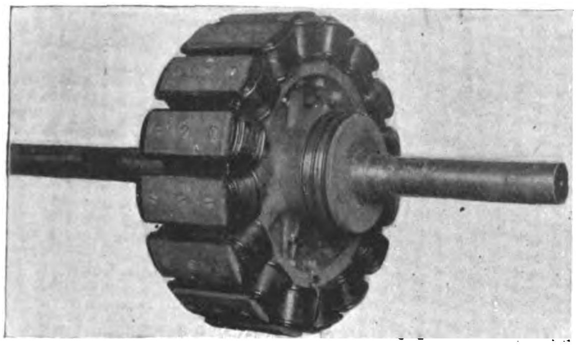

FIG. 4.—ROTATING FIELD MAGNET.

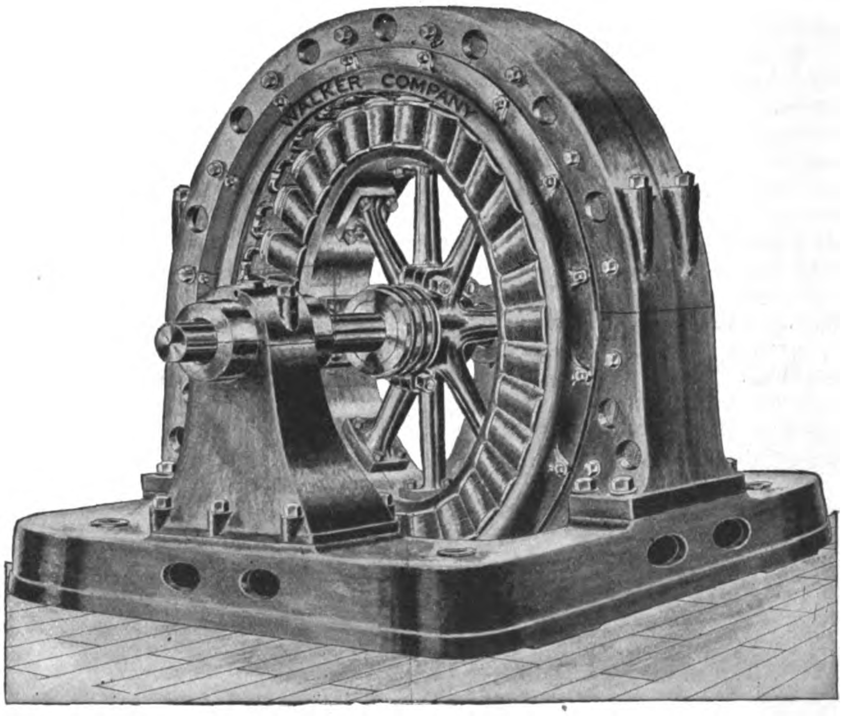

FIG. 5.—GENERAL VIEW OF ALTERNATOR TO BE USED AT THE "SOO" PLANT.

Two steel draft tube collars are inserted into each penstock floor and I-beam turbine supporting frames are constructed on the floor resting on the pit walls. The dynamo floor is the northern continuation of the penstock floor inclosure, being sandstone masonry mill walls. A second floor above is provided. Each penstock will contain two pairs of wheels with center discharge, coupled with a universal horizontal shaft, and will develop 500 h.p. at 250 r.p.m.

A movable headgate of wicker dam type is to be erected at the terminal of section 3, its superstructure being a highway bridge, and two floating service penstock gates of the dry dock gate type are to be constructed. Five of the penstocks are to be arranged for spillways, having together a discharge capacity equal to the total volume of water diverted.

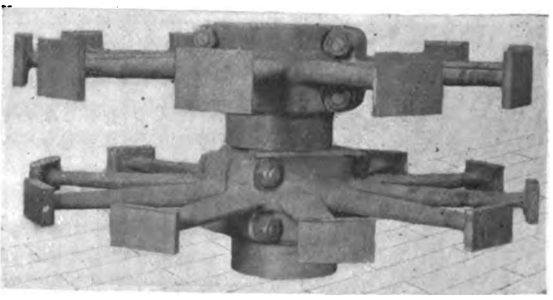

FIG. 6.—FIELD MAGNET SPIDERS.

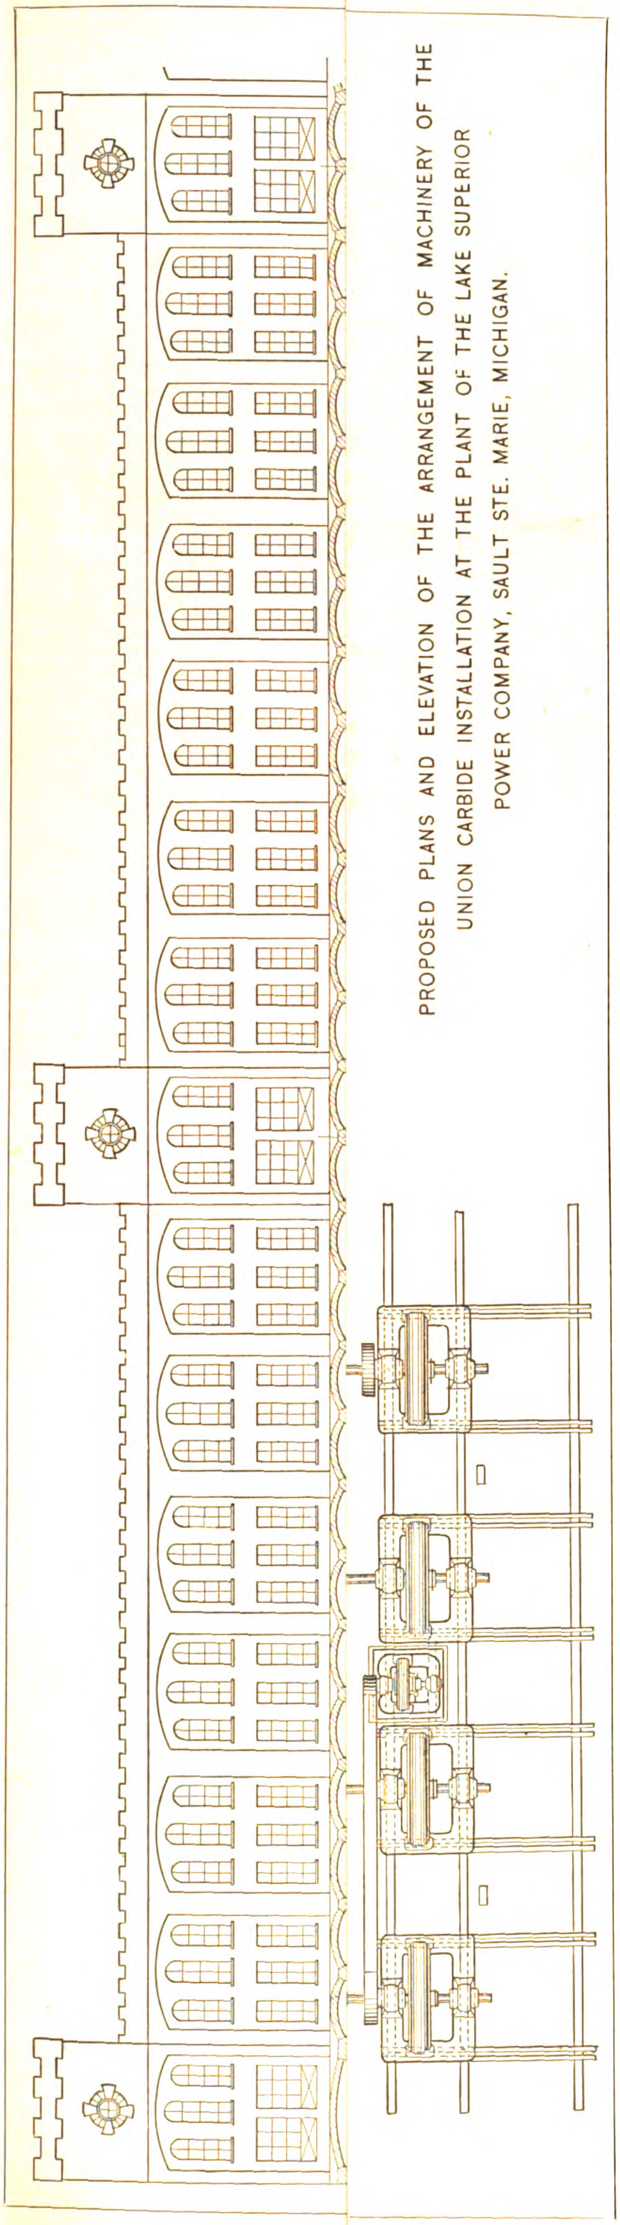
The power house arrangements will be better understood by reference to the drawings on the inset page.



PROPOSED PLANS AND ELEVATION OF THE ARRANGEMENT OF MACHINERY OF THE UNION CARBIDE INSTALLATION AT THE PLANT OF THE LAKE SUPERIOR POWER COMPANY, SAULT STE. MARIE, MICHIGAN.

An idea of the gigantic proportions of this project can be gained from the following: The quantities of material to be moved are: 560,000 cubic yards of rock, 2,200,000 cubic yards of other material. The other materials required in construction are about 15,000,000 ft. of square timber, 2400 tons of structural steel, 300 tons of bolts and spikes, 70,000 barrels of Portland cement, 40,000 cubic yards of sand stone masonry, 25,000 cubic yards of sand, 60,000 cubic yards of broken stone, 320 turbines and 80 dynamos.

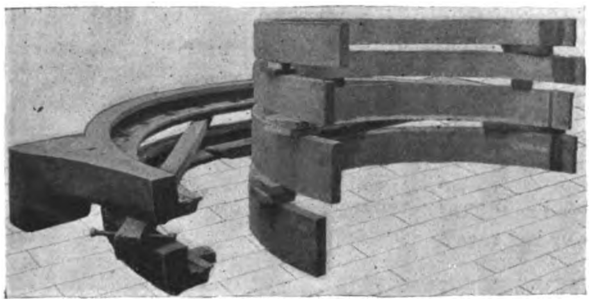


FIG. 7.—ARMATURE TRAINS AND FIELD MAGNET RINGS.

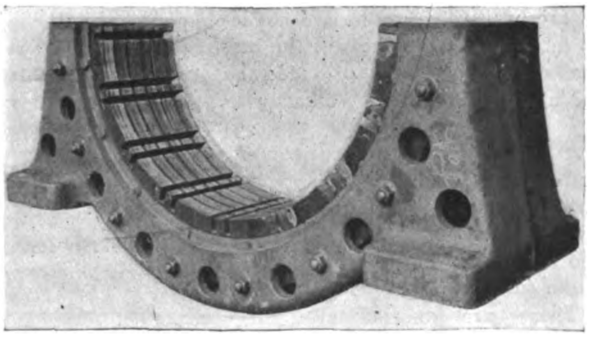

FIG. 10.—CONSTRUCTION OF ARMATURE.

All of this construction is to be completed in about two years.

The electrical equipment will consist of one 375 k.w. slow speed alternating current Walker dynamo coupled to each turbine shaft. The dynamos, as shown in the diagram on the inset page, are located on the first floor. They will deliver their output at a voltage of 200 and a frequency of 60 cycles per second. There will be ten belted exciters of 100 h.p. each. The arrangement is such that a single exciter can be belted on to the shaft of the machine next removed on either side, so that if one is shut down for any reason the belt can be shifted and applied to the other. The leads of the dynamo go directly to the furthest floor above. The currents are so large, that it is highly important that these leads be very massive, and, moreover, closely placed together to avoid inductive drop. The furnaces will be connected six in multiple with four machines, but only four furnaces are supposed to be in operation, and therefore a single furnace practically consumes the output of one machine. An arc of 200 volts and over 1800 amps. represents a deflagrating power of no mean proportions, and twenty furnaces each consuming such power as this will produce a great deal of carbide. The daily capacity of each furnace is three and one-half tons. The machines will be provided with the customary volt and ammeters, and in addition each will have a recording wattmeter.

A feature of interest in this plant is the construction of the Walker machinery, of which this is the first important installation. Inasmuch as the dynamos contain many distinctively new features, a detailed description will be in order. The machines have stationary armatures and rotating fields. A general view of the type of machine to be used at the Union Carbide Works is shown in Fig. 4. It has thirty poles on its field magnet and can deliver 375 k.w. at 240 r.p.m. The voltage is 200 and the frequency 60 cycles per second. The field magnet poles are all salient, each carrying a coil, as shown in the general view of the field magnet, Fig. 5. The construction of the field magnet is as follows: A massive cast-iron hub is provided with rotating arms. This hub is divided on a diameter, and the two halves strongly bolted together. Two finished hub castings are shown in Fig. 6, and it will be seen that the arms are not connected together by a continuous rim. In this way there is no danger of strain from expansion or contraction, such as might obtain if the rim was continuous. Mounted upon the ends of the arms are massive steel rings, which form a surface on which to mount the pole pieces, and also a return magnetic circuit for them. These rings, which are shown in Fig. 7, are securely bolted to the cast-iron arms of the hub, and to them the pole pieces are secured, also by bolts. The pole piece has a T-shaped section and is constructed of rather thick laminæ of iron, which are tightly compressed together and securely riveted, enabling them to be drilled and countersunk like a solid mass of iron. The pole pieces before drilling are shown in Fig. 8. It is to be noted that the polar surface is sloped away from the armature coil at the tips, thus shading the magnetic field and rendering the current wave less jagged. The winding on the pole pieces consists of flat copper ribbon, wound edge on with shellacked paper between. The winding is a somewhat difficult one to accomplish, but the bending is readily done by a special tool used by the company, and the result is extremely compact and mechanically secure, a very important consideration, this is moving wire. The bobbin is mounted on a spool with brass heads and a sheet-iron waist and the spool is sufficiently long, so that when the pole piece is bolted in place it compresses it very tightly in position. In this way there can be no shift nor movement. An idea of the general construction of the field magnet can be obtained by the photograph shown in Fig. 5, a picture of a Walker alternator field magnet of a smaller machine. Attention is called to the fact that this machine is wound with square wire instead of flat

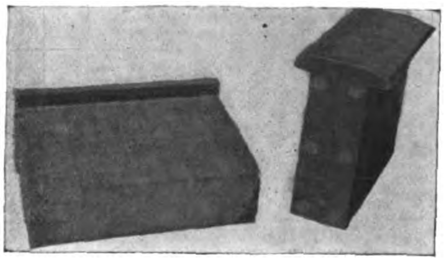

FIG. 8.—POLE PIECES.

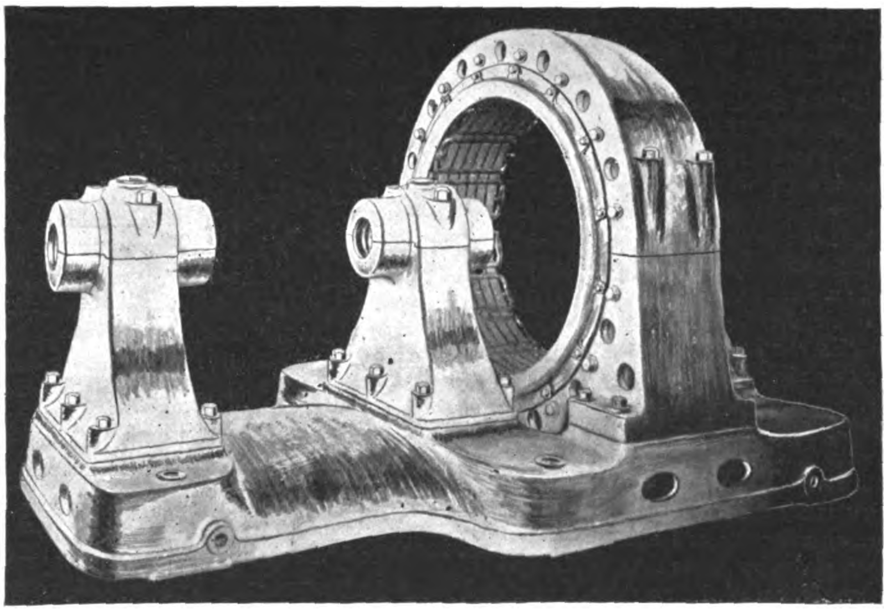

FIG. 9.—COMPLETED ARMATURE AND BEARINGS.

ribbon, and in that respect differs from the type of machine which is to be installed at the Union Carbide Works. It is easy to see that the bobbin is readily removed for repairs, by simply disconnecting it and withdrawing the two or more bolts which hold the pole piece in place. The field magnets are all connected in series and the terminals are brought down to two collector rings mounted on the shaft of the machine, the excitation being provided by means of a small standard Walker generator.

The armature construction is very simple and effective. The frame consists of four castings. It is divided both vertically at right angles to the shaft and horizontally parallel to the shaft. The vertical division of the frame serves to hold the laminæ in place. These are exceptionally large stampings of iron, deeply notched at proper intervals to receive the coils of the armature. These laminæ in sizes up to and even exceeding 100 k.w., consist of but a single piece for a half circumference. They are stacked together with the slots coincident and with suitable separator plates at intervals to provide for ventilation. The cast-iron halves of the frame are cored out sufficiently to admit of an air chamber behind the outer circumference of the laminae. The ventilating holes in the side of the casting, which appear in the photographs, give access to the outer air. The laminæ are insulated with paper and a sufficient number of them are placed in the armature frame, so that when the latter is set up by bolts parallel to the shaft they will be tightly clamped together. These bolts are never intended to be removed, and so they are set up with great pressure and the ends are closely filed off to the nuts. Fig. 10, a photograph of the lower half of an armature frame, displays its construction to good advantage. This frame is that of a single phase machine and is similar in construction to those to be used at the Carbide Works. If the machine were to be two phase, there would be intermediate notches at 90 degs. with slots for the single phase coils, and both sets of coils would have to be slightly bent in order to avoid each other.

The coils are wound on forms and are very heavily insulated, so heavily, indeed, that there is no necessity of insulating the armature core in any way; the coils are slipped on directly. They are held in place by two brass clamps secured by a single bolt. This construction renders the rapid removal and renewal of a coil very simple. The bolts securing the two halves of the armature frame together are external, thereby facilitating the dismantling of the machine and making all the parts easily accessible. The ends of the protruding armature coil are protected by cast-iron plates on either side, as shown in the general view of the machine, and also in the cut of the armature frame mounted on its bearing base, Fig. 9.

This latest essay of Prof. Short has proved remarkably successful. The first alternating machines, as designed and built at the Walker Works, immediately and satisfactorily responded to the demands for which they were built, and were sold at once, and the construction of others has been rapidly going forward.

The production of a line of alternating current dynamos is by no means as easy as a production of a corresponding line of direct current machines. The formulæ for proportioning the parts are more empirical and the principles less well understood, and it is surprising that such a complete line could be built at once without radical modifications from the original working drawings.

◆

INCANDESCENT LAMP RESISTANCE.

JOHN C. SHEDD, M. S.

Ordinarily resistance is defined as "*That property of a conductor by virtue of which under a given E. M. F., it limits the flow of electricity through it.*" **Another definition is** "*The ratio between E. M. F. of a circuit and the current flowing therein.*" **A third definition calls it** "*That property of a conductor by virtue of which it transforms electrical energy into heat energy.*"[*]

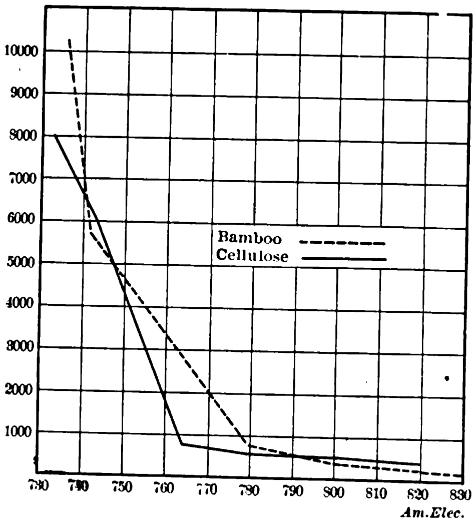

FIG. I.—SHOWING CHANGE OF RESISTANCE OF CELLULOSE AND BAMBOO FILAMENTS WITH RISE OF TEMPERATURE.

From the first definition we see why high resistivity is a valuable property in a lamp filament, since it is desirable that the lamps be placed across comparatively high voltage mains. The second definition enables us to predict the exact amount of current that will be taken; while the third shows us that the same property is depended upon for transforming the electrical energy into heat, and thence into light.

We too often look upon the subtle flow along the wire, as if it were merely the flow of an invisible fluid, and we fail to realize that it is in reality a flow of energy as well. Viewed from the latter standpoint, we are much better prepared to appreciate and understand the many really wonderful conclusions that have been reached in the study of electricity.

The difference in the two views is well illustrated by the two methods of rating in lamp service. One style of meter is so standardized as to record ampere-hours, and is specially designed for the particular voltage used. With the newer type the registration is in watt-hours, and is the more scientific of the two, giving as it does, directly, the amount of energy consumed.

It has been found by careful experimentation that the electrical energy transformed into heat in a circuit of resistance, R, in which a current, C, is flowing, is $C^2 R$, or the square of the current multiplied by the resistance.

We thus see that a filament of high resistance will transform a large amount of electrical energy into heat energy, and if the filament be of small enough bulk, the temperature may rise high enough to render it luminous. A good filament, therefore, should be made of a substance of high resistivity.

If the resistivity (i. e., the resistance of unit cross-section and unit length) of silver be taken as unity, that of the various conductors is given by the following table:

TABLE I.

RESISTIVITY OF VARIOUS MATERIALS:

Silver	1.
Copper	1.08
Aluminium	1.95
Platinum	6.
Iron	6.4
Lead	12.6
German silver	13.9
Platinum-silver	16.2
Graphite carbon	2,600.0 (about).

No better demonstration of the superiority of carbon, as a material for filaments, could be desired than is afforded by this table.

The next point to be noticed is the temperature coefficient; and here carbon presents an anomaly among solid conductors, of having a negative coefficient. That is to say, as the temperature of carbon rises its resistance falls. The effect of this is that a carbon filament behaves slightly differently from an iron or platinum filament.

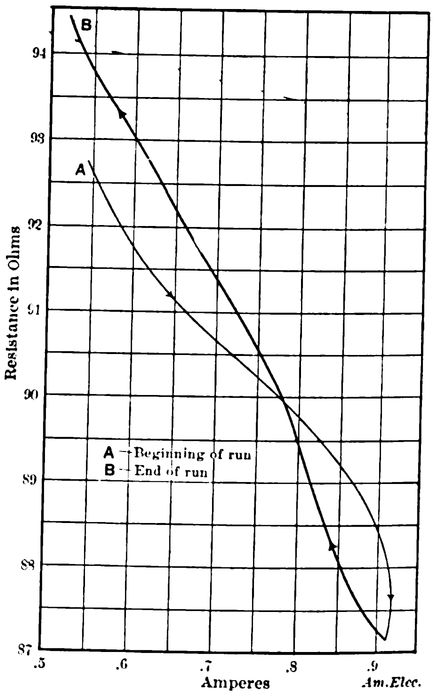

FIG. 2.—SHOWING CHANGE OF RESISTANCE OF FILAMENT DUE TO HIGH TEMPERATURE, LONG RUN.

---

[*] Parham & Shedd, "Dynamo and Motor Testing," p. 69.—Carhart & Patterson, "Electrical Measurements," p. 15.

In the case of the metal, the current in the lamp would be greatest at the instant that it is turned on, and hence the lamp would flash out brilliantly, and then dim as the current is cut down by the rise of resistance. The rise of temperature in such a lamp upon turning on the current would be exceedingly rapid, and it may be that the frequent breaking down of the platinum filaments was due to this initial shock.

With the carbon filament the situation is reversed. Upon turning on the lamp the cold filament has its highest resistance, the current gradually rises as the resistance falls, and the lamp comes to its full brightness. There is then no initial shock as with the metal, and to this fact the long life of the carbon filament is partly due.

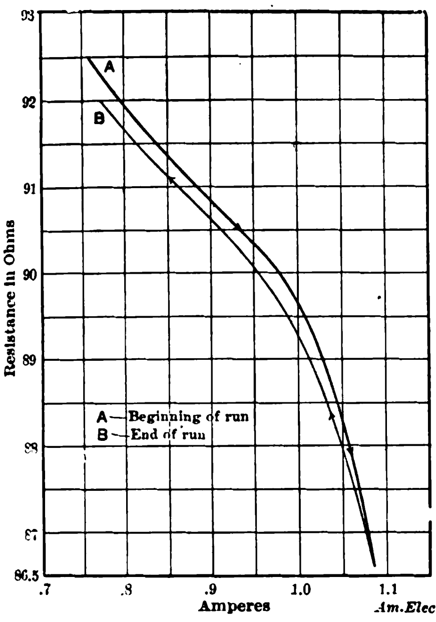

FIG. 3.—SHOWING CHANGE OF RESISTANCE OF FILAMENT DUE TO HIGH TEMPERATURE, SHORT RUN.

Comparing the temperature coefficient of carbon with those of other conductors we find the following table for cold resistances:

TABLE II.

RISE IN RESISTANCE PER DEGREE CENTIGRADE:

Substance.	Temp. Coef.	Rise in R. per deg. C
Silver	.004	.4 %
Copper	.0042	.42 "
Iron	.0065	.65 "
German silver	0003	.03 "
Carbon	—.0039	—.39 "

Thus if a silver wire had a resistance of 100 ohms at 0 degs. C., at 1 deg. C. it would measure 100.4 ohms, while a similar conductor of carbon would measure 99.61 ohms at 1 deg. C. It is not possible to assert that this law holds for all temperatures, and indeed, we are sure that it does not.

The study of the resistance of the carbon filament is exceedingly interesting throughout its history, from the time that it becomes a conductor, until, in a dim and blackened globe, it finally dies of old age. The following stages may be noted:

(1)—The lamp filaments, whether of bamboo or of cellulose (i. e., cotton thread—see article in March issue of "American Electrician"), are not at first conductors, but become so during the process of carbonization. The curves of Fig. 1 taken from an article by George Brian in the London "Electrician" for Feb. 8, 1897, show the change of resistance of the filament with rise of temperature, the latter being plotted horizontally.

(2)—Secondly, while at temperatures above 760 deg. C. the filament is a good conductor, yet the resistance will again rise with lapse of time, unless the temperature has been raised above 820 deg. C. At this temperature the resistance becomes stable.

(3)—In the third place, the resistance of a cold filament is about twice that of a hot filament, and its rise of temperature is about 1200 deg. Thus, a lamp that will measure, when cold, 180 ohms, will measure about 90 ohms when at full incandescence. An interesting point must be noted here. It was stated above that the temperature coefficient of cold carbon is —.0039, or — 39%. Now, if this remained constant for all temperatures, we can easily see that it would only require a rise of about 175 deg. to cause the resistance to fall to 90 ohms. But the temperature has risen about 1200 degs., and we must conclude that the temperature coefficient has correspondingly decreased. Thus the average temperature coefficient from 0 deg. C. to 1200 degs. C. for the above change of resistance would be .0004, or one-tenth its former value.

(4)—The fourth point to be noticed is, that when the filament is raised to an abnormal incandescence and again cooled, the resistance is found to have changed. The reason for this change is probably that at the high temperature the carbon begins to evaporate at a rapid rate, and so to change its structure somewhat. If the evaporation has gone on long enough the resistance of the filament is raised, as shown in Fig. 2, while in Fig. 3 the final resistance is found to be lower than before; due perhaps to the fact that the carbon in cooling has become more compact.

We thus see that there is a molecular disturbance and rearrangement, which goes on at high temperatures, and which is not altogether reversed as the temperature falls. This shows us that we are not to regard a lamp filament as an inert bit of carbon; but as an active agent, quivering with energy, which it is transforming with great rapidity into **heat and light.**

ARMATURE WINDINGS AND CONNECTIONS.

BY PROF. ARTHUR L. RICE.

CABLE WINDINGS.

It has been assumed, for almost all of the multipolar windings, that formed coils were to be used. This will be the case for armatures which are to be wound with rather small wire, say No. 8 or smaller. With larger sizes it is very difficult to bend the wire so as to get the formed coils into shape; also, with the large wire, there is comparatively little danger of a burnout from short circuit, requiring the replacing of an armature coil. Again, in machines where it is desirable to wind the wire more than two layers deep it is inconvenient to use formed coils, because different shapes will be needed for the outer and inner layers of coils.

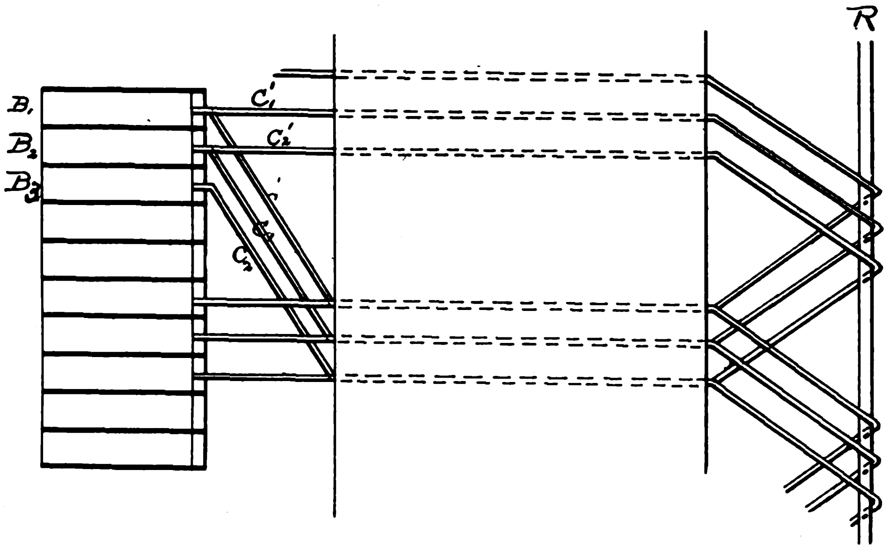

FIG. 1.—TOP VIEW, PART OF CABLE-WOUND ARMATURE.

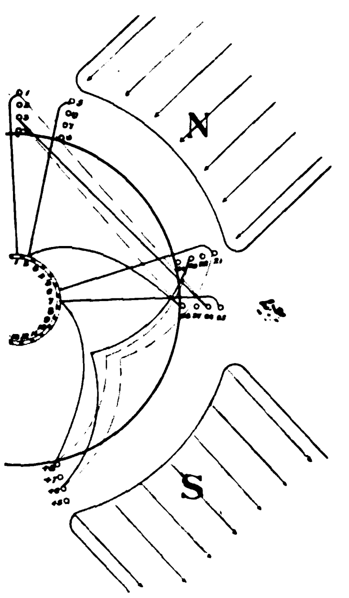

FIG. 2.—COILS FOR CABLE-WOUND ARMATURE.

For these cases, therefore—large wire, many layers and two-pole machines—the cable winding is used. The wire is cut in lengths and wound directly on the armature core by hand. For the sake of convenience in winding, several small wires in parallel are often used in place of one large wire; they form a single conductor, and are to be so treated. Generally there is but one turn per coil in two-layer armatures. The conductors are wound in slots which are either closed or nearly so at the top, and are wedged firmly in place after winding by a hardwood stick driven into the top of the slot. The slot insulation is made in the form of tubes of oiled muslin and oiled paper, which are slipped into the slot, and through which the conductor is pushed. At the back end of the armature, where the wires change direction in passing from one slot to another, it is necessary to have some means of holding the ends of the coils in position both during the winding and afterward during the running of the machine. For this purpose an iron ring—the "throat ring"—well insulated with tape is used. As in Fig. 1, the conductor, C_1, of the under layer is carried back from bar B_2 through the slot, and the back end is bent at such an angle as will carry it half way to the next slot which it is to enter. The same is done for C_2 and for all other conductors in the lower layer. The wires are bent somewhat toward the shaft, as well as being carried forward. When all the wires of the first layer are in place, the throat ring, R, is slipped over the back ends; these ends are then bent up and forward, shoved through the proper slot to the front of the armature, and carried to the commutator, C'_1 and C'_2. The position of the coil, when completed, will be as shown in Fig. 1. C'_1 and C'_2 are in the top layer.

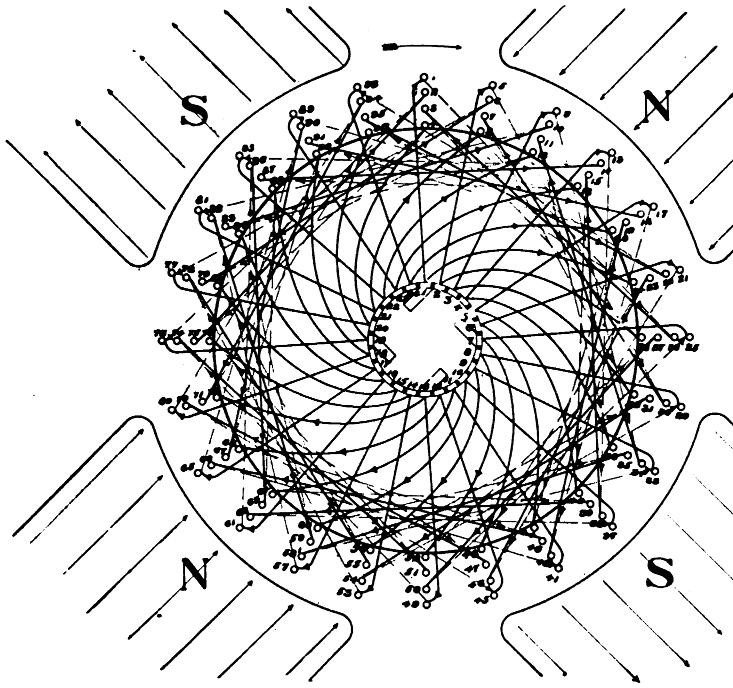

FIG. 3.—FOUR POLE FOUR LAYER, WAVE WINDING, CABLE WOUND.

From a consideration of the above it will be seen that the cable winding can be made of any size wire, but, as the wires must pass around the throat ring with a somewhat sharp turn it will be inadvisable to use a very large wire; No. 4 is as large as can be handled with any comfort, and this only on large machines.

The winding would be difficult to repair in case of a burn-out, and is not adaptable to a case where many conductors are to be wound into a single coil on account of the great amount of labor involved as compared with the winding by formed coils.

If more than two layers are to be used—as sometimes happens in a high-voltage machine, or in a low-voltage machine of the slow speed parallel circuit type, with a large number of poles and few slots per pole—it is hardly possible to use anything but the cable winding. In a four-layer winding, for instance, if the wire were small enough to work easily, two of the layers would be wound into one formed coil; but it would not then be a four-layer machine, since the two wires of one coil would be treated as a single conductor. If the wire needed is too large to wind into coils it must be wound up directly on the armature. Wire larger than No. 8 is to be avoided, except for the largest machines, on account of the difficulty of making the sharp bends required in winding on small armature cores.

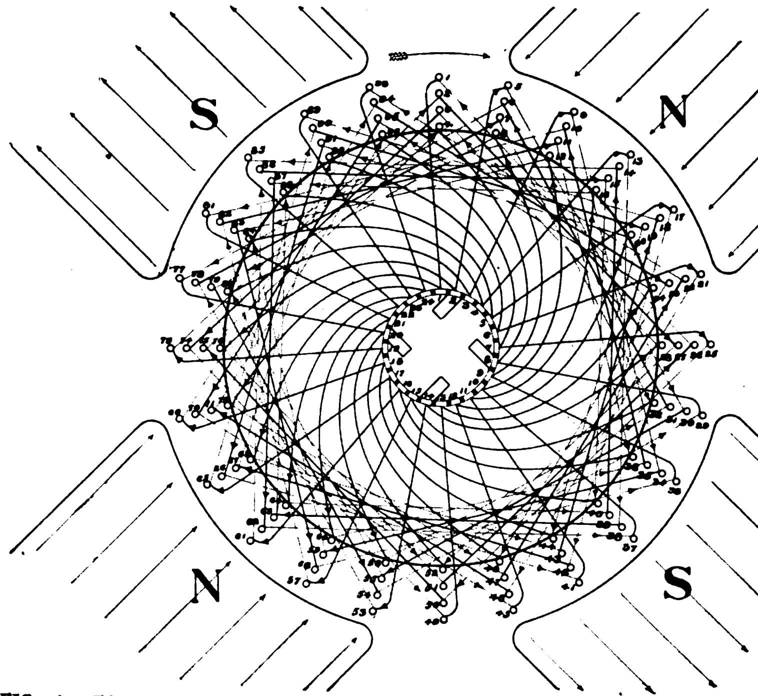

FIG. 4.—FOUR POLE, FOUR LAYER, WAVE WINDING, CABLE WOUND, PROGRESSIVE.

For a two-layer armature, the winding diagram will be the same whether cable or coil winding be used. For a four-pole machine which is to have four layers on the armature and has twenty-four slots there will be ninety-six couductors to be connected. Ordinarily, as a two-layer machine, the commutator would have twenty-four bars, and there would be two conductors per bar. It will be necessary, for economy's sake, to use the same commutator; also, if the winding is to be four-circuit, the number of coils must be divisible by four. Hence there must be four conductors per bar in the four-layer winding. Since it is to be a four-pole machine, conductors at approximately 90 degs. apart must be connected into a coil, and for twenty-four slots this gives $24 \div 4 = 6$ slots, or a coil must be made up of conductors in the first and seventh slots. Let the conductors be numbered as in Fig. 2. One conductor from each layer must be wound into a coil in order to make all the coils alike; to accomplish this the pitch must be odd, and it must be about $96 \div 4 = 24$. Naturally, 25 and 23 are chosen for back and front pitch, so that the average is 24. It would be necessary in any case to use unequal pitch front and back, for, suppose 25 were chosen for both, the winding would go from conductor 1 forward 25 to conductor 26, then back 25 to conductor 1, etc., and no progress would be made. In order to get a progressive winding, 25 is taken for the back pitch and 23 for the front, instead of the opposite arrangement.

The top conductors are supposed to connect straight down to the bar underneath. The winding then goes from bar 1 to conductor 1; on the back, forward 25 to conductor 26; on the front, backward 23 to conductor 3; on the back, ahead to conductor 28; on the front, to conductor 5 through bar 2, and so on. If the armature is small the winding will best be laid on as shown in the coil just considered; if large, it is better to use throat rings for holding the front and back connection as indicated in the coil which contains conductors 21, 46, 23 and 48, Fig. 2. The straight coils have been shown in the complete winding following (Fig. 3) for the sake of the greater clearness possible.

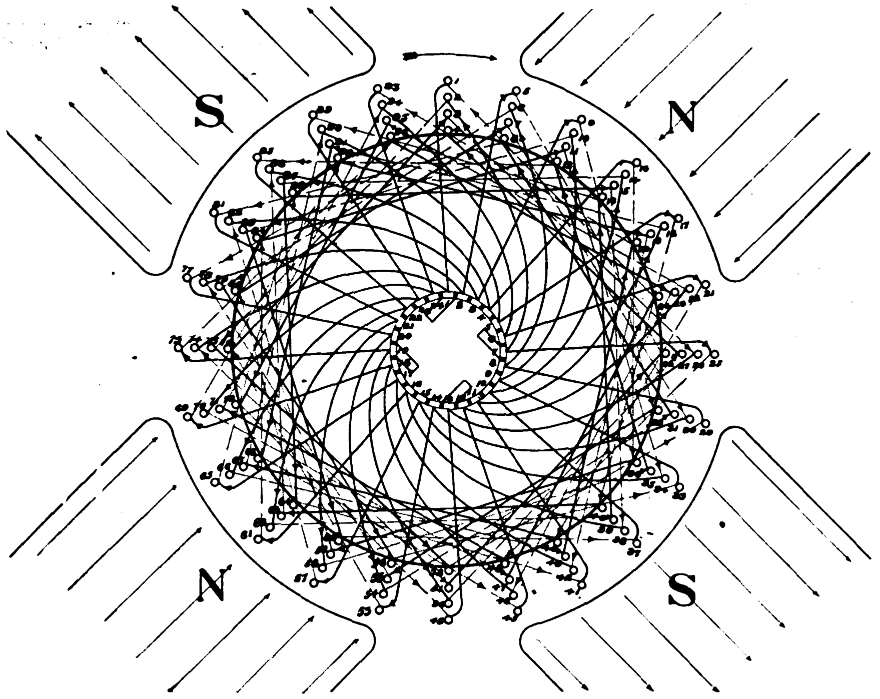

FIG. 5.—FOUR POLE, FOUR LAYER, WAVE WINDING, CABLE WOUND, RETROGRADE.

Between bars 1 and 2 there have been wound up four conductors—one from each layer—into a coil, as seen in Fig. 3. Electrically, this amounts to the same thing as a formed coil of two turns; mechanically, the difference is apparent.

It is important to so choose the actual front and back pitches that one conductor from each layer shall be taken in going from one bar to another, so that the winding shall be mechanically symmetrical. No rule can be given for doing this; it is a matter of inspection and trial.

By the direction of e.m.fs. the brushes are found to belong on bars 1, 7, 13, 19, at 90 degs., i. e., six bars apart; as there are four conductors per bar this gives 4 × 6 = 24 conductors, one-quarter of the number on the armature between brushes, which is correct for a four-circuit machine. To get the length of conductor needed between bars one coil should be wound in place and the length measured, allowing something for what will be taken up at the ends in crossing the other conductors.

In putting on the winding the wires in the bottom layer must all be put in place first, with the ends left long enough to connect to the commutator in the proper position. There will then be in place conductors 4, 8, 12, 16, etc., and the front end of conductor 28 must be long enough to reach around to bar 2.

When the lowest layer is in place the front ends may be tied down for convenience; the back end of conductor 28 is carried around to its place as conductor 3 above conductor 4, and the others are carried in the same direction and by the same amount, until all wires of the third layer are in place. The front end of conductor 3 is now carried forward to its position as conductor 26 in the second layer, directly over conductor 27, and in the slot where that wire started out as 28. All the other wires are carried ahead in the same way and by the same amount to complete the second layer. The back end of conductor 26 is then wound into its place above conductor 2 and becomes conductor 1, and the front end is carried straight down to bar 1; the other wires follow in the proper order, until the winding is complete.

If it is desired to make a wave winding—which has some advantage in point of convenience in winding and symmetry of the ends of the armature—either 23 or 25 may be used as the front and back pitch, because, by the condition for wave windings, $96 + 4 = 4 \times$ pitch; pitch $= 25$; or $96 - 4 = 4 \times$ pitch; pitch $= 23$. The same pitch must be used both front and back; 25 pitch will give a simple winding, as will be seen later.

The connection will be seen in Fig. 4. The winding starts at bar 1, goes to conductor 1, thence on the back ahead 25 to conductor 26; on the front ahead 25 to conductor 51; on the back ahead 25 to conductor 76; on the front to bar 2, which connects to conductor 5, 25 ahead of 76. There are four conductors between bars, and six bars between brushes, so that there will be $6 \times 4 = 24$ conductors per circuit, as in Fig. 3. The process of winding up will be the same as for Fig. 3, except that the wires must be carried ahead 25 each time as indicated in Fig. 4. The whole of one layer must be wound on before the next one is started.

If 23 had been chosen for the pitch conductor 1 would have connected on the back to 24, which is in the lowest layer, then to 47, which is in the third layer, and to 70 in the second layer, as seen in Fig. 5.

The lowest layer being connected to the uppermost layer necessitates a different order of winding. Of course, the bottom layer must go in place first, but, as the third and second layers have to go on before the outermost layer can be put in place the back end of the wires in the lowest layer must be left long enough to wind up later into the outermost layer, and the front end of the lowest layer will then be wound on as the third and second layers; the leads to the commutator will come from the outermost and the second layers.

The length of wire needed for a coil must be found, as for Fig. 3, by winding on one coil and allowing something for the crossing at the ends. The lowest layer of wires are all put in place with the back end of conductor 24 projecting far enough to allow of its being carried backward and laid in as conductor 1 in the top layer and then going to bar 1. The front end of conductor 24 will be wound up into conductor 47 of the third layer and conductor 70 of the second layer, and thence carried to bar 24. The back end of conductor 24 will then be brought around into place as conductor 1 and carried to bar 1. Each of the other wires will follow its similar course, as shown in Fig. 5.

THE PREDETERMINATION OF THE RESISTANCE IN CIRCUIT WITH DIRECT CURRENT MOTORS TO REDUCE THE SPEED TO A DEFINITE AMOUNT FOR VARIOUS CLASSES OF WORK.

BY P. M. HELDT.

In calculating the resistance that must be placed in circuit with a motor to reduce the speed to a given fraction of its normal value, one has to consider not only the characteristics of the motor, but also the nature of the load the motor is driving. It is required to know the torque the motor has to exert when running at this speed, which depends, of course, on the load. The problem then resolves itself into two parts, first, to determine the torque at the given speed, and secondly, to find the resistance which, when placed in circuit with the motor, will give the right speed. We will take up the last part first, supposing the torque to be known. In the latter part of the article some rules will be given applying to different classes of work, by means of which the torque at any speed can be calculated, when the torque at a certain speed is known.

A few explanations of terms used in motor work may enable those not familiar with them to better follow the methods of calculation given hereafter.

The mechanical energy delivered by the motor is composed of two factors, speed and torque. The speed is expressed in revolutions per minute and the torque in pound-feet. One pound-foot is a force of 1 lb., acting at a radius of 1 ft. from the center of the shaft. It must not be confounded with the foot-pound. The former is a measure of angular force, the latter of energy or work. If we represent the number of revolutions of the motor per minute by n, the space described by the point of application of the torque in one minute is $2\pi n$ ft. Multiplying this distance by the torque, T, we have for the work done in foot-pounds per minute,

$$\text{Foot-pounds} = 2\pi n T;$$

and as one horse-power is equal to 33,000 ft.-lbs. per minute, we have for the horse-power developed:

$$\text{H.P.} = \frac{2\pi n \text{T}}{33{,}000}.$$

From this equation we get:

$$\text{T} = \frac{33{,}000 \text{ H.P.}}{2}, \quad (1)$$

which enables us to calculate the torque when the speed and the power developed are known.

In Fig. 1 are given curves showing the relation between speed and torque of a shunt and a series motor when operated at constant potential. From the curve of the shunt motor it will be seen that this motor only drops slightly in speed as the torque increases. The drop in speed is proportional to the torque within the limits of the working range. The curve of the series motor shows a much larger variation of speed with the torque. This difference between shunt and series motors is due to the fact that in the former the magnetization is practically constant, while in the latter it varies with the torque.

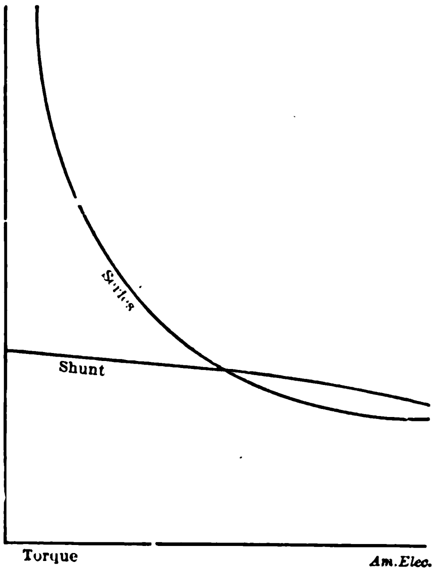

FIG. I.—CURVE SHOWING RELATION BETWEEN SPEED AND TORQUE OF CONSTANT POTENTIAL SHUNT AND SERIES MOTOR.

The following two equations hold for any direct current motor:

$$\text{Speed} = \frac{6 \times 10^{9} \times \text{E}}{\text{N} \times \text{F}} \text{ r.p.m.} \quad (2)$$

$$\text{Torque} = \frac{117 \times \text{N} \times \text{C} \times \text{F}}{10^{11}} \text{ lb.-ft.} \quad (3)$$

Here E is the back e.m.f. of the motor, N the number of armature conductors (twice the number of conductors in series), F the total magnetic flux through the armature, and C the armature current. Let us first apply these equations to the case of a shunt motor. Here N is constant, supposing that the brushes are not moved; F, the magnetic flux, is also constant, as stated above. In a shunt motor the speed is, therefore, directly proportional to the back e.m.f. and the torque to the armature current.

By torque here is understood not only the useful torque transmitted to the belt, but also the bearing and brush friction. The friction we may consider as independent of the speed, which is not exactly true, but it will simplify our calculations, while at the same time it does not introduce any serious error. Without any extra resistance in circuit there is only the resistance of the motor armature to cause a drop of potential. The approximate value of the percentage drop in voltage at full load in the armatures of well-designed motors of various sizes is as follows:

H.P.	1	3	5	10	15	25
Arm. drop. in per cent	6	5	4.5	4	3	2.5

In order to calculate the resistance necessary to bring down the speed to a certain value, we now proceed in the following manner: First, we determine the torque the motor has to exert at this speed. To this we add the brush and bearing friction. Next we find the ratio of this total torque to the total torque at full load. Multiplying the full load armature current by this ratio we obtain the armature current for the lower speed. (According to the principle, stated above, that the torque is proportional to the speed.) Next, we multiply the supply voltage, which is practically equal to the back e.m.f. when the motor runs free, by the ratio of the lower speed to the maximum speed, which gives us the back e.m.f. of the motor at the lower speed. The difference between it and the supply voltage must be used in overcoming the resistance of the circuit. Dividing this difference by the armature current we obtain the total resistance in circuit, and subtracting from this the armature resistance we have the resistance of the rheostat. This operation may be expressed algebraically, thus:

$$\text{R} = \frac{\text{E}}{\text{C}}\left(\frac{\text{n}-\text{n}^1}{\text{n}}\right)\left(\frac{\text{T}+\text{f}}{\text{t}+\text{f}}\right) - \text{r} \quad (4)$$

where R is the rheostat resistance, E the supply voltage, C the full load armature current, n the maximum speed, n^1 the lower speed, T maximum useful torque, t torgue at lower speed, f motor friction, and r the armature resistance. This formula is quite general and applies to any kind of work. There are various special cases for which it takes a simple form.

Supposing a motor running a pump used for pumping water into a tank, from which it is drawn irregularly. Let it be desirable to keep the tank nearly filled. When the demand on the tank is large the motor must run fast, when the demand is small the motor must run slow, and stop altogether when the tank is full. The torque the motor has to exert is greatest when the tank is full, because then the back-pressure of the water is greatest. When the tank is full the following conditions should therefore be fulfilled:

$$\text{t} = \text{T}; \ \text{n} = 0.$$

Substituting these values in our equation above, we find for the resistance to be placed in circuit with the armature:

$$\text{R} = \frac{\text{E}}{\text{C}} - \text{r} \quad (5)$$

In practice it is, of course, advisable to allow at least 10 per cent resistance more, because the motor may not have been geared exactly so that its torque counterbalances the maximum water pressure.

In a case where it is desired to have full control of the motor under any conditions of load, the resistance required will stop the motor even when there is no load on it. Here we have:

$$\text{t} = 0; \ \text{n} = 0$$

and substituting in the general equation we find:

$$\text{R} = \left\{\frac{\text{E}}{\text{C}}\,\frac{(\text{T} \times \text{f})}{\text{f}}\right\} - \text{r}$$

In this case it would generally be easier to measure the current that will just start the motor. Dividing the supply voltage by this current gives the rheostat resistance. This last case, however, rarely occurs in practice.

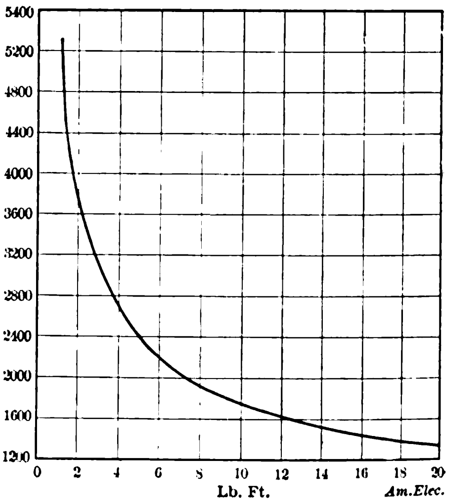

FIG. 2.—SPEED-TORQUE CURVE OF A 3½-H.P. SERIES MOTOR.

We may now work out a practical example to illustrate the foregoing. A 2-h.p. motor runs at 1200 r.p.m. without load. It is required to also run at 600 r.p.m., the nature of the load being such that at this speed the motor has to develop ½ h.p. It is required to find the resistance to be placed in circuit to effect the desired result. Applying our formula (1) we can calculate the torque at full load, and at the lower speed. It should be borne in mind that at full load the speed is not 1200 revolutions, but about 5 per cent less, which makes it 1140 revolutions.

$$\text{T} = \frac{2 \times 33{,}000}{1140 \times 6.28} = 9.2 \text{ lbs.-ft.}$$

$$\text{t} = \frac{\tfrac{1}{2} \times 33{,}000}{600 \times 6.28} = 4.38 \text{ lbs.-ft.}$$

We may assume the friction to be 10 per cent of the total useful torque of the motor:

$$f = .92 \text{ lb.-ft.}$$

Having thus fixed the friction and the armature loss, we have as the armature efficiency at full load 86 per cent. This gives for the full load armature current at 110 volts:

$$C = \frac{2 \times 746}{110 \times .86} = 15.6 \text{ amperes.}$$

The armature resistance is about .35 ohm. We may now substitute in formula (4):

$$R = \frac{110}{15.6}\left(\frac{1200-600}{1200}\right)\left(\frac{9.2 + .92}{4.38 + .92}\right) - .35$$
$$= 6.33 \text{ ohms.}$$

With series motors there is only one particular case which admits of ready solution, namely the case of constant torque. Here the magnetization remains constant, and formula (5) becomes applicable by simply substituting armature and field resistance for armature resistance. It thus becomes:

$$R = \frac{E}{C} - (ra + rf).$$

The field resistance is generally about equal to the armature resistance.

In all other cases where fairly accurate results are desired, we require a speed-torque curve, or at least the necessary data to construct one from. Such a curve for a 3½-h.p. motor is given in Fig. 2. This motor runs at 1600 r.p.m. when fully loaded. Let it be required to find the resistance that will cut down the speed of this motor to 1200 revolutions, the voltage being 110 and the power required at this speed 1½ h.p. The useful torque at the lower speed equals:

$$\frac{1\frac{1}{2} \times 33{,}000}{1200 \times 6.28} = 6.57 \text{ lbs. ft.}$$

The friction would be about 1 lb.-ft., and the total torque, therefore, 7.57 lb.-ft. The torque indicated by the curve is the total torque. The drop in voltage in armature and field at this torque may be put down as 8 volts, and the back e.m.f. at 110 volts would therefore be 102 volts. Looking now at our speed-torque curve, we see that at 110 volts and 7.57 lb.-ft. torque the speed would be 1970 r.p.m. The back e.m.f. at this speed being 102 volts, at 1200 revolutions it is $\frac{1200}{1970} \times 102 = 62$ volts. Forty volts must therefore be used up in the rheostat. To find the rheostat resistance we have to first find the current that will flow.

The mechanical energy derived from the motor plus the mechanical losses must be equal to the electrical energy put into the motor minus the electrical losses. If we express both in the same units, their numerical coefficients will be equal. We will express both in h. p. here:

$$\frac{\text{Back e.m.f.} \times \text{current}}{746} = \frac{(t+f) \times 6.28 \times \text{speed}}{33{,}000}$$

From this we get:

$$\text{Current} = \frac{(t+f) \times \text{speed}}{7 \times \text{back e.m.f.}}$$

This equation may also be obtained by multiplying together equations (2) and (3) and holds therefore for any direct current motor. In our present example we find for the current

$$C = \frac{7.57 \times 1200}{7 \times 62} = 20.9 \text{ amps.}$$

The rheostat resistance must, therefore, be

$$\frac{40}{20.9} = 1.9 \text{ ohms.}$$

The power that any machine requires at any speed may be found by actually running the machine at that speed, and measuring, with a dynamometer, the power it absorbs. Or, we can drive the machine at the required speed by an electric motor, the efficiency curve of which is known. The energy taken in by the motor may then be measured and this divided by the efficiency of the motor at this output. Both these methods are, however, mostly unhandy and often impossible, and recourse must then be had to calculation. A few remarks in regard to the factors that condition the variation of the torque in various classes of work may therefore be of value.

There is one class of applications of the electric motor in which the torque is independent of the speed, but varies periodically. As examples may be mentioned: The hoisting of weights, the pumping of water into a tank, and the operation of organ and other bellows. The pumping of water was considered above. The operation of organ bellows is now often effected electrically. The rheostat is operated automatically by the bellows. When the limit of pressure has been reached, all the resistance of the rheostat is in circuit and the motor stops. In case the motor is shunt-wound formula (5) should be used to calculate the rheostat resistance. A ¼-h.p. 100-volt motor, for instance, driving a small organ bellows, requires a rheostat of 60 ohms.

In another class of work, that of rotating propellers in a fluid, the torque varies as the square of the speed, and the power required as the cube of the speed. Under this head come electrically propelled boats, fans and ventilators. In the first of these the regulation is always effected by other means than a rheostat. Electric fan motors are, however, in most cases provided with a rheostat to reduce the speed. Reducing the speed of the fan to one-half reduces the torque to one-fourth and the power absorbed to one-eighth. The torque or power required at full speed is generally known, and that required at any other speed can therefore be easily calculated.

Electric elevator work really comes under the first division, but the conditions that govern the design of elevator controller rheostats are different from those in any other work. As a factor to start from, we have the time of acceleration of the elevator car, which is generally fixed before hand. It is desirable that the acceleration be constant, as this gives the least maximum stress on the motor for a given time of acceleration. From the speed of the elevator car, weight of moving parts and time of acceleration, the force required to produce acceleration is now calculated. To this is added the unbalanced weight of the elevator car and the friction. This force is reduced to the speed of the motor and is then equal to the torque the motor has to exert while the car accelerates. By the methods given above we can now calculate the current corresponding to this torque, and from the current and the supply voltage the rheostat resistance.

WINDINGS OF MULTIPHASE ARMATURES.

BY J. P. STONE.

The rapidity with which alternating-current machinery has come into practical use within the last few years, and the many different types of machines now in use, has brought forth a great variety of armature windings. Both ironclad and smooth-core machines have been built. Some have even been made without iron cores in the armatures, but these latter have not found very extensive application in this country, although at one time were quite popular on the Continent.

It is the object of this paper to describe a few of the most useful windings that are used in American practice.

While there is a wide variety of styles of armature construction, many of the windings will be essentially the same whether used on a revolving or stationary armature, and a description of one will answer for all.

In the examples given in this article the winding has been laid out as for a revolving armature, and it has been assumed that the windings (whether bars or coils) are laid in slots, and that the necessary connections are made at the ends of the armature. The end where the principal connections are made and the leads brought out has for convenience been called the front or collector end. The conductors lying in the slots on the periphery of the armature are shown diagrammatically by radial lines, and when there is more than one coil or bar per slot, which in practice are usually arranged vertically one over the other, the lower ones are shown in the diagram by radial dotted lines.

As the smooth-core armatures with pancake coils, and also the Gramme ring windings, are rapidly falling out of use, chiefly owing to difficulty of insulating them properly now that higher potentials are used than formerly, no examples of them have been given.

As the various methods of connecting polyphase armatures have been treated in a previous article no mention will be made of it here, and all three-phase diagrams have been shown connected "Y," and all quarter-phase diagrams have been connected in two independent circuits.

Usually high voltages are desired, and in such cases windings are generally adopted in which heavily insulated coils are imbedded in slots in the armature surface. Often one slot or coil per pole piece per phase is used, as this practice permits of the most effective disposition of the armature conductors as regards the generation of e.m.f.; such a winding is called a uni-coil winding, and will be described further on. If more slots or coils are used, or, as in the case of face windings, if the conductors are more evenly distributed over the face of the armature, the e.m.fs. generated in the various conductors are in different phases, and the total e.m.f. is less than the algebraic sum of the effective e.m.fs. induced in each conductor; but, on the other hand, the subdivision of the conductors into several slots or angular positions per pole, or, in the case of face windings, their more uniform distribution over the surface decreases the self-induction of the winding with its attendant disadvantages. It also utilizes more completely the available space and tends to bring about a better distribution of the heating of core and conductors. Therefore, in cases where the voltage and corresponding necessary insulation permits the conductors are sometimes spread out to a greater or less extent from the elementary groups necessary in cases where very high potentials are used.

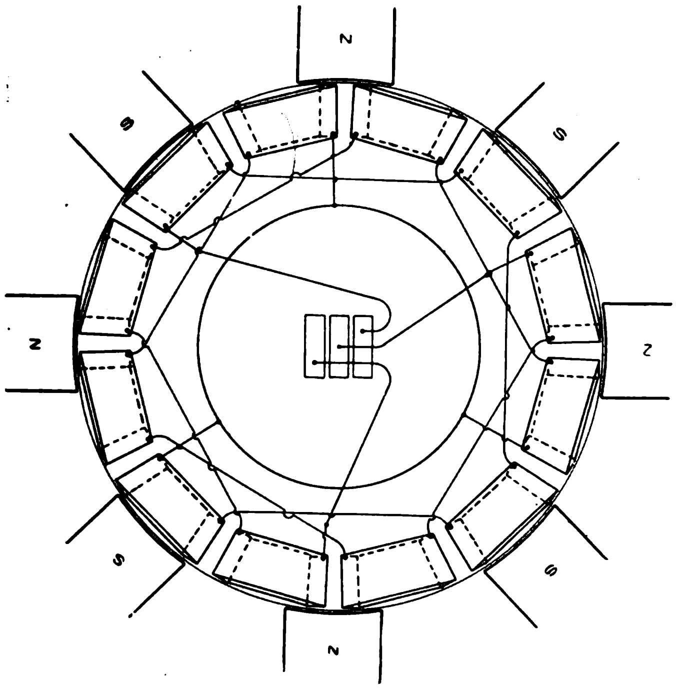

FIG. 1.—THREE-PHASE NON-OVERLAPPING UNICOIL WINDING.

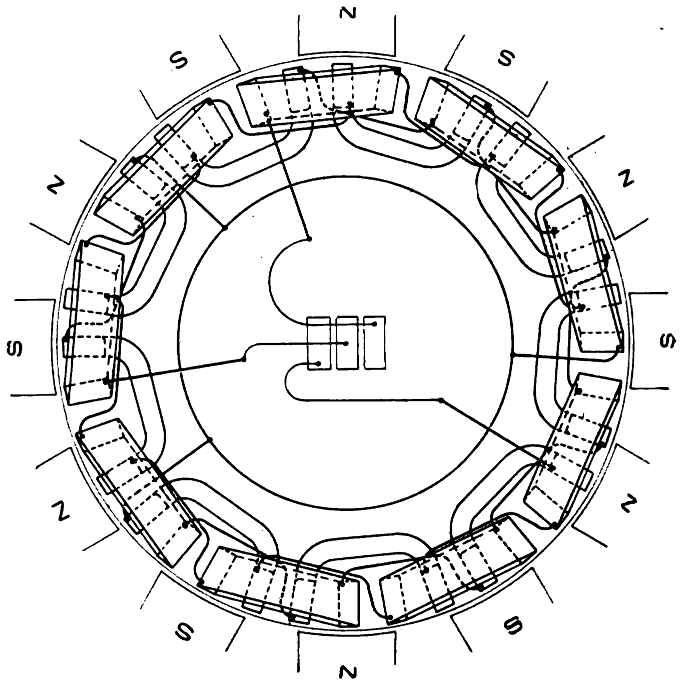

FIG. 3.—THREE-PHASE UNICOIL WINDING WITH OVERLAPPING COILS.

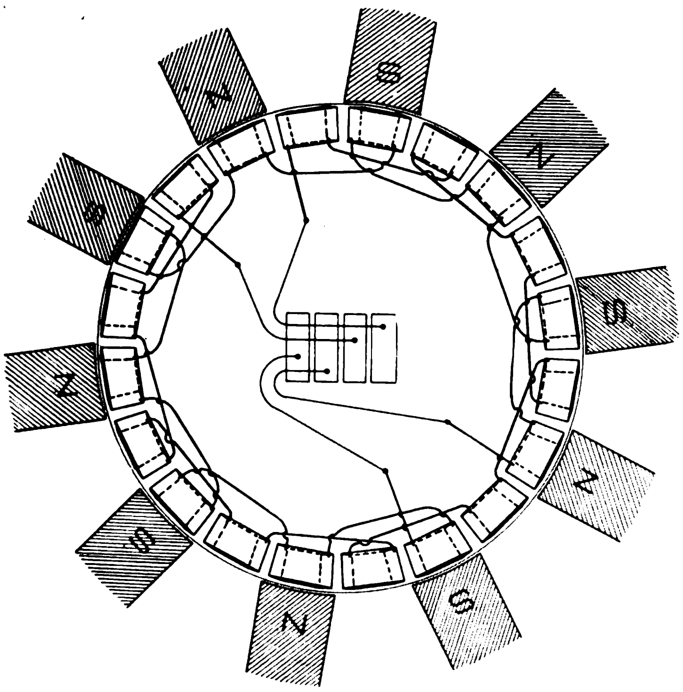

FIG. 2.—QUARTER-PHASE NON-OVERLAPPING UNICOIL WINDING.

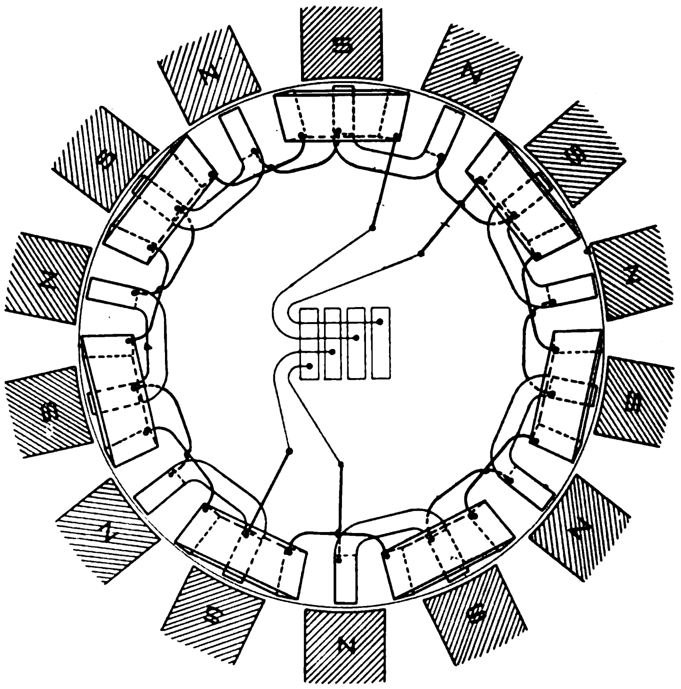

FIG. 4.—QUARTER-PHASE UNICOIL WINDING WITH OVERLAPPING COILS.

Windings in which such a subdivision is adopted are called a multi-coil winding, having two or more coils per pole piece per phase, as distinguished from the form in which the conductors are assembled in one group per pole piece per phase, which latter are called uni-coil windings, or windings having one coil per pole piece per phase.

It will be seen later that in most multiphase windings multi-coil construction involves only very little sacrifice of e.m.f. for a given total length of armature conductor and in good designs is generally adopted to as great an extent as proper space allowance for insulation will permit.

Often in alternating-current installations step-up and step-down transformers, or both, are used, and in such cases the other extreme is approached, and the apparatus is built for very low voltages. This permits the use of very small space for insulation, and conductors of very large cross section, often arranged in only one conductor per group, are used. Here the multi-coil construction is less difficult, although still attended to some extent with the disadvantage of obtaining less than the maximum possible voltage per unit length of armature conductor.

Examples of windings adapted respectively to both the above extremes will be given.

With a given number of conductors arranged in a multi-coil winding, less terminal voltage will be obtained at no load than would have been the case if they had been arranged in a uni-coil winding, and the discrepancy will be greater in proportion to the number of coils into which the conductors per pole are subdivided, assuming that the spacing of the conductors is uniform over the entire surface.

Thus, if the terminal voltage at no load be taken as 1 for a uni-coil construction, it will, for the same total number of conductors, be .7 for two coil, .67 for three coil, .65 for four coil, etc.

But, when the machine is loaded, the current in the armature causes reactions which play an important part in determining the voltage at the generator terminals, and this may only be maintained constant as the load comes on by increasing the field excitation, often by a very considerable amount (this is overcome by the Stanley Company by having the armature winding so arranged that more turns may be switched into circuit at full load than at no load, thus maintaining the voltage constant). Now, with a given number of armature conductors, carrying a given current, these reactions will be greatest when the armature conductors are concentrated in one group per pole piece, that is, when the uni-coil construction is adopted, and they decrease to a considerable degree as the conductors are subdivided into small groups over the entire surface; that is, they decrease when the multi-coil construction is used.

Multi-coil design also results in a much more equitable distribution of the conductors, and, in the case of ironclad construction, permits of coils of small depth and width, which require less insulation for the same amount of wire.

The form of the potential wave of the machine is also determined to some extent by the style of winding adopted, being more peaked as the conductors are concentrated; as in the case of a winding having one coil per pole piece per phase the potential curve is very sharp or peaked, and becomes more flat and rounded as the

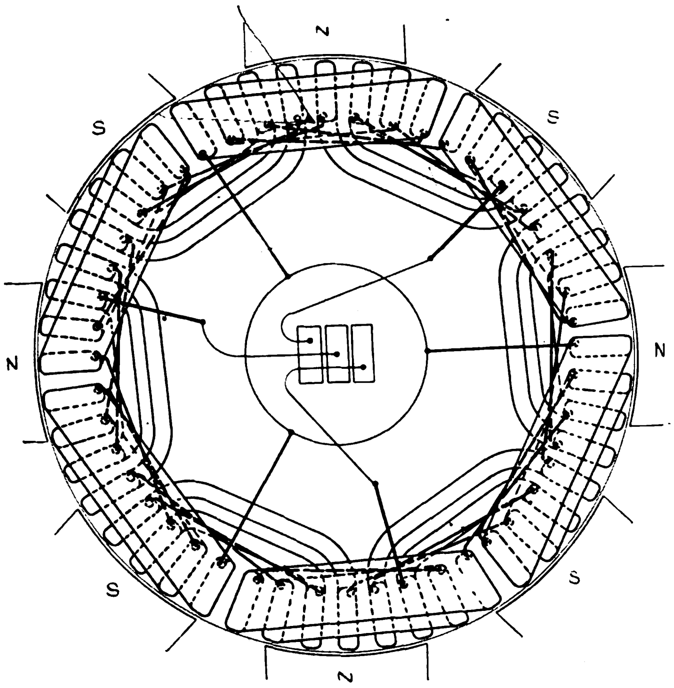

FIG. 5.—THREE-PHASE MULTICOIL WINDING WITH TWO COILS PER POLE PER PHASE.

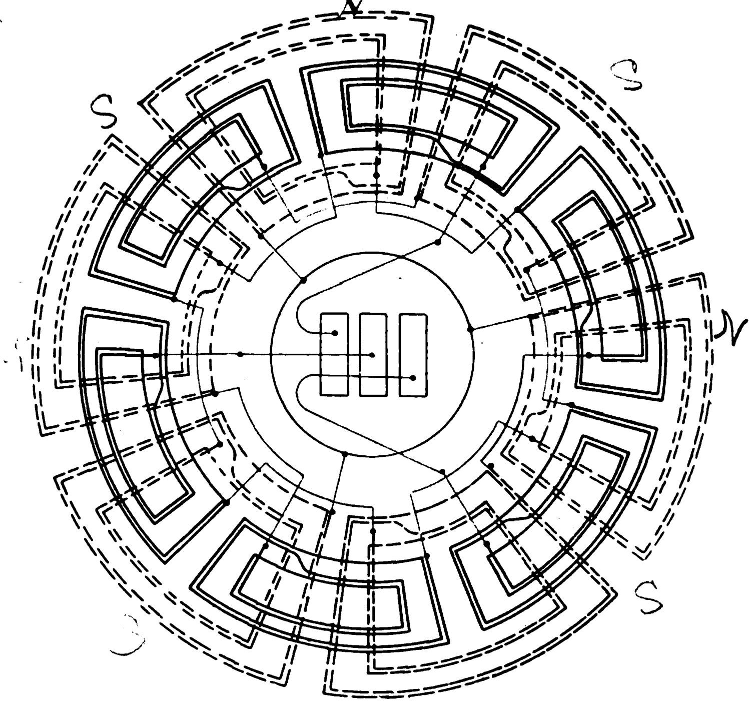

FIG. 7.—THREE-PHASE MULTICOIL WINDING, HAVING TWO SLOTS PER POLE PER PHASE.

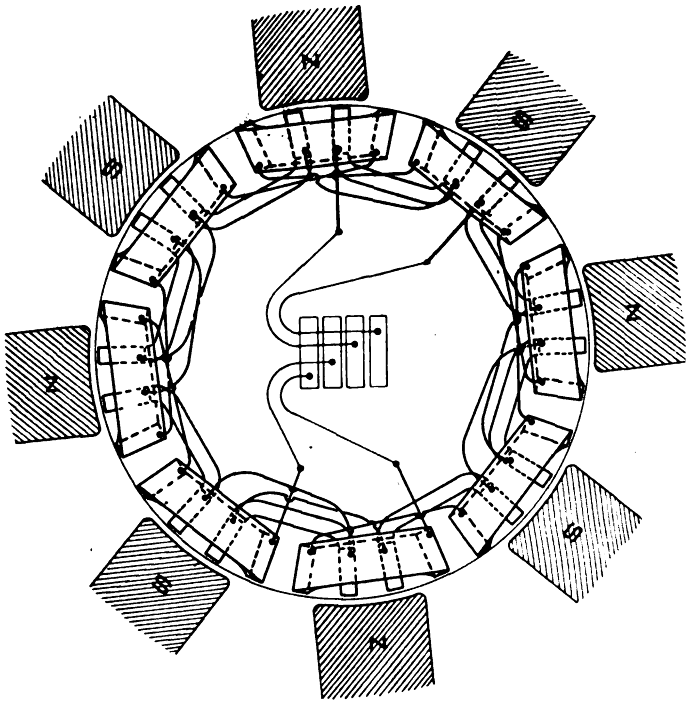

FIG. 6.—QUARTER-PHASE MULTICOIL WINDING WITH TWO COILS PER POLE PER PHASE.

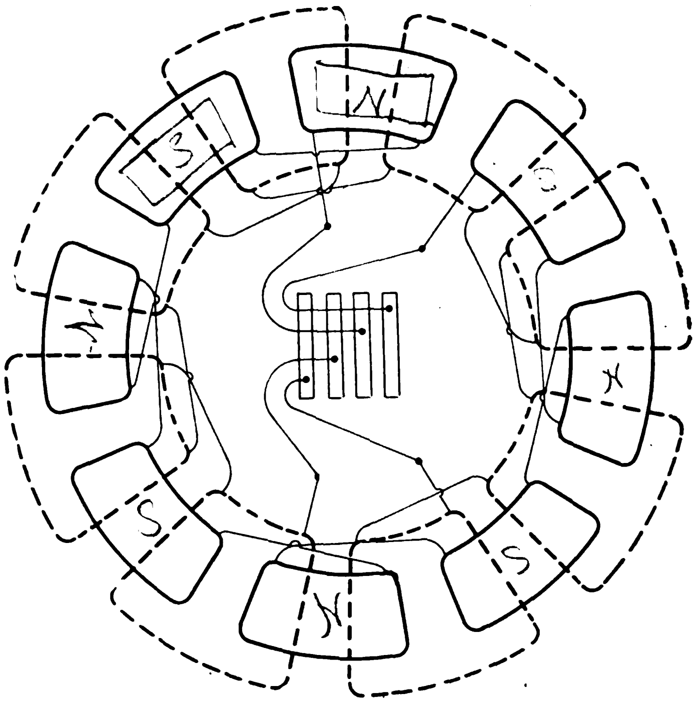

FIG. 8.—QUARTER-PHASE MULTICOIL WINDING, HAVING TWO COILS PER POLE PER PHASE.

winding is spread out, until with a uniformly distributed winding a sine wave is produced.

Usually if the winding is arranged in three or more coils, or groups of conductors per pole piece per phase, the curve of e.m.f. is sufficiently close to a sine wave to fulfill most requirements.

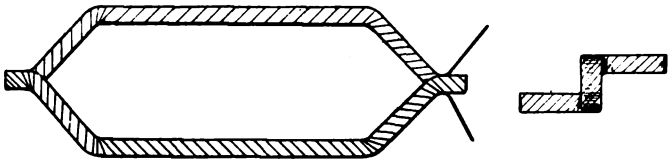

FIG. 9.—FORMED COIL FOR DRUM WOUND ARMATURE.

Thus, it will be seen that the type of winding to be adopted may, in a general way, be determined by the form of wave shape desired, and possibly make a type of winding necessary that for other considerations would not be used.

A class of apparatus, such as rotary converters, is now being found of much value in various ways. They are in a general way used for feeding continuous-current circuits from alternating (single or multiphase) circuits, and sometimes for feeding alternating circuits of one class from those of another, thus, for instance, transforming from single-phase to three-phase or quarter-phase, etc.

UNI-COIL WINDING.

The first winding we will consider is the non-overlapping uni-coil winding, having only one group of conductors per pole piece per phase. The end connections for both a three-phase and quarter-phase armature are shown in Figs. 1 and 2 respectively, as will be seen from an examination of the diagrams; this is necessarily a fractional pitch winding; that is, the pitch, or spread, of the coils is less than the distance between the centers of pole faces, so that the coil can never embrace the total flux coming from one pole piece, especially in the case of the three-phase winding, and will not in the quarter-phase winding unless the pole arc is very small. This fact renders the winding objectionable from an electrical point of view, but mechanically it is excellent, as there are no crossings. This winding might be well adapted to motors, especially in the case of the three-phase, on account of its weakly defined dead points. The manner of connecting the coils can be readily traced.

A uni-coil winding having overlapping coils is shown in Figs. 3 and 4, where there are the same number of coils per pole piece per phase as in the previous diagrams, but half the coils are straight and half bent the straight coils overlapping the bent ones. In the quarter-phase winding the two circuits are brought out independently to four collector rings, which is the usual practice, although the two phases could be interlinked and only three rings used, one of them being common to both phases.

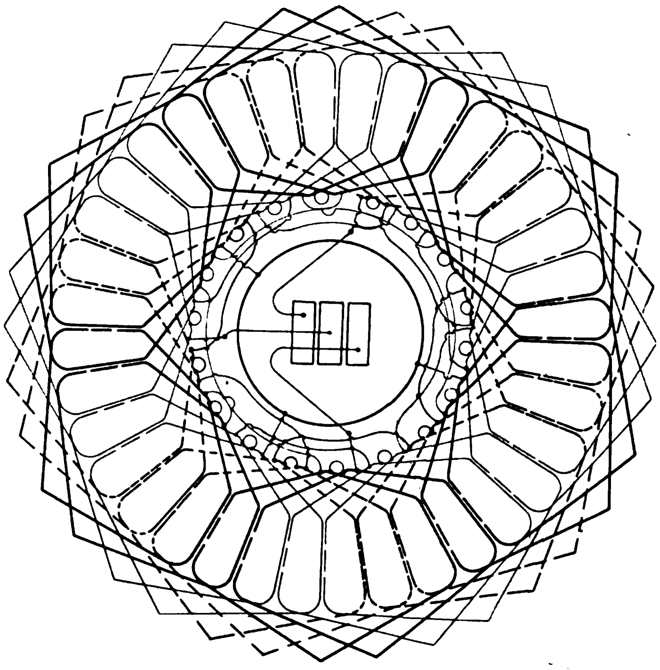

FIG. 11.—THREE-PHASE DRUM WINDING, HAVING TWO SLOTS PER POLE PER PHASE.

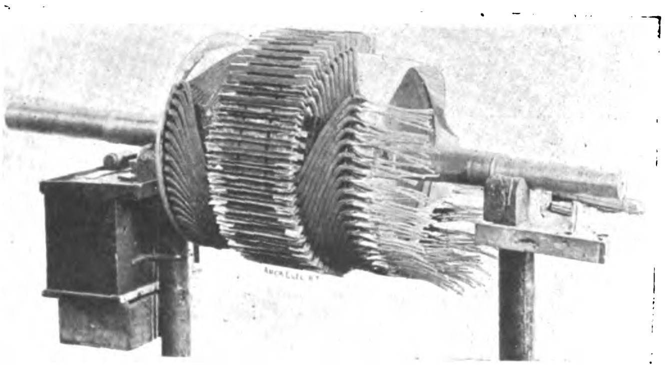

FIG. 10.—DRUM WOUND ARMATURE PARTLY WOUND.

The three-phase winding is shown Y connected, that is, one end of each of the three phases is connected together, the other three going to collector rings. The coil connections can be readily traced from the diagrams.

This is, perhaps, the best polyphase winding for a uni-tooth construction, having one coil per pole piece per phase.

MULTI-COIL WINDING.

Figs. 5 and 6 show an overlapping winding similar to the preceding, but having two coils per pole piece per phase. The quarter-phase winding (Fig. 6) is similar to the preceding three-phase winding, which shows an armature having the same number of coils, but connected three-phase. From this it seems that the three-phase winding shown in Fig. 3 could be used for a quarter-phase winding in a field having two-thirds the number of poles by changing the coil connections; similarly, the three-phase winding shown in Fig. 5 could be used as a quarter-phase winding in a field having six poles by changing the pole connections so that all the straight coils are connected for one phase and all the bent coils for the other phase.

It may be noticed from these and from the preceding diagrams that the three-phase winding has twice as many coils in a group, i. e., the straight coils overlap twice as many bent coils in the three-phase winding as they do in the corresponding quarter-phase winding, which might make it appear as though there were more coils per pole piece per phase in the case of the three-phase winding than there were in the corresponding quarter-phase winding. This is due to the fact that the straight coils have to span over the coils in the remaining phases, so that in the quarter-phase winding there is only one remaining phase to be crossed, while in the three-phase winding there are two, thus making twice the number of coils. This also makes possible the using of the same armature as a three-phase or quarter-phase by changing the number of poles.

As the end connections from coil to coil, as shown in the diagrams, become somewhat complex and indistinct when there is more than one coil or group of conductors per pole piece per phase, the winding diagrams corresponding to Figs. 5 and 6 are **shown in Figs. 7 and 8, where the connec**tions can be more readily followed, the bent coils being shown by full and the straight coils by dotted lines.

This winding and the uni-coil winding are the best adapted to high voltages. The insulation on the coils being of a necessity very thick, it is advantageous to make the winding in as few coils as possible. For this reason the uni-coil winding would have the advantage, but when better regulation and less armature reaction are desired, for long-distance transmission work, the winding is best arranged in two coils per pole piece per phase, as shown in Figs. 5 and 6.

If a still further distribution of winding is desired, it can be carried out on the same plan as that shown in Figs. 5 and 6, but in the case of the quarter-phase winding, if the number of slots per pole piece per phase is an odd number, it will make **an uneven distribution and arrangement of** the coils, making the winding unsymmetrical; hence, it is usual to adopt another style of winding when there are more than two slots per pole piece per phase.

In the case of the three-phase winding the same style of winding can be used as shown in Fig. 5 by putting three or more coils together and the winding will still remain symmetrical, but if more than three coils are used in a group the end connections become very long, thus making the copper losses high. It also requires a large number of different sized coils, which is a disadvantage, as it makes necessary a multiplicity of winding forms.

Hence, where there are more than two coils per pole per phase in the case of the quarter-phase and the coils for the three-phase, a drum winding is usually used.

In a drum winding all the coils are alike, and, as the coils must cross each other on the ends of the armature, it is necessary to make them interlock in some manner. This can be done in a number of ways, but is perhaps best accomplished by making one-half or side of a coil in one plane and raising the other side to another plane, as shown in Fig. 9.

In this manner it is possible to make all the coils symmetrical. From this it will be seen that all one side of a coil will occupy the bottom and the other side, or half, the top of a slot; therefore, in order that all the slots may be entirely filled, two coils are put in each slot.

The coils are laid in the slots one after another around the armature, as shown in Fig. 10, until the winding is completed, the connecting being done after all the coils are in place. To facilitate connecting the leads are brought out of the coil at one end close together, as shown in Figs. 9 and 10.

The connections for a six-pole three-phase winding of this description are shown in Fig. 11. For simplicity, a winding is shown having only two coils per pole piece per phase, the coils being drawn in heavy lines, one side of a coil being in the bottom of a slot under one pole (shown by a dotted line in diagram), and the other side in the top of another slot in the corresponding position under an adjacent pole.

A winding of this type can be made for any number of coils per pole piece per phase, the connections being similar, but having a greater number of elements per group.

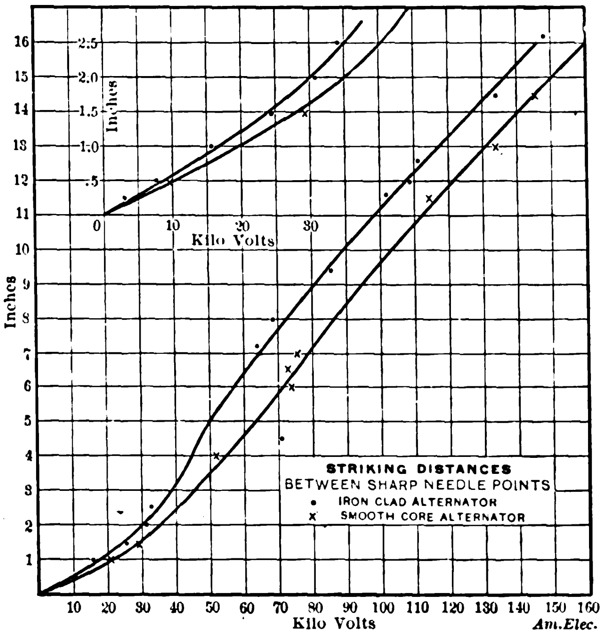
CURVES OF DISRUPTIVE DISHARGE.

In the accompanying figure is an interesting little chart containing valuable information on the subject of high-voltage discharges, the more so because Mr. Charles P. Steinmetz, who is a well known authority on such subjects, is responsible both for the curves and the statements concerning them. The experiments of which these curves are a record were made with powerful discharges generated by powerful alternators.

Two curves are shown here, with striking distances for ordinates and kilovolts for abscissæ. The upper curves are the results of experiments made using as a source of power a modern toothed alternator armature, and the lower curves were similarly obtained using one of the old style smooth body armatures with pancake coils. The striking distances were accurately measured, the terminals being fine sewing needles. It was found necessary to renew these needle points at every experiment, as the action of the discharge vaporized the points and made subsequent results incorrect.

Between balls, plates and rounded conductors the striking distance is very nearly the same for voltages above 100,000, but it is very much less for low voltages, striking only across ⅛ in. between balls of 1 in. or so in diameter. The melted needle points produced this ball effect, and hence the necessity for their renewal with every discharge. The discharge between needle points is much more reliable for fairly low voltage than that between balls, and therefore needle points are preferably used. Temperature, moisture, etc., seem to have no noticeable effect on the striking distances between sharp points, which at a given voltage is very closely the same under all conditions.



CURVES OF DISRUPTIVE DISCHARGE.

WHAT IS GOOD PRACTICE IN ARMATURE MAGNETIZATION?

Every dynamo engineer has his own ideas on almost every point in the design of a machine, but on no point do they differ more widely or adhere more stubbornly to their own ideas than on the question as to what is the best density to use in the magnetization of an armature. An examination of the various machines in practice and, it may, be added, good practice, discloses the fact that armature densities varying from 40,000 to 90,000 lines to the sq. in. are considered as suitable by various designers. The school of high density is essentially of English extraction, while machines of low armature induction are mostly American designs.

The high density advocates argue that their practice renders a smaller armature permissible and improves commutation, and that the added reluctance that the contracted area inserts in the magnetic circuit is a negligible amount. The low density engineers hold that the employment of a high induction entails a very careful selection of iron or the loss by hysterisis will become so great as to overheat the armature, and further that the low density armature is inherently larger, affording a greater radiating surface and rendering a much larger copper loss permissible. In this way the machine may be made to carry large overloads. Moreover, they state that the art of designing windings that will commutate satisfactorily is so far advanced that it is no longer necessary to overpower the armature with the field magnet.

Both are right, but the desirable features of the one practice may often be profitably sacrificed to secure the advantages of the other. The strength of the induction, therefore, depends more on the conditions that are to be met in the design. If, for example, slow speed is desired above all else, there is no escape from high density. If, on the other hand, overload capacity is desired, high density is to be avoided. It is not to be inferred that a machine in which the armature is highly magnetized is of light weight, for as a usual thing little is gained in this direction by such a practice. The diminished area of the air gap will increase the reluctance and the leakage in sufficient measure to demand a field magnet and exciting coils of added weight. A ring armature which is inherently larger than a drum armature of equal output may work at a higher density, for it does not suffer as seriously by a diminished air gap. The necessity of carefully selecting the iron to be used in armatures to work at high densities is by no means imaginary. Iron, or rather steel, for all modern sheet iron is such, is frequently so highly susceptible to hysterisis losses that if incorporated into a core, it would heat dangerously when in operation from hysterisis alone. Indeed, of two armatures made of different iron but otherwise identical, one will often burn out and the other show itself capable of carrying heavy overloads. The difficulty, if not the impossibility, of uniformly procuring good iron is certainly a temptation to lower the induction. The consensus of modern opinion seems to be that density is somewhat like speed; it may be increased above a certain limit to gain other advantages, but as a general rule the density cannot be increased over 50,000 lines to the sq. in. without serious sacrifice.

◆

THE INDUCTION MOTOR.

III.—INDUCTION MOTOR FIELD WINDING.

By ALFRED E. WIENER.

The winding frequently called the field or primary winding which produces the rotary field of an induction motor consists of two or three coils, respectively, subdivided into sections and placed around the field-core in such a manner as to form a number of magnet poles on the inner periphery of the stator when traversed by electric currents. Figs. 1 and 2 are diagrams of two-coil windings (for bi-phase currents), the former being connected up in ring-fashion, having the turns completed in the form of spirals around the external periphery of the magnet-core, and the latter in drum-fashion, having all the connections upon the end faces of the field-frame. In Figs. 3 and 4 the respective developments of these windings are shown, from which can be seen that the direction of the current in the conductors near the inner periphery of the magnet-frame is the same in both windings. For the sake of simplicity both windings are arranged so as to form but four greater number of poles, simply being formed by a repetition of the connections shown, can readily be derived from the illustrations given.

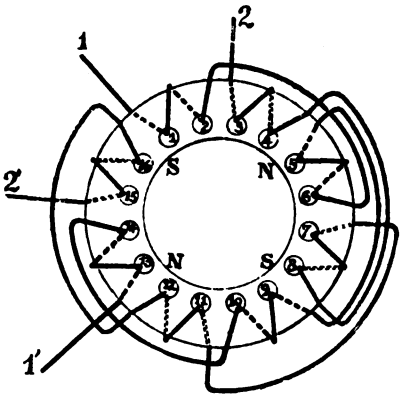

FIG. 1.—TWO-PHASE FIELD RING WINDING FOR INDUCTION MOTOR.

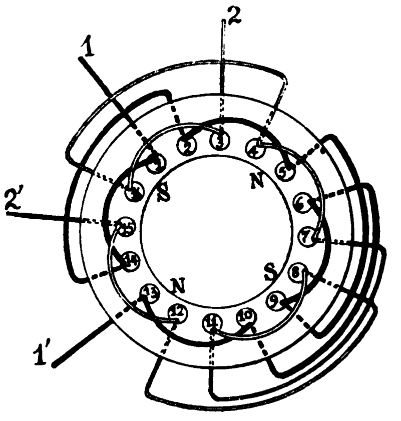

FIG. 2.—TWO-PHASE FIELD DRUM WINDING FOR INDUCTION MOTOR.

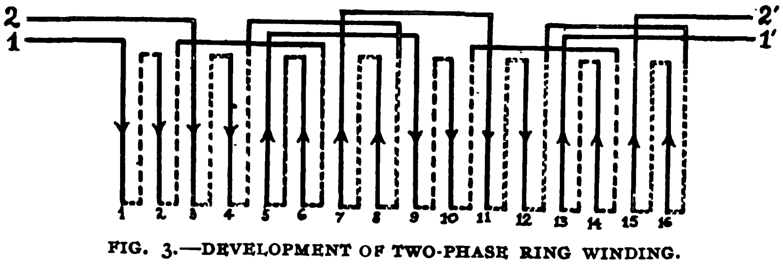

FIG. 3.—DEVELOPMENT OF TWO-PHASE RING WINDING.

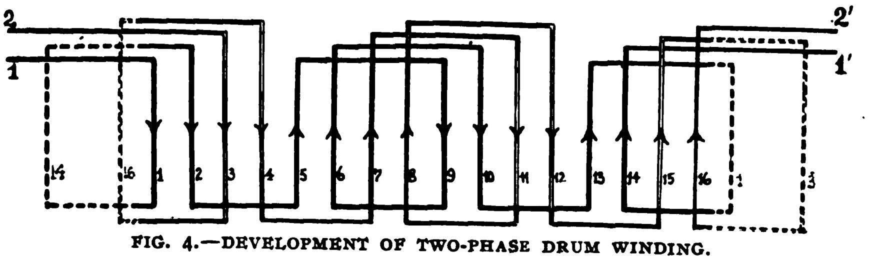

FIG. 4.—DEVELOPMENT OF TWO-PHASE DRUM WINDING.

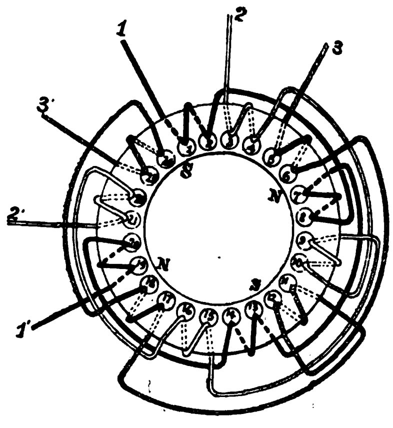

FIG. 5.—THREE-PHASE FIELD RING WINDING FOR INDUCTION MOTOR.

In Figs. 5 and 6 the corresponding three-coil windings (for three-phase currents) are illustrated, the former being a diagram of a three-phase ring-winding, the latter that of a three-phase drum winding. Fig. 7 is the development of Fig. 5, and Fig. 8 the development of Fig. 6. In the windings represented by Figs. 1 to 8 only one conductor per slot is taken for simplicity, Fig. 9, therefore, is added to show how the field-winding will have to be executed if, as is usual in practice, there are a number of conductors in every slot, three conductors per slot being chosen for illustration.

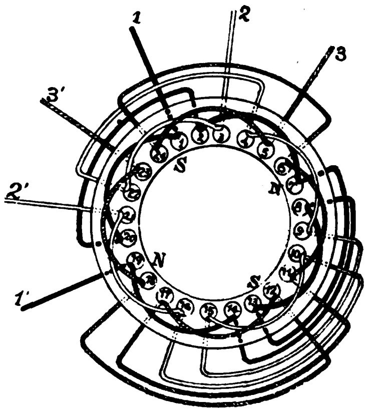

FIG. 6.—THREE-PHASE FIELD DRUM WINDING FOR INDUCTION MOTOR.

To supply the field-coils of a two-phase motor there generally are needed four line wires, one for each of the terminals, 1, 1', 2, 2' (Figs. 1 to 4); in case of a three-phase motor, however, since the algebraical sum of the currents in three-phase systems is always zero (see Fig. 21, page 194), the three coils can be connected in such manner that only three line wires are required, a fact in which lies one great advantage of the three-phase over the two-phase motor. If the two coils of a two-phase winding are not connected in the form of a closed circuit but are independently wound, two terminals of different phases may be joined together to a single return wire. In this case, however, the reduction of the number of line-wires does not constitute a saving in copper, as, on the contrary, the weight of the line for the same maximum voltage then is about 45 per cent in excess of the four-wire line arrangement.

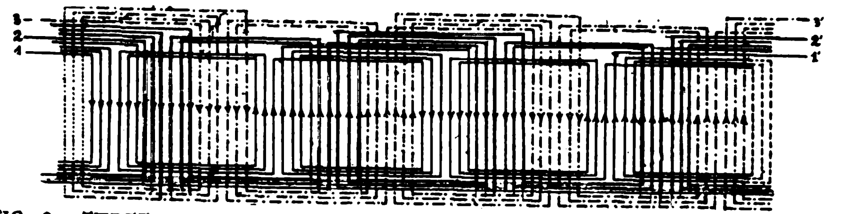

FIG. 9.—THREE-PHASE DRUM WINDING HAVING THREE CONDUCTORS PER SLOT.

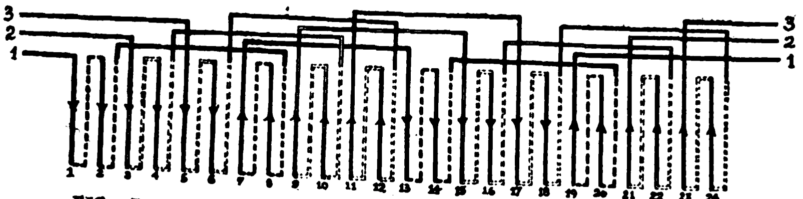

FIG. 7.—DEVELOPMENT OF THREE-PHASE RING WINDING.

For the relative weight of copper in the various systems of electrical distribution Messrs. Edgecomb and Fox, in a recent paper read before the London Institution of Electrical Engineers, give the following figures:

System.	Relative weight of copper for given maximum voltage.
Direct current	100
Single-phase	200
Two-phase, 4 wires	200
Two-phase, 3 wires	291
Three-phase	150

There are two methods of connecting the field-coils of a three-phase motor, (1) the mesh, or Δ (delta) connection, and (2) the star, or Y connection. The former consists in joining the three coils in series with each other and connecting the line wires to their junctions, as indicated diagrammatically in Fig. 10; while in the latter the three coils are joined in parallel, one end of each being connected to a common point and the free ends to the three line wires, see Fig. 11. The difference, electrically, between these two connections is shown in Figs. 12 and 13, which give the distribution of the line potential E and current I in the Δ- and Y windings, respectively. It will be seen that in the Δ-winding, since there is but one coil between each two line wires, the potential in each coil (that is, the potential per phase) is equal to the line potential; and that in the Y-winding two coils of 120 deg. phase-difference are in series, from line to line, hence the voltage per phase—the base of a 120-deg. isosceles triangle being 2 sin 60 deg. = $\sqrt{3}$ times one of its equal sides—is $\frac{E}{\sqrt{3}} = .577$ E. For the same reasons the maximum current per phase in a mesh-connected field is $\frac{I}{\sqrt{3}} = .577$ I, and in a star-connected field is I, or equal to the line-current, while the corresponding currents in the two remaining coils in each case are one-half the respective maximum value (see Fig. 21, page 194).

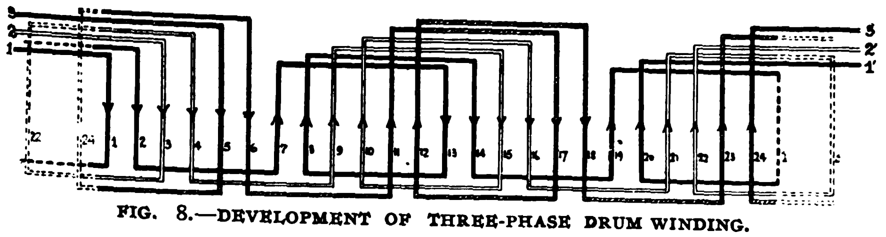

FIG. 8.—DEVELOPMENT OF THREE-PHASE DRUM WINDING.

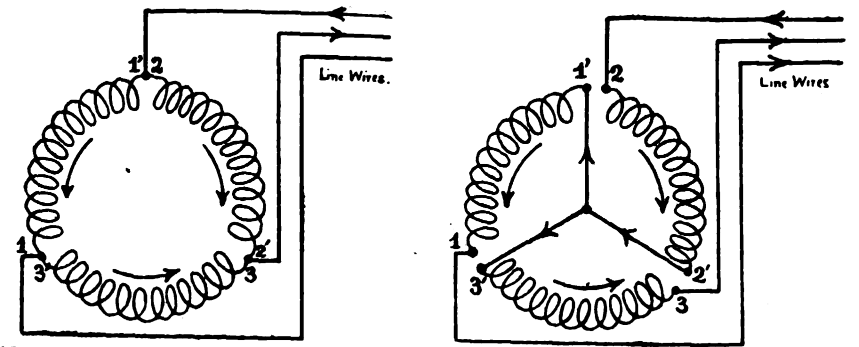
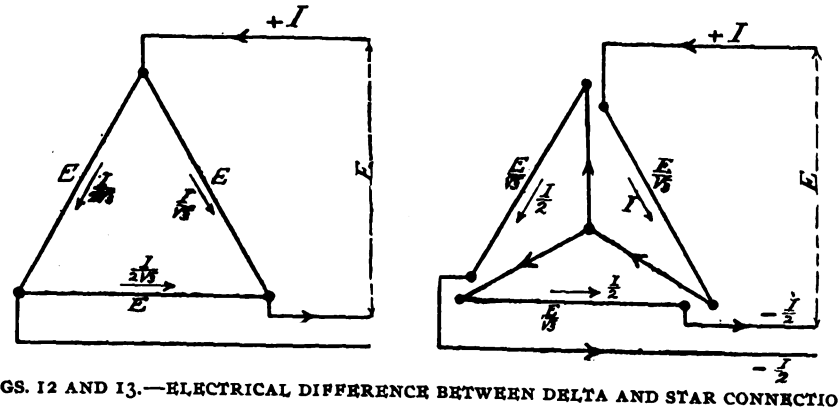


FIGS. 10 AND 11.—DIAGRAMS OF DELTA AND STAR CONNECTIONS FOR THREE-PHASE INDUCTION-MOTOR.

Any three-phase winding may be connected up in the Δ or in the Y form, but, as can be derived from the above, the Δ-winding will give $\sqrt{3} = 1.732$ times the current, but only $\frac{I}{\sqrt{3}} = .577$ of the voltage of the Y winding, and vice versa: and to supply a Δ-connected three-phase motor it will, therefore, take 1.732 times the current and .577 of the voltage required for a Y-connected motor.



FIGS. 12 AND 13.—ELECTRICAL DIFFERENCE BETWEEN DELTA AND STAR CONNECTIONS.

ACCURACY IN WIRE FORMULAE.

The ill-advised pains which many electricians and mechanicians take to measure certain quantities, the results of which are to be incorporated with other considerations of doubtful accuracy into calculation, is surprising. A result which is calculated from numerous data by means of simple factorial methods is no more accurate than the accuracy of the least accurate measurement of the component qualities. An example which is of every-day occurrence may be cited. In the calculation of wire, formulæ are devised in which the specific resistance of copper is conscientiously quoted from Matheissen's tables, and after the wire has been calculated the nearest standard size is chosen, even though it differ several per cent from the true result, for the reason that it would not pay to draw special wire for such a case. The measurement of linear distances by means of a clothesline with a micrometer attachment is scarcely less absurd than some of this fantastic effort to obtain accuracy in a result which is ultimately approximated.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Aluminum Dynamo Brushes.—According to "L'Elettricitá" aluminum has many advantages as a material for dynamo brushes. While its resistance is higher than that of copper, it is about 100 times lower than that of carbon, and the metal is to a certain degree non-arcing. For the collection of high tension current of small volume from commutators it has many advantages over copper. Used on the rings of alternating current dynamos, aluminum brushes are said to have given most excellent and satisfactory results.

New Battery Fluid—According to the "Revue Independante des Sciences Médicales, Pharmaceutiques et Veterinaires," a new liquid, called "calcide" by its inventor, Dr. Busse, of Hanover, has been brought out as an excitant for primary batteries. It consists of oxychloride of calcium dissolved in a solution of sal ammoniac. These two substances are easily obtained and are cheap. The liquid is said to possess high conductivity and not to freeze above —22 degrees Fahrenheit. Excellent reports of its value as an excitant are given.

Snow on Overhead Wires.—Some interesting figures concerning the weight of snow which can be borne under some conditions by wires are given in "La Nouvelle Gazette de Zurich." The specific gravity of wet snow was found by the meteorological station at Zurich to be 0.02, and a wire 630 ft. long was found to have carried 120 lbs. of snow, or forty times its own weight. It is not stated whether this wire was supported at various points, but as its gauge was only about 18 B. & S., it is supposed that it was. Some poles exposed to this storm carried as many as 250 wires, and it is by no means remarkable that they were broken.

Plating Aluminum.—A durable method of plating aluminum goods, according to the "Practical Engineer," is the Wegner process, in which the article to be plated is first pickled in a bath composed of oxide of iron, acetate of copper, sulphur and chloride of alumina dissolved in vinegar. After taking out of the bath it is brushed with a soft wire brush. A metallic coat then develops on the surface of the aluminum, closing its pores and rendering it perfectly smooth. After washing in clean water, the article is plated in a bath in the usual way.

Electricity on Belgian Railroads.—The Belgian Government, which controls the railways in its territory, has asked for bids for the electrical equipment of the line from Mons to Boussu, a distance of about 6 miles, this, according to the "Moniteur des Chemins de Fer," being the first section of an installation that is to be greatly extended. A central station of great size and thoroughly modern is to be built, and the whole work is to be completed within twenty-five weeks from its commencement. Cars similar to those used on the Charleroi and Centre lines will be used, about $50,000 being set aside for the rolling stock.

Calcium Carbide from Basic Slag.—A new method of extracting phosphorus and calcium carbide from basic slag has been brought out in Germany, says the "Practical Engineer." Tricalcium phosphate is mixed with an excess of powdered coke and heated in the electric furnace, whereby calcium carbide, phosphorus and carbonic oxide are formed. The phosphorus passes over into a condenser and is recovered, the yield being said to be about 80 per cent of the total present in the mixture. Some experiments have also been made toward converting the phosphates in these slags into phosphides to serve as deoxidizing material for overblown iron. The results, however, were negative.

Glass Conductors.—According to the electromagnetic theory of light, all conductors except electrolytes should be opaque to light. If, therefore, under certain conditions glass becomes conducting, the conduction must be, as an approximation, regarded as electrolytic. In "Electra" (Amsterdam) A. Vosmaer describes a striking illustration of the conductivity of glass. Two electrodes terminating in glass rods are connected to the terminals of a high-tension transformer. Nothing happens while the glass rods are cold, but if they are heated by a Bunsen burner they become conductors, and an arc strikes between them. The heat of the arc is sufficient to keep up the conductivity of the glass.

A Huge Electrical Scheme.—A bill embodying a scheme of electrical development of power of ultra-American magnitude is now being considered by a committee of the House of Lords, says the "Practical Engineer." The bill empowers a corporation to supply electricity for lighting, traction, power and other purposes over a district of about 2000 square miles, including the towns of Sheffield, Lincoln, Nottingham and others. The central generating station is to be at Worksop, in the midst of a coal mining district, where coal slack may be had for about 50 cents per ton, and the promoters expect to be able to supply electrical energy to a large market at an extremely low rate.

A Long Land Line.—The Canadian Pacific Railway Company is now building a land line of copper wire from Montreal to Vancouver, which will contain, when completed, no less than 2900 miles of copper wire. Some interesting practical tests on insulators for this line have been going on recently at McGill University, and are described in the "Canadian Engineer." The tests are for the resistance to fracture of various types of glass and porcelain insulators, the result being that the porcelain resisted much heavier and more blows than the glass. With a 32-calibre revolver fired from a distance of 8 ft. the glass insulators flew to pieces at nearly every shot, while the porcelain frequently showed no mark except a blackening from the lead of the bullet; when they did break it was generally in such a way that, had they been attached to the pole, the wire would not have fallen. The wire used on this line weighs 300 pounds per mile, and shows a conductivity of 97 per cent.

Aging Transformer Iron.—Mr. R. C. Clinker, in a letter to "The Electrician," confirms Roget's researches on the aging of transformer iron. During a period of two years he made a series of tests on different brands of iron, and noticed that at a certain temperature the iron commences to improve after having been "aged." As an example, he quotes the case of a sample of Swedish iron which showed the very low initial hysteresis loss of 0.15 watts per pound at 2500 lines per sq. centimeter and 100 cycles per second. After twenty-six days at a temperature of 90 degs. C. the hysteresis loss had gone up to 0.31 watts per pound. The sample was then put in an oven at a temperature of 120 degs. and after seven days showed a loss of only 0.19 watts per pound. In other samples the same effect was found, but in less degree. Another specimen of iron started at 0.31 watts, and rose in five days, at a temperature of only 90 degs. to 1.07 watts per pound, after which it slowly improved.

Melloni Piles.—Dr. H. Rubens discusses in "Zeitschrift für Instrumentenkunde" the value of the thermopile for investigations of minute temperature changes. This instrument has lately been supplanted by the bolometer of Langley, Boys' radiomicrometer and the sensitive photo-electric pile of Minchin, but the author thinks that the thermopile may be made more efficient than any of these by properly reducing its thermic capacity. Antimony and bismuth, while showing a high thermal e.m.f. are mechanically weak and unsuited to the construction of such apparatus. He proposes to substitute iron and the nickel-iron allov called "constantin" in the form of very fine wires. The thermoelectric power of the iron-constantan couple is only about half that of the bismuth-antimony combination, but the gain in sensitiveness due to the diminished size and thermic capacity of the apparatus more than compensates for the difference. Dr. Rubens has lately constructed such a thermopile having twenty couples, its resistance being 3.5 ohms and its e.m.f. 0.000106 volt per deg. Centigrade. This instrument he regards as marking an important advance in radiometry.

Nickel Plating on Wood—To successfully nickel plate wood it must first be coated with a thin layer of metal. "Le Génie Civil" gives the following formulæ: Prepare three solutions: (1) 1½ grammes of pure gum rubber dissolved in 10 grammes of carbon bisulphide, to which is added 4 grammes of melted wax. In another vessel make a mixture of 5 grammes of phosphorus, 5 grammes spirits turpentine, 4 grammes asphalt powder and 60 grammes carbon bisulphide, and add this to the first solution while stirring. (2) Make a solution of 2 grammes of nitrate of silver in 600 grammes of water. (3) A solution of 10 grammes of chloride of gold in 600 grammes of water. Place the object to be nickeled, with the conducting wires in place, in solution No. 1 and dry well after taking out. Then pour the second solution over it until it takes a dark metallic appearance. Rinse off with water and apply the third solution in the same way. Through this treatment the wood takes on a yellowish color and is now fully prepared for nickel plating. The bath for plating should consist of 500 grammes of ammonium nickel sulphate, 50 grammes of ammonium sulphate and 10 litres of water. The liquid must be neutral, which may be arrived at by the addition of ammonia chloride solution until litmus paper is unaffected.

Electric Painting.—Under this title "L'Eclairage Electrique" contains an article by M. P. Marcillac, describing a system of protecting vaults, rooms, etc., against burglars. It consists of a coat of conducting paint, which is furnished at a convenient point with a connector. This is laid on and dried, then varnished with an insulating varnish. On the top of this is put another coat of the conducting paint, also furnished with an appropriate terminal, and over all is put the usual veneering, papering, paint or other surface finish. By connecting a battery and bell to the two layers of paint a signal is sounded as soon as any attempt is made to penetrate the paints with any metallic instrument. Another use for this paint is in the compartments of vessels, which may be thus painted in stripes at definite distances below the water-line. In case of a leak the sea water completes the circuit and shows on an annunciator the location and depth of the entering water. Still another use is found for the paint as a covering for long-range targets, an annunciator showing where the bullet has made contact between the conducting layers. The ingenuity and simplicity of this system of alarms are probably greater than its utility.

Heating Switchboards.—In a paper read by Mr. J. R. Blaikie before the (English) Municipal Electrical Association on Switchboard Apparatus, he made the curious suggestion that the place for the field rheostat is on the switchboard, because it keeps the latter warm, and thus prevents the disastrous effects of condensation of steam and fog. The placing of such rheostats on the lower panel of the switchboard is so general in this country, that there has been little opportunity to see what effects might follow their removal and the consequent cooling of the board, but it is certain that there is a distinct element of danger in a switchboard colder than the surrounding air, especially in high tension work. The film of moisture that will certainly form on it under these circumstances may lead to disastrous results, but it is not likely that it will persist, as the passage through it of any considerable current will electrolyze and dissipate it, at the same time locally heating the board. Still, the point is a good one, and is worthy of attention. Another suggestion of Mr. Blaikie's is that switches, etc., should be given a coat of some of the various paints that change color when heated, this being a safe and simple indication of local trouble.

Cost of Electric Cooking.—A manufacturer at Frankfort has been trying some pleasant experiments upon the cost of electric cooking, which are described in "Elektrotechnischer Anzeiger." Luncheons for four or six persons were prepared by a restaurant cook, the current being supplied by the local electric light company at 3.75 cents per k.w. hour. A specimen bill of fare is as follows:

	Amps. current.	Minutes.	Cost.	
Cooking 3 pounds of beef....	8.7	20	1.186	cents.
Keeping beef warm..........	2.6	154	2.75	"
Parboiling 1 cauliflower.....	8 8	22	1 33	"
Baking the cauliflower......	8.8	20	1.21	"
Egg-sauce for cauliflower....	0.6	1	0.04	"
Keeping above warm........	3 1	14	0.29	"
Broiling 4 cutlets....	5.5	10	0.43	"
Heated pan too soon (wasted)	5.5	5	0.19	"
Frying potatoes in butter...	5.	25	0.86	"
Total cost of current for cooking luncheon for four........................			8 29	cents

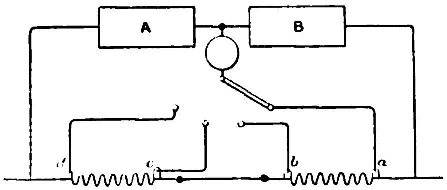
An excellent luncheon for six, including a steak, fish with tomato sauce, potatoes and rice à la condé was cooked at a cost for current of only 6.91 cents. To heat water for washing the dishes and utensils the cost is given as 1.75 cents for 2.5 gallons. A quart of coffee can be made for 0.5 cent. The cost to a family of four for three ordinary meals is calculated to be about 11 to 12.5 cents per day.

Power from Blast Furnace Gases.—Great interest is being manifested in Europe in the power than can be obtained from the generally wasted gases of blast furnaces. Great advantages are gained by utilizing these gases in gas engines rather than by burning them under boilers. The "Revue de Mécanique" sums up the discussion of this matter, and quotes the following figures: The calorific power of these gases is about 1000 calorics per cubic metre, and they produce when burned under boilers about 1 pound of steam per cubic metre (35 cubic ft.). It thus requires about 800 cubic ft. of gas per h.p.-hour by this method as against about 100 cubic ft. required for developing the same power with a good gas engine, the latter developing a capacity of about 2000 h.p.-hours for each ton of pig iron produced by the furnace. At Seraing (Belgium) an Otto engine of 200 h.p. has been installed. The gas goes through three coke scrubbers and is washed by a spray of water before going to the engine. After washing it contains about 1 grain of impalpable dust to the cubic foot, but this is said not to have any harmful effect, the washing being sufficient to remove any acids that might injure the cylinder. Two blast furnaces, making 1600 tons of Bessemer pig per week with a consumption of 9.75 tons of coke per hour, will give, after deducting the 1000 h.p. necessary for the blast and the gas used in heating the air, 10,780 h.p. effective for use. This assumes the employment of gas engines, which show for this work a superiority of 450 per cent over steam engines using the same gas as fuel.

Comparison of Very Low Resistances.—"L'Industrie Electrique" gives the following method of comparing very low resistances, due to Messrs. A. E. Muller and Hermann Wallau: Referring to the illustration, let R be a standard resistance and x the resistance to be compared. Current is allowed to flow through these low resistances in series, and they are provided with the terminals a, b, c and d. The resistance coils A and B, connected in series and shunted around the two resistances to be compared, are each of about 10,000 ohms, one of them having all its plugs in, the other none. A galvanometer of great sensitiveness is connected, as shown, between the junctions of the coils A and B, and each of the four terminals of the resistances to be compared. For each position of the switch the resistance of the two coils A and B is varied, so that their sum remains constant at, say, 10,000 ohms, and until the galvanometer stands at zero. If the resistances cut in in coil A for the four positions of the switch be called a, b, c and d, corresponding to the connections of the switch with the terminals thus lettered, the value of x is given by the formula:

$$x = \frac{a - b}{c - d} R$$

While this method is slower than that of the double Thomson bridge, it is simpler with the apparatus usually found in laboratories. The main current should, of course, be kept rigorously constant throughout the experiment. By using an alternating current and a telephone the same method may be applied to the measurement of the internal resistance of an accumulator.



LOW RESISTANCE MEASUREMENT.

A Rival for the Electric Furnace.—In a rather rhetorical article in "L'Industrie Electrique," M. Georges Claude discusses the possibilities arising from the manufacture of oxygen by the Linde process. This process, as is well known, consists of the liquefaction of air, the oxygen content of the mixture being least volatile evaporating last, so that liquid oxygen or highly oxygenized air may be obtained by the partial evaporation of the liquid. The author states that by this process it is possible to produce more than 185 cubic ft. of oxygen per h-p.-hour, and thus the oxygen may be had for the insignificant sum of 5.4 cents per 1000 cubic ft. The possibility of obtaining very high temperatures by combustion in pure oxygen is well known, and the author avers that he has made calcium carbide by the combustion of a mixture of lime and coke dust in this gas. He goes on to argue that this method, being cheaper than the electric furnace method of producing high heats, will displace the latter for all work where electrolytic action is not required at the same time. As the air is simply a mixture of nitrogen and oxygen, the energy required for their separation is almost *nil*, but in practice, owing to losses of various sorts, it amounts to a respectable figure. Notwithstanding, M. Claude is convinced that carbide will be made in future through the agency of the oxygen of liquid air—a sort of paradox in which the lowest attainable temperature is employed as a step toward producing the greatest possible heat.

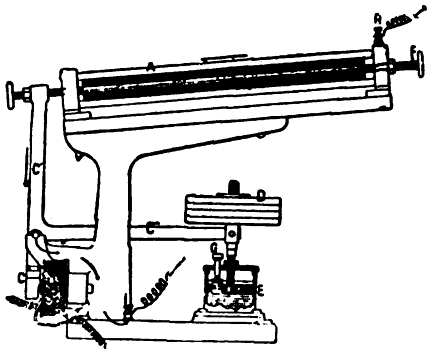
A Regenerative Electro-Zincing Process.—The (London) "Electrical Review" gives a short account of an interesting electro-galvanizing process due to Mr. Cowper-Coles. It appears that the chief difficulty hitherto encountered in processes of this character have been due to the fact that neither cast nor rolled zinc electrodes dissolve in a proper way to keep the electrolyte in good working order. Mr. Cowper-Coles obviates this by the use of zinc dust or "tultz," which is a grayish amorphous substance obtained as a sublimate in the flues of zinc smelting furnaces. It contains about 97 per cent of metallic zinc, and is not to be confused with the oxide of that metal. This dust is placed in regenerative tanks in the shape of a mixture with fine coke or sand on grids so placed as to form a filter bed. The solution used is allowed to circulate through these tanks so that any free acid is neutralized. If the zinc dust is allowed to get into the electrolyte it is found to increase its electrical resistance. A zinc sulphate solution containing 12.6 per cent of free acid, after passing through such a filter bed containing 10 per cent of zinc dust was found to hold only .7 per cent of free acid. These filters not only serve to keep the solution up to its full strength, but also to rid it of impurities in suspension, which are a cause of spongy deposit. The best electrolyte is composed of 40 ounces of zinc sulphate to the gallon of water, and has a specific gravity of 1.177. Lead anodes are used, the current density being 17 amps. per sq. ft. and the e.m.f. being 6 volts.

Electricity and Agriculture.—Dr. C. Kottgen, a well-known German savant, has just made an elaborate report upon the possibilities of electricity in agricultural operations, which is briefly summarized in the "Practical Engineer." He concludes that, sooner or later, the use of electric power in agriculture is sure to come, but that electrotechnics must first make many advances. Electrical machinery has in its favor that it is light and easily transported, and perfectly adaptable to the application of power over an extended area, while the most favorable conditions for the use of electric power are when water power is available or the waste product from some other industry can be had for steam raising. Electric motors, while better adapted to plowing than to any other farm operation, are still useful in threshing, feed-cutting, grinding, irrigation, drainage and for other uses. Experiments have shown the technical possibility of the application of electricity for these purposes, but its economical use on farms smaller than 600 acres is very questionable.

All this is especially interesting when it is considered that the straw from an ordinary Dakota wheat farm is generally burned to get rid of it, and that it possesses sufficient potential power to move all the machinery of the farm. Notwithstanding the rather faint praise of the German engineer, there seems to be an opportunity for considerable development of electrical machinery for farm purposes, especially where these are conducted on a gigantic scale, as in our own Western States and the sugar plantations of Cuba.

Electric Rock Drill.—In the iron mines at Bindt, Austria, an installation of electric percussion drills has been set to work, and "Zeitschrift für Elektrotechnik" gives some interesting data of its performance, omitting, however, to give the most important figures—the speed of the hammers. The apparatus for drilling consists of two solenoids mounted in an iron tube and alternately attracting an iron armature mounted on the piston of the machine. Current is furnished by a special alternating dynamo, and there are no commutators or switches about the apparatus. A system of spiral feathers and clutches allows the piston of the drill to strike out straight when the blow is delivered against the rock and turns the drills and piston the proper amount on the back stroke. The machine, after setting in position, can be advanced 2 ft. by a screw, thus boring to this depth without resetting. The cylinder, containing all the working parts, is 34 ins. long, 5 ins. in diameter, and weighs only 160 pounds, being the lightest of all percussion drill apparatus. Its capacity is for holes between 1 and 2 ins. in diameter. A table of the speeds of drilling through various materials is given by our German contemporary, but neither the diameter of the holes nor the number of strokes per minute are stated. From this it appears that the speed in very hard siderite iron ore is 15.6 ins. in ten minutes, and for the same length of time is 18.3 ins. in fairly hard ore, 18.6 ins. in quartzite schist, 21.4 ins. in hard schist, and over 30 ins. in soft schist.

Automatic Carbon Rheostat.—A very ingenious and simple self-regulating rheostat, adaptable to a great variety of uses, has been designed by M. J. Ferrand and described in "L'Electricien." Its operation will be readily understood by reference to the accompanying figure, which shows the apparatus in section. The resistance consists of a pile of carbon discs, A, which are held in place by four glass tubes forming a cage about them. At one end of the pile is a regulating screw, F, which bears upon a bronze end plate. At the other end of the pile of discs the end plate rests upon a screw attached to the extremity of the lever C. The tension upon the pile of discs is regulated by the action of the counterpoise D and the electromagnet B, a dashpot E being provided to avoid too rapid and sudden movements of the lever. By properly connecting this machine and varying the counterpoise, it may be made to accurately regulate the amount of current flowing through it, or the difference of potential at the extremities of the carbon resistance. In the latter case, of course the coil B is of high resistance and shunted around the carbon, while in the former case it is of low resistance and connected in series with the regulating discs. It is said that by the use of this rheostat the designer has been able to hold the terminal potential of a 10-kw. machine constant while the speed varied between 1000 and 2000 r.p.m. Its principal use is expected to be found in connection with field regulation for dynamos, as its automatic qualities are especially valuable for this purpose.



AUTOMATIC RHEOSTATS.

Nerve Currents.—In a communication to the Royal Society, Messrs. F. Gotch and G. J. Burch describe their investigations of the electrical responses of nerves to a single stimulus, which they have observed with a capillary electrometer. The stimulus employed was a relatively feeble induced current caused by the opening of the primary circuit of an induction coil, to which was attached one cell of battery. In all the experiments the sciatic nerves of large frogs were used. The stimulus was applied to the sciatic plexus about an inch from the nearest of the electrometer contacts. The shock traveled along the nerve past a pair of unpolarizable contacts connected with the electrometer, and was in each case immediately followed by the nerve current in rapid succession. Photographic records were taken, the exciting current showing on them, but being readily distinguishable from the larger following nerve currents. Some of these nerves used were freshly prepared, while some had been kept in cold salty solution for twenty-four to ninety hours. The two sets of nerves showed marked differences. In the fresh ones the first indication of the presence of the reaction occurs 0.002 second after the stimulation. The decline commences 0.001 second after that. In the nerves that were kept the loss of vitality showed both in the initial change and the rate of propagation. The latter falls from 10 or 15 to about 6 metres per second. The actual e.m.f. of the nerve currents may be put as high as 0.032 volt, which is a suggestive fact in view of the various theories of the electrical organs of fishes.

An Alternating Current Watt-Hour Meter.—A novel and interesting form of watt-hour meter for alternating currents is described in the (London) "Electrical Review." The illustrations show the meter in plan and cross section. The field is of a four-pole type, each pole having an extension on one side and all these extensions pointing the same way. The series coil is wound on Gramme fashion, while the shunt coil is in two semi-circular parts on frames, each part surrounding two of the field poles. The core of the armature, shown at E, is stationary, the revolving part being a copper bell, G, Fig. 1. To the shaft of this is attached a copper disc running between damping magnets. The whole of the moving part weighs less than 2 ounces, and has its weight further decreased by the upward repulsive action of the field. An external inductive resistance, which can be adjusted, is used, so that the scale can be read directly in k.w.-hours without the use of a constant. The torque due to the shunt field alone is a little more than sufficient to compensate for friction in the apparatus, so that the moving parts would constantly revolve at a very slow speed. This tendency is counteracted by a small piece of iron wire adapted to be caught in the field of one of the permanent damper magnets, so that the meter does not move, even if violently shaken, with no current in the series coil. The slightest current in this coil, however, is said to start the meter, which will register at ½ per cent of its full load. Obviously such a meter, while free from commutators and sliding contacts, has to be adjusted to the frequency at which it is to be used. A second non-inductive resistance in shunt with the shunt coil is used to regulate the lag of phase in the meter.

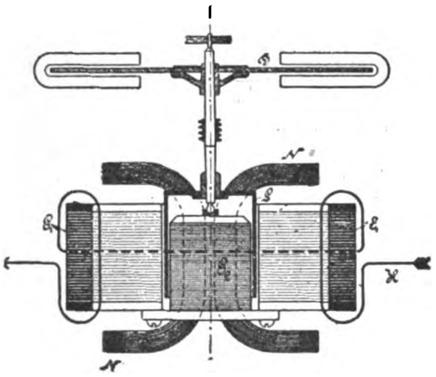


FIG. 1.—SECTION OF ALTERNATING CURRENT WATT-HOUR METER.

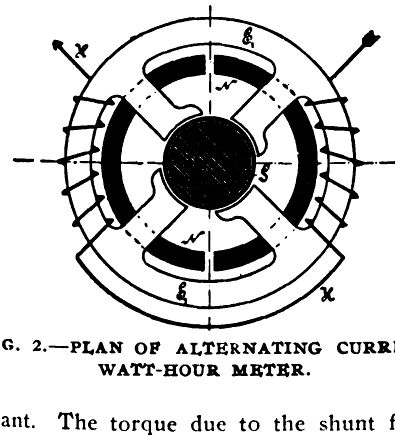

FIG. 2.—PLAN OF ALTERNATING CURRENT WATT-HOUR METER.

Electrical Resistance of Steel.—M. H. Le Chatelier has contributed to the Académie des Sciences the results of a series of experiments on the electrical resistance of steels of various composition, and the conclusions that he draws concerning the effect of various constituents.

The effect of carbon is to increase the resistance per cubic centimeter about 7 michroms for each additional per cent of carbon. Silicon produces an augmentation of about 14 michroms for each per cent added (by weight) or 7 michroms for each atom of silicon to 100 atoms of the alloy. The author concludes that the silicon is not isolated in the steel as the definite compound Fe Si$_2$, but is distributed through it in a homogeneous mixture. Manganese increases the resistance very considerably. While this metal forms isomorphous mixtures with iron in all proportions these alloys show two allotropic states in which the magnetic qualities are widely different, the conducting qualities also differing. In the 13 per cent manganese alloy the resistance, in the magnetic condition, was found to be 66 microhms and in the non-magnetic state 80 microhms per cubic centimetre. Nickel shows the same double properties, its iron alloys having two magnetic as well as two conductive states. The variations due to the presence of carbon, silicon and other ingredients, however, cause the resistance of these specimens to be very uncertain. Chromium, tungsten and molybdenum have a very small effect upon the resistance of steel. The author thinks that the small influence of these metals on the resistance shows that they are isolated in the metal as definite combinations, and not distributed through it.

Producing High Temperatures with Aluminum.—At the recent annual meeting of the Deutsche Elektrochemische Verein a paper was read by Dr. Goldschmidt, describing an interesting method for producing very high temperatures by the combustion of aluminum through the aid of the oxygen combined in an oxide such as that of iron. The mixture of powdered aluminum and the oxide is lighted with a match and burns quietly. In a furnace made of an ordinary wooden bucket lined with sand a large iron rivet weighing 6.6 pounds was readily heated to a white heat. The cost of the process is said to be very small, as very little aluminum is consumed. The method is especially well adapted for hard soldering and brazing. One of the principal uses of the process will be to obtain certain metals in a pure state free from carbon. Chromium can be easily obtained in this way in the free state. Another use is the uniform and powerful heating of particular parts of metallic objects. It suffices to surround the part to be heated with powdered aluminum and a cheap and fairly refractory oxide, such as iron oxide or silica, and to kindle the mass by a fuse or charge of a mixture of aluminum powder and an easily reducible oxide. The temperature resulting can be adjusted with precision by varying the proportions of the mixture and the size of the charge. It is thought that this process may become a formidable rival to electric welding.

The process is really a secondary method of applying the heat of the electric furnace, for the heat set free is that absorbed in the reduction of the metal during its manufacture. A point of great practical importance is that commercially impure aluminum answers the purposes of this process, a high content of iron being no detriment.

Diaphragms for Electrolysis of Alkaline Chlorides.—A very interesting description of the various diaphragms used in electrolytic alkali processes is contributed to "L'Industrie Electrochemique" by M. H. Becker. The difficulty of obtaining good diaphragms is one of the greatest in connection with these processes, and the success of several of the best known has been through their suppression of this auxiliary. The qualities necessary are low electrical resistance, sufficient lack of porosity to prevent the mixture of the solutions on the two sides, and slow deterioration in the presence of caustic alkalis and chlorine. Among the oldest types are the paper parchment diaphragms of Le Sueur and others. These parchment septa have also been utilized in connection with a protecting layer of a chloride of one of the alkaline earth metals. Rieckmann has used diaphragms made of albuminized paper and of pure albumen, the latter being prepared by flowing a solution of blood albumen between two plates of oiled glass and heating it to the coagulating point. The glass is easily stripped away from the albumen film. Hoepfner uses paper covered with collodion, which becomes sufficiently porous after soaking in water for some time. Porcelain and porous clay have been often proposed, but do not seem to have met with much favor in practice. Many attempts to use asbestos or some of its products have been made, one due to Roberts and McGraw being to subject a sheet of asbestos pulp to the action of hydrochloric acid for twenty-four hours, after which it is washed and rolled under heavy pressure. An English process makes use of a perforated sheet of metal, which is covered with a paste of lime and asbestos, dried and washed with a solution of silicate or phosphate of soda. These diaphragms can also be used as cathodes, but for this purpose the covering of the metallic sheet should be sufficiently strong and porous to resist the action of the hydrogen evolved. Wiernick prepares diaphragms by superposing layers of asbestos and kaolin or asbestos saturated with soda silicate solution, the whole being rolled. Waite makes porous plates by the use of bichromated gelatine and asbestos, the gelatine being "fixed" by exposure to sunlight. A similar process in which the bichromate is replaced by formic aldehyde is in use by Rieckmann. Numerous other methods of using asbestos alone or in combination have been tried. Portland cement has also been used in the manufacture of diaphragms, a British patent describing the addition of salt, which is dissolved out after the cement has set. Coke, sand, powdered pumice stone, ravelings of linen and chopped hair are also mixed with the cement to increase its porosity, the organic substances dissolving out under the action of the electrolyte.

Central Stations in Spain.— Dr. Arthur Lietke, of Madrid, writes for "Elektrotechnische Zeitschrift" an interesting article on the electric lighting industry in Spain. There appears to be no genuine electrical industry in that country, the business being in the hands of foreigners, principally Germans. At the middle of last year there were 300 central stations in Spain, which, as that country has about one-third the population of Germany, indicates that the electric light is used there to a considerably greater degree than in the more progressive Empire. About 90 per cent of these stations are in small cities and towns. In nine of the forty-eight provinces there is no town of 4000 inhabitants or over not provided with a station. These towns were not generally provided with gas plants, and the high price of petroleum oils has assisted the progress of the electric light. About 60 per cent of the installations are driven by water power. While franchises are easily obtained, they are not ever exclusive, and there is much competition, there being five stations in Madrid, and from two to three each in Barcelona, Seville, Malaga, Valencia, Saragossa, Bilbao and Cordova.

It is difficult to obtain accurate data of these stations, as may be imagined from the general character of the inhabitants. About 48,000 h.p. is used for dynamo driving, or about 30,000 k.w. in round numbers. This is about one-half as much as is devoted to the same purpose in Germany, but considering the difference in population indicates that there is a greater use of electric light per inhabitant in Spain. Of this power about 35,000 h.p. is generated by steam and about 13,000 by water power. Gas engines and steam turbines are very little used. Of the small stations about one-half the number use water power, but the average power developed is only 70 h.p.

A number of statistical figures are given. Direct current is used in only 40 per cent of the stations, but supplies 70 per cent of the total light. Accumulators are used in only 5 per cent of the stations, most of which are operated only from dark until midnight. As much as 95 per cent of the wiring is overhead, but few poles are used, the wires being attached to the fronts and roofs of houses. This feature of Spanish installations was commented upon in one of these notes in the June number. Dr. Lietke makes the remarkable statement that in Spain is found the greatest proportion of electric street lighting to population in the world.

The installation cost for one of the little 70-h.p. stations generally falls between 100 to 200 pesetas per 10-c.p. lamp (a peseta at par is equal to a franc, about 20 cents, but is now at a large discount). The charge for lighting is about 3 pesetas per month from the water power stations and 4 pesetas from the steam stations for a 10-c.p. lamp. It is not stated whether these figures include renewals. In the southern provinces the mass left after the extraction of the oil from olives is used as fuel, and it is said that an economy of about 40 per cent over coal firing is thus obtained. The average price of coal is 35 pesetas ($7) per ton.

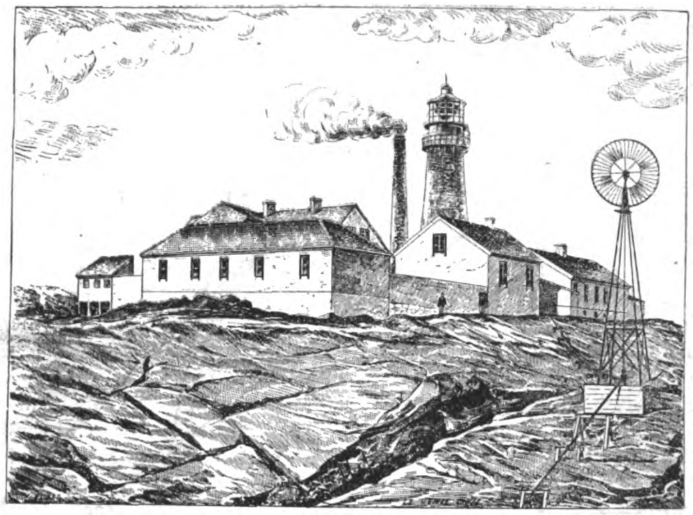

FIG. 1.—ELECTRIC LIGHTHOUSE AT RYVINGEN, NORWAY.

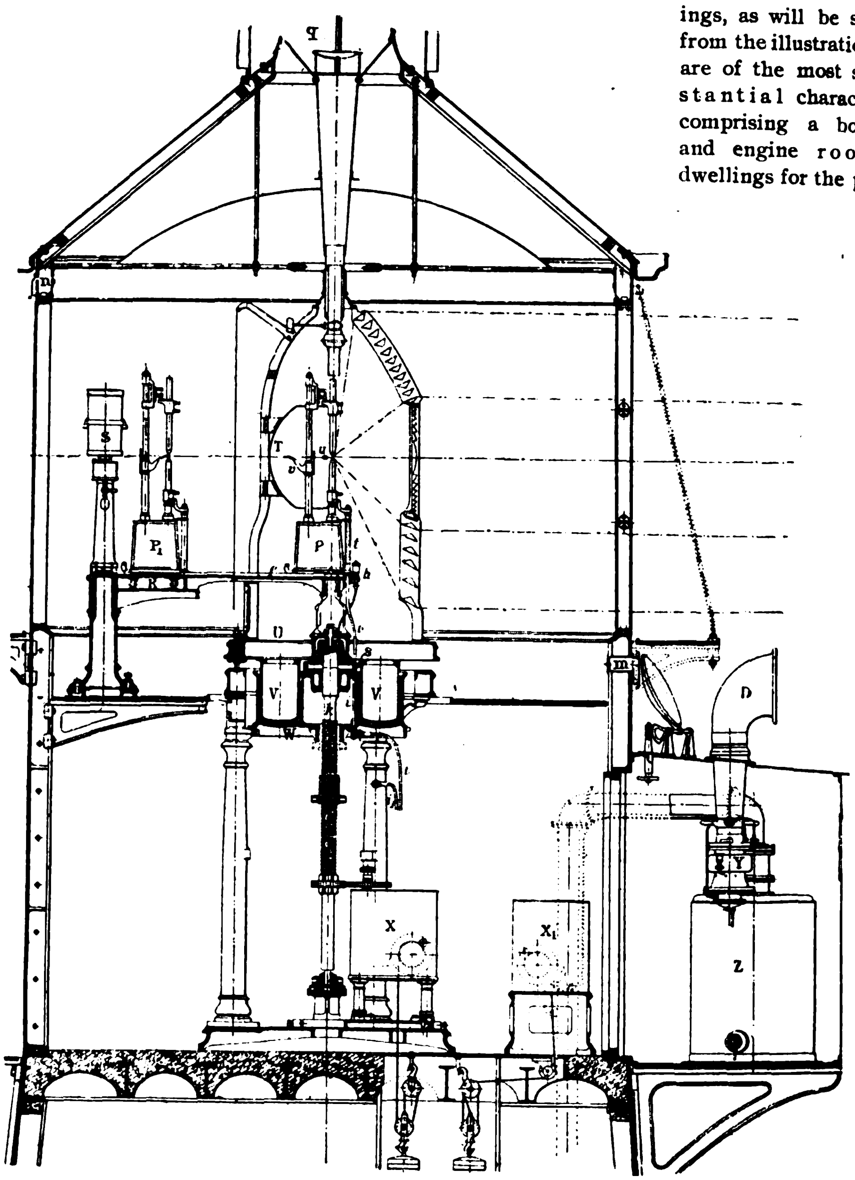

FIG. 2.—LANTERN OF ELECTRIC LIGHTHOUSE.

A Norwegian Electric Lighthouse.—An electric lighthouse of the "flashlight" type has been erected at Ryvingen, on the coast of Norway, and is described at great length in "Le Génie Civil." The principal points points of interest in this lighthouse are the electric generators and the lamps, both of which are of a type so ancient as to appear novel. The buildings, as will be seen from the illustrations, are of the most substantial character, comprising a boiler and engine room, dwellings for the personnel of the establishment, coal sheds, etc. Fresh water is collected in a pool in the rocks near the light, the rainfall being abundant, and pumped by a windmill to a tank under the boiler house. Rainwater from the roofs is also collected and stored for the use of employees. The tower carrying the light is built of 1-in. cast iron plates, and is about 70 ft. high, its base being about 100 ft. above the sea level.

In the boiler house are two Babcock & Wilcox boilers of 400 sq. ft. heating surface each, and working at 120 lbs. pressure. There are two high-speed automatic engines of 25-h.p. each, working at 220 r.p.m. A mixture of gas-coke and Welsh coal is used to avoid smoke. One engine and boiler are sufficient to furnish power both for the light and the fog siren, so that there is an ample reserve of power.

The generators are Meritens magneto machines, the fields being composed of permanent magnets. Each of the two machines has five sets of magnets, each set containing eight radial bundles of magnets, eight magnets of horseshoe form, 18 ins. long and made of steel plate ⅜ by 2 ins. to the bundle. There are thus 320 of these magnets to each machine. The armature cylinder is 17 ins. in diameter. Each machine gives 110 amps. at 45 volts and 60 cycles per second. In addition to these magnetos there is a very small 110-volt dynamo for lighting the engine room and tower stairs. Three arc lamps are provided for the lantern. Each is arranged to consume 50, 100 or 200 amps. at 45 volts, using carbons of ⅝, 1 or 1⅛ ins., respectively, with a corresponding candle power of 5000, 10,000 and 20,000. The lamps are of the Serrin clockwork focussing type. On account of the heat generated, these lamps cannot work over one hour continuously on the heaviest current, or over four hours at the lowest consumption, and they have to be shifted by hand when they become too hot for service. A turntable, shown in the illustration of the lantern, has a reserve lamp arranged for service upon it, and the change can be made in about 15 seconds. An oil lamp, shown at S, is also kept in reserve to provide against the failure of the electrical apparatus. The flashes from the lantern, which is turned by clockwork and floats on mercury, are sent out 2½ seconds apart until four are given, then a period of eclipse of 12 seconds is succeeded by four more flashes, and so on. With the largest carbons and heaviest current the intensity of a flash (in the meaningless units employed for this sort of photometry) is stated to be 34,312,500 c.p.

It is interesting to see the Meritens machine revived after more than twenty years of well-earned repose. Why clockwork is used to turn the lantern when alternating current is on hand in abundance, and why vertical feed lamps are used, are questions that are not answered by our contemporary.

Lithanode Accumulators.—In a long illustrated description of the process of manufacturing what are called "Lithanode" accumulators the (English) "Electrical Review" describes a method of making cakes or pellets of lead peroxide which will not disintegrate. It is simply by mixing litharge with a solution of sulphate of ammonia, which causes the litharge to harden and "set" like a cement. These pellets are then formed in the usual electrolytic way, but in the original process forming was conducted in a bath of sulphate of magnesia.

Aluminum Brass.—About 1 per cent of aluminum in brass, according to the "Mechanical World," is extensively used for electrical purposes, as this metal casts free from pinholes, and the addition of the aluminum gives a greater strength than the brass would otherwise show. From this it follows that a cheaper grade of brass can often be made to do the work of a higher priced grade by the addition of aluminum. In cases where the best results are desired it is very important that the ingredients of the brass shall be pure, as the nature of some of the impurities commonly contained in copper and zinc are such as to absolutely prevent the production of good alloys with aluminum. For aluminum alloys the metals should not contain more than ¼ per cent of iron, arsenic or antimony, or more than 0.02 per cent of bismuth.

Some Water Power Station Tricks.

To the Editor of American Electrician:

In at least one case where water and steam are coupled together for driving a generator there are several things the attendant has to look out for. One of these is the speed of the water wheel which drives the generator. The case is this: The generator which supplies the lines is in a building in town, while the water wheel, which does a good share of the work, is two or three miles distant.

Current is generated there at 110 volts and transformed up to 2000 two-phase alternating, and thus sent to town where a synchronous motor receives it and transforms the energy into rotative form again. The amount of power derived from the wheel is not enough, and neither is it steady enough to be used alone for driving a unit. Therefore the motor is belted direct to the wheel of a steam engine, and from the wheel on the other side of the engine a belt leads direct to the generator which feeds the lines. The water wheel governor keeps the speed at practically its proper value.

There are, however, times when things do not go well with the water wheel. When water is low, and the generator is loaded heavily, the governor does not work as well as would be desired. When the water is low and it is necessary to run at almost half gate, there must be some regulation at the main station, or the load put on the water wheel will cause the governor to work the gate wide open, even when it is set at half gate. Therefore constant watching of the instruments and adjustment of the gate regulator is necessary.

It is not that the governor is not a good one, for it is—it is one of the very best in the market—a pneumatic governor, and a very sensitive one, too. While the load is below a certain amount the governor will take care of it if there is water enough to give the regulator full swing. But with low water, when the speed drops by the load being more than half gate can carry, the synchronism of the generator and the motor is destroyed, and the water wheel does hardly any work until the governor is "doctored a little" and more water given for a few minutes.

Another thing with this plant is that it cannot be shut down at will, without causing trouble somewhere on the line. It would naturally seem as if, were the water wheels shut down—there are two of them geared to the same shaft—that the engine at the power house would have to work all the harder to make up for so much extra power which the wheel formerly supplied. This in a measure is so, but it does not work at all in the manner which would be expected. It does overload the engine at the power house, but that machine is powerful enough to carry the extra work and goes right along without even a hesitation.

But the motor which is connected with the steam engine, instead of continuing to be a motor after the speed of the generator which drives it falls below a certain speed, becomes a generator, and transmits current back to the water wheel station sufficient to run all the machinery, consisting of the two water wheels, the generator, transformer, several hundred feet of shafting in the water wheel station which is connected thereto for the purpose of driving other machinery.

All this machinery will be driven by the engine at the city power house, provided that the water is shut off gradually, and the speed of the machinery allowed to decrease gradually. Should, however, the water wheels be shut down quickly, the motor at the power house will respond with such a rush of current that one or more of the fuses will blow and cut off connection between the machines.

There is one more pecularity which I have noted in connection with this installation, and that is that when water is scarce, and both wheels have to be throttled down to about half gate, and when the load in the spool shop is also considerable, there will be periods when the generator at the water power station and the motor at the power house are both acting as generators, and seem to be running one against the other. The instruments indicate that very little current is being sent to the power house, while at the same time the wheels are both running, but are evidently driving nothing but themselves, as is evident from their excessive backlash, which will prove destructive to the wooden cogs if permitted to continue.

It is evident that during these periods of "neutral activity" the plant, or at least the generator, should be stopped, and the water allowed to accumulate until there is enough to do more work. The steam engine is getting no help under those circumstances.

Railway Feeders and Ground Returns.

The necessity for a good ground return is so widely and thoroughly appreciated by railway managers that it has created and supported a number of well-to-do supply companies, who make bonding their specialty. It is interesting, however, to note the significance of property distributing the copper between the overhead and underground circuits, and it is frequently the case that in a given line the same copper differently distributed could effect a substantial reduction in line losses.

Consider, for instance, a concrete case in which a certain feeder delivers 500 amps. at a certain point 5000 ft. from the station with a loss of 50 volts. Its resistance is, therefore, one-tenth of an ohm. If the return circuit have the same resistance, the total resistance would, of course, be two-tenths of an ohm, which is the smallest possible value that the amount of conducting material used can afford. If, for example, we increase the size of a feeder by 50 per cent and correspondingly diminish the conductivity of the ground return, it is evident that the resistances would be, line one-fifteenth of an ohm, return one-fifth of an ohm. Thus the return would have a resistance equal to the entire original line, constructed from the same conducting metal on the equal resistance plan, and the total resistance would be greater the further the deviation from the condition of equality.

The power lost is inversely proportional to the resistance of the line, and this is, therefore, a most serious consideration. Curiously enough, many railway systems attempt to reduce their line losses by increasing their insulated copper, when the rail return, if more heavily bonded, would produce the same results at a fraction of the expense. In not a few cases the laws of maximum economy have been so grossly violated that better results could be obtained by disconnecting several feeders and tapping them into the rails at intervals, thus utilizing them to improve the ground return. Frequently this has been done where managers have had the feeders and have not had the money to pay for the necessary bonds. As a means for making the best of the mistake in the expenditure of money it is commendable, but as a practice in initial installation it is unpardonable.

If bonding were as expensive as insulated copper with poles, it is obvious that the condition of equal conductivity should prevail, but such is not the case; the bonding is cheaper. It follows, therefore, that for maximum economy the resistance of the rail return should be less than that of the corresponding feeders, and the difference, of course, is dependent on the relative costs of feeders and bonds. Unfortunately for the easy mathematical determination of the problem, the cost of the bonds is not a simple function of the conductivity they add to the ground return, as is the case of feeders. It makes a pretty problem in maxima and minima, but it should at least be approximately solved by anyone who has to lay out a feeder system, even if nothing more refined than the rule of thumb is at his disposal.

The Candle-Power Rating of Electric Lamps.

The great pains and ingenuity which various eminent associations and institutes have expended in estimating the value of old standards of light and estimating new ones has been and will continue to be ill-advised unless more care is taken in the commercial use of such units. The photometer is indeed used, and perhaps accurately, but the choice of results upon which rates are based and the relative merits of lamps determined is more absurd than the measurement of the area of a piece of land by its frontage or the performance of a dynamo by its electrical efficiency.

The error consists in taking the c.p. measured in one direction or plane as a measure of the c.p. of the lamp. The commercial measure should be the mean spherical c.p., for in practice the lamp is expected to give light not only from its sides, but from the crown and lower parts of the base. Indeed, in many cases, the useful illumination comes largely from those areas. It is evident at once that the ingenious lamp manufacturer may so dispose his filaments as to give a large c.p. in a plane parallel to the axis of the lamp, while the other parts suffer, and such a lamp, if tested in one direction, may easily show a greater efficiency in watts per candle than a lamp of greater mean spherical c.p. taking the same electrical energy. It is not to be inferred from this that a lamp of large horizontal c.p. is not advisable or desirable, but to rate its efficiency upon that function is wrong, and the practice infinitely wrong.

It cannot be alleged that this is an evil that does not exist. It may easily be that electrical engineers and lamp manufacturers scrupulously measure and accurately know the mean spherical c.p. of the lamps they test, but the fact remains that many sales to-day are decided upon the results obtained by the use of photometers measuring the c.p. only in one direction. Such photometers are cheaper and more easily improvised, and hence more plentiful. Moreover, the measure of the mean spherical c.p. is a tedious process and requires careful manipulation, even if the means are at hand. Such a state of affairs creates a keen competition in the arrangement of filaments in bulbs rather than in the production of filaments burning for many hours at high temperature.

In the case of an arc lamp the absurdity is so patent that it deceives no one. The old device of adding together the north, south, east and west c.p. to make up a total of 2000 or 1200 in lamps whose maximum c.p. in any direction does not exceed 800 or 500, amuses more persons than it misleads, but, strangely enough, it does not seem to set them to thinking about their incandescent lamps and the way they are awarding their contracts.

The case is one involving the tedious tack of educating the public, and as long as there remains an element to be educated, gold bricks will be bought and the vendor of goods who gives them the best external appearance will prosper and flourish, whether it be the humble Italian polishing his apples on a trousers leg or the ingenious twister of filaments. It is further evident that until the single position determination of candle power is no longer used as a criterion of efficiency that the simple standard candle is amply sufficient for commercial purposes .

Transformers in Series.

In another column is an article on the construction of a transformer by the use of simple materials. The information which it affords will be of undoubted value both to the experimenter and the student, for large currents of low voltage and small currents of high voltage are very frequently desired and, as the writer has pointed out, the utility of the instrument is very sweeping. For the production of very high voltages the writer recommends a number of transformers connected in series with the primaries, presumably connected in parallel. It may be added that as a precautionary measure it is very important that transformers to be used for such a purpose have a very heavy insulation between primary and secondary; in fact, sufficientlv thick to withstand the total voltage of the system. A moment's reflection will show the necessity of this. The extreme secondaries are immediately adjacent to a practically common mass of metal, the primary, and the total insulation between them consists of but two thicknesses of the separating insulation between primary and secondary. Not a few experimenters have connected together a number of station transformers for the purpose of producing high voltage and discovered this fact at the expense of disabling one or more of the transformers.

The Calcium Carbide Industry.

In another page is described an extensive and particularly well equipped plant for the manufacture of calcium carbide; and while the electrical enthusiast may congratulate himself on the ultimate installation of 40,000 h.p. of the most modern electrical machinery, there is room for reflection in the purpose to which this apparatus is to be put. The argument certainly is that the calcium carbide industry is a profitable one and that acetylene is beginning to be used as an illuminant, for otherwise it would be hard to justify the installation of a plant of more than double the capacity of the extensive carbide works at Niagara, and, moreover, involving a much greater first cost, than its consort on the lower lakes.

It behooves us, therefore, to improve the efficiency and economy of the electric lamp and produce more light for less current. There is no question but that the electric light has a long lead on acetylene. As an illuminant it is doubtful if acetylene would ever produce a better light, even though it might produce a less expensive one. But we have no right to assume that trouble in the management of the carbide or danger from explosions will be its commercial death blow. The pioneer days of the electric light saw quite as many formidable objections, which ingenuity has overcome. We cannot expect less of our competitors. Acetylene as it is at present can never hope to rival the electric light, but acetylene as it may be is likely to make the race interesting, if electrical inventors deceive themselves with the idea that in the field of illumination we have attained perfection.

Modern Alternator Design.

The field magnets of most modern alternators revolve, and their construction has been varied by many makers, and we may soon expect to see designers settle down to preferred types in much the same way that direct current engineers have universally adopted the drum armature and the internal radial pole. At present, alternator field magnet construction, that is to say, those of the rotating class, seem to be divided between single coil branch circuit affairs, inductor dynamos and magnets involving many salient poles, each carrying a coil.

The feature of no moving wire, which obtains in the inductor dynamos, is certainly, on first sight, a most attractive advantage, but it is too often secured at the expense of the design and the efficiency of the machine, and it is questionable whether it is not more of a trade-talking point than a real advantage. Such machines almost invariably involve a concentric coil of large internal diameter. If this coil is not to move it must be secured rigidly in position about the revolving core, and a sufficient clearance must be provided between them. To be mechanically secure it must be mounted on a heavy spool. Comparing this construction with the device of winding the concentric coil directly on a revolving core on a moderately thin spool, the advantage of the lesser mean length of turn at once obtains, and, almost invariably in such a case the pole pieces of the machine can be much more advantageously disposed and the general accessibility improved. Inasmuch as a coil wound concentrically to the shaft is in an ideal position to be secure from the strains of centrifugal force, and as in good designs the current supplied to such a coil is very small and requires only two collector rings of moderate size, it becomes an open question whether the stationary coil is such a decided advantage after all. The brushes of such collector rings are independent of angular position. If they make moderately good contact, they can never spark or give trouble. The voltage of the moving system is low and not liable to pierce the insulation. It is not surprising, therefore, that many makers have preferred to abandon the idea of the inductor machine and wind the concentric coil directly on the moving member.

In order to be efficient, the polar projections of such a construction as this must be suitably mortised and tipped with laminated plates, and in very large machines such a gigantic coil is difficult to wind, and, should it be disabled, it would involve a serious delay before it could be repaired. These disadvantages and others have undoubtedly induced many makers to adopt the multicoil field in large machines. The subdivision of the coils is a decided advantage as regards repair, although their mechanical arrangement is not as good as in the case of a single concentric coil. The labor expended on fitting the pole pieces is no greater than in the case of a single coil machine of equal efficiency, and the leakage factor is said to be considerably less, for the concentric coils surround and heavily magnetize the shaft, which frequently finds a circuit through the frame; indeed, many makers have found it necessary to provide massive brass bearings for their frames in order to break the continuity of this serious shunt on their magnetic circuits. We have yet to see very large alternate current machinery built on the single coil plan, and it will be decidedly interesting to note just what form American designers will finally decide to standardize.

A HOME-MADE TRANSFORMER.

The occasion often arises for the employment of a transformer in the test room or laboratory, and frequently for one constructed with some unusual ratio of transformation. The design here illustrated is for a small transformer which can easily be made by a student or experimenter for his own use, it requiring no machine work whatever, though a winding lathe or some substitute for one is a great help in its construction.

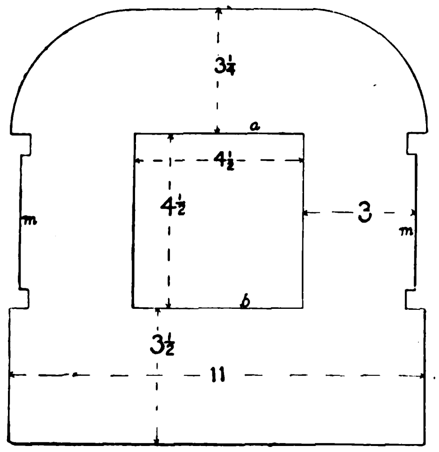

FIG. 1.—END BOARD OF IRON WIRE SPOOL.

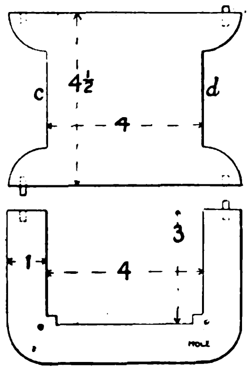
The frame of the transformer is made of hard wood boards, ½ in. thick, 12-in. stock being required. The field iron consists of a square coil of No. 18 soft iron wire, upon which the copper wire current-carrying coils are wound. To make the frame, cut out of the board two pieces, as shown in Fig. 1, these being the heads of the spool upon which the iron wire is wound. Two other pieces, shown in Fig. 2, are nailed or screwed to these at the points a and b (Fig. 1) so as to hold them separated at a distance of 3 ins. apart, inside to inside. The frame thus constructed is a sort of spool having two vacant sides, the square hole shown in the center of Fig. 1 being the axis of the spool. After it is assembled the edges c and d of the piece shown in Fig. 2 should be protected with strips of sheet iron or brass bent to a square corner and tacked on, as otherwise when the iron wire is wound on it will cut into these corners and make a rough and unmanageable coil. A wooden mandrel, 3½ by 4½ ins., should now be made and driven into the hole through the spool to hold it securely while the iron wire is being wound.

The iron wire should be of the softest obtainable quality, free from kinks and in long lengths. No. 18 is the best size, but smaller wire will answer excellently, though somewhat more expensive and troublesome to wind. The winding of this iron wire is by all odds the hardest part of the work of making the transformer, as it should be neatly done and care should be taken to avoid kinks or unevenness in the lay of the wire. A good plan is to bore a small hole through the side of the spool (the part shown in Fig. 2) as close as possible to the head, and start the end of the iron wire in this. Wind the first layer under very strong tension and as evenly as possible. The tension can be relaxed a little after the first two or three layers are on. A carpenter's handscrew with pieces of leather glued to its jaws makes an excellent clamp for holding the wire and regulating its tension while winding.

Each third or fourth layer should be well painted with black asphalt varnish, used very thick. If the wire breaks or if it is necessary to splice it, solder down the end to the coil with a drop of soft solder and start the next end as close thereto as possible, also soldering it fast to the coil. This iron wire must be wound 3 ins. deep, or until it stands flush with the edges of the heads at the points mm, Fig. 1.

The pieces shown in Fig. 3 are the heads for the coils of copper wire, four of them being required. These are provided with dowels, as shown, arranged to engage with the ends of the pieces of Fig. 2, with which they have the relation shown in the illustration. These heads fit in the notches shown in the edges of Fig. 1, small projections ¼ in. each way being left for this purpose, as shown in Fig. 3. When these pieces are in place the core of the transformer is ready for its windings.



FIGS. 2 AND 3.—HEADS FOR COPPER-WIRE WINDINGS.

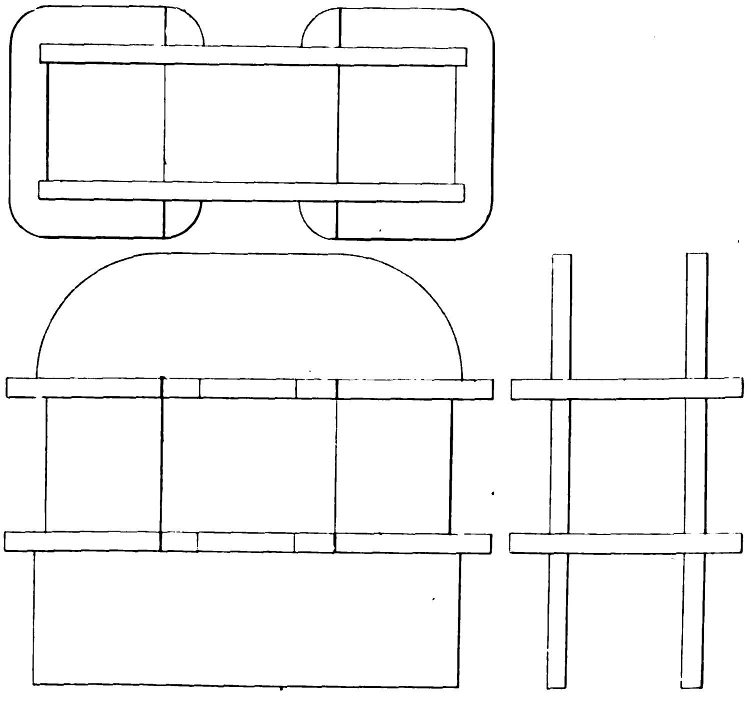


FIG. 4.—PLAN, SIDE AND EDGE ELEVATIONS OF COMPLETE WOODEN FRAME.

In the bottom of the space for each coil a piece of cotton cloth should be wrapped around the leg of the iron wire coil, and shellacked down to keep the winding away from the iron wire of the core. Holes about ⅛ in. in diameter should be drilled in the corners of the pieces, Fig. 3, as shown, for the terminal wires of the coils. The view of the finished machine, Fig. 6, shows how the ends of the primary and secondary coils are brought out and attached to binding posts on a board at the top of the whole.

The winding naturally depends upon the transformation ratio required and the frequency. That given below is for 55 or 110 volts on one side and 550 or 1100 on the other, at the ordinary frequencies of 7000 to 16,000 cycles per minute. It is not safe to use higher voltages than these on a transformer built upon this pattern, unless the whole is immersed in an appropriate vessel of oil.

The coarse wire winding consists of one layer of No. 12 double covered wire on each spool. These layers will contain approximately thirty-five turns each, but the space should be filled full and the number of turns requisite carefully noted. Beginning at the top of each coil space wind the wire neatly on and bring out the end through the hole in the lower head. To facilitate the winding a spool should be made of three circular pieces of wood, two of them 3 ins. in diameter and ¼ in. thick, and the third 1½ ins. in diameter and 1½ ins. thick. The latter is held between the two former to make a flat spool, upon which the wire for the coil is first wound for convenience in handling it in winding the coil on the core of the transformer. The No. 12 wire for each leg of the coarse wire coil is 44 ft. long, and this length should be cut off and wound up on the spool before commencing the winding.

The two coils, one on each side of the square core, should be wound oppositely, that is, the wire spool should be passed through the frame always in the same direction, so that the wire is laid right handedly on one leg and left handedly on the other of the core. By this arrangement the two bottom wires can be connected to the binding posts 2 and 3 (Fig. 6) and these used for a middle terminal of the coil, while the two upper terminals of the coils are carried to binding posts 1 and 4 on the upper board and serve as end terminals of the coarse coil.

The fine wire coil is laid on over the top of the coarse coil in the same way, but is more carefully insulated. A surface for it is prepared by wrapping a thin sheet of asbestos paper or micanite paper around the coarse coil on each leg, this being temporarily tied in place with a string until several turns of wire are in place to hold it. The terminals of this coil should be brought out through the other holes in the heads as described above. Number 20 double covered wire is used for this coil and exactly ten times as many turns as the coarse coil contains are laid on. If the coarse coil contains thirty-five turns in each leg (as it will approximately) the fine coil should contain 350 turns on each leg, which would come conveniently in five layers, each coil space holding about seventy turns of this size wire. The length for each coil is 450 feet.

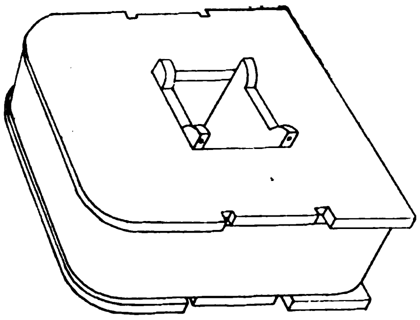

FIG. 5.—SKETCH PRESPECTIVE OF IRON WIRE SPOOL READY FOR COPPER WIRE WINDINGS.

After the coarse wire coil is wound it should be painted with P. & B. or other good insulating compound. In winding the fine wire coil, where high potentials will be used, great care must be taken with the insulation. Each layer should be painted with the compound and wrapped with one thickness of micanite paper before the next is laid on. The terminals of the fine wire coil going to the binding posts on the top board and those on the lower part of the frame should be run in small rubber tubing. The upper board for the posts must be made of hard rubber, or better of slate, which is easily sawed and drilled. Fig. 6, which is a sketch perspective of the finished machine, shows the side carrying the middle terminals of the coarse winding. The fine winding is arranged in a similar way on the other side, two binding posts which are normally connected together being used, but those for the high tension side are to be mounted on a block of hard rubber or slate attached to the wooden frame of the machine. It will add to the safety of the apparatus to put fuse blocks on the upper part of the frame and run the wires from the coils to the upper binding posts through these. After the coils are wound a wrapping of micanite paper should be put on and taped in place for the protection of the coil from mechanical injury.

Referring to Fig. 6, if current at 1100 volts is supplied to binding posts 5 and 8, 110-volt current may be withdrawn from posts 1 and 4, 2 and 3 being connected with a short wire. Or, by connecting 3 to 1 and 2 to 4, 55-volt current may be withdrawn from 1 and 4. Of course the reverse is equally true, the transformer thus acting to either step up or down in the ratios of 10 to 1 or 20 to 1. By supplying 110 volt current to 5 and 8, either 11 or 5.5-volt current may be withdrawn from 1 and 4, while with any voltage supplied to the primary up to the capacity of the machine two voltages may be withdrawn from the secondary, or the transformer may be used as a source of currents for a three-wire system by connecting the middle wire to one of the middle posts of the secondary.

With the winding given 1100 volts is the highest pressure that may be applied to the fine wire coil and 110 volts the greatest allowable for the coarse coil. It is not possible to give the constants of the transformer, as these depend entirely upon the quality of the iron wire, but its efficiency will be excellent, for so small an instrument, if good soft wire be used. The resistance of the coarse coil will be about 0.22 ohm, that of the fine coil about 9.5 ohms, and the capacity of the instrument about 700 watts, or about fifteen lights.

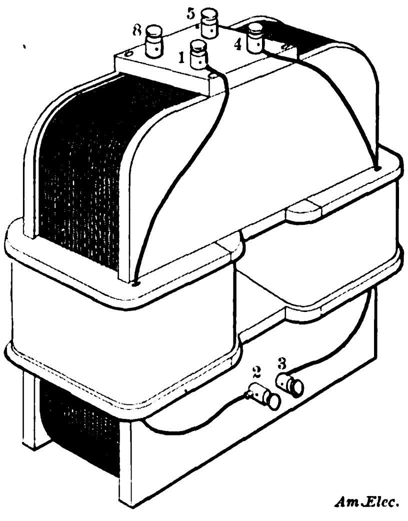

FIG 6.—SKETCH PRESPECTIVE OF COMPLETED TRANSFORMER.

The calculation of a winding for any other ratio of transformation or range of voltages is very simple. Assuming the maximum voltage that is to be applied to the primary, it is necessary to put on this coil a sufficient length of wire to generate a proper counter e.m.f. under the assumed conditions of frequency and voltage. In the figures given above an induction of about 1.25 volts per foot of wire is assumed and this figure should not be exceeded, while for low frequencies 2 or even 3 ft. of conductor per volt should be allowed. Having thus determined the length of the primary coil the next process is to calculate the size of wire needed to carry the current that will be used without undue heating. In coils of this character and of moderate dimensions it is safe to allow a current density of 1 amp. per 1000 c.m. of wire cross section.

The size of the wire being determined, the number of turns in the primary coil should be calculated. Then for the secondary coil the number of turns is given by a simple proportion, the number of turns in each coil being proportional to the voltage at which it is to be used. Thus, if the primary is to work at 100 volts and has 650 turns and the secondary is to work at 25 volts, it must have

$$\frac{25}{100}\ 650 = 162 \text{ (nearly)}$$

turns. All that then remains to be calculated is the size of wire for the secondary and the amount in each coil for convenience in cutting off the wire. If a transformer of larger capacity than that indicated here is desired it may be made in the same way, the dimensions being enlarged so that the cross section of the iron core of the coils is increased proportionally.

If it is desired to work the transformer at high voltages, as, for example, in testing insulators, etc., the fine wire winding should be put outside and divided into sections. The insulation between the coils should be made of heavy asbestos board, say ¼ in. On this should be built up a number of mica rings or separating partitions, made by cutting mica into the desired shape, and making a cut across one corner of the form so that it may be opened out and sprung into place. The thickness of these separating pieces should be about ⅛ in., and the coil included between two of them should not be worked to over 500 volts. In winding the coils into the spaces between the separating mica washers every few layers may be insulated by one or two layers of dry linen or cotton cloth.

When the whole transformer is assembled it should be placed in a stoneware jar large enough to hold it comfortably, and supported in the middle of the jar by wooden pegs of proper length. The jar should then be filled to about 1 in. above the highest point of the transformer with paraffine oil. In this oil insulated type no insulation other than the oil should be applied to the iron wire core or to the windings, that is, no varnish or compound, the cotton cloth being used dry. When the jar is filled with oil it should be gently warmed for a day or two, or better, the transformer should be connected to a low tension source of current (not enough voltage to cause a possible rupture and burn-out anywhere) and short-circuited until it is quite hot and all the air bubbles expelled. The fumes of boiling paraffine oil are very inflammable, and on no account should this oil be boiled on a stove or where its fumes can have access to a fire. Kerosene is an excellent insulating material, but dangerous on account of the inflammable vapors given off when it is heated. In using any oil the jar should first be filled so that about an inch of the transformer is immersed. In half an hour add another inch of oil, and so on, filling the

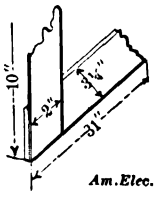

FIG. 7.—END CONNECTION FOR STRIP WINDING.

jar very slowly. In this way the oil ascends through the structure of the transformer by capillary attraction, displacing the air which would, if the jar were suddenly filled, form in bubbles and probably cause a break-down and burn-out somewhere. The wood used in this high voltage type should be absolutely dry.

All leading-out wires should be run in stout glass tubes dipping below the surface of the oil, these tubes being held by the lid of the jar, which is best made of slate. The tubes are put through drilled holes in the slate and cemented in place with plaster of paris. Using the dimensions given above it will be unsafe to wind a transformer of this type for more than about 6000 volts. If higher voltages are required it is far better to make a number of transformers and connect them in series. It should never be forgotten when working with transformers giving these high voltages in the secondaries, especially when insulation tests, etc., requiring the merest trace of current are going on, that fuses just sufficient to carry the magnetizing current for the primary should be included in that circuit. These are very easily made by using a number of tin-foil strip telephone lightning arrester fuses, which blow at about 0.20 to 0.30 amps. in parallel. Unless this percaution is taken the energy of a transformer of the size indicated is quite sufficient to cause fatal results from a shock from the high tension side.

For experiments where large current at low voltage is required, as in electric welding. etc., the secondary is very conveniently made of sheet copper, cut the full width of the winding space and wound on with a sheet of blotting paper soaked in shellac between the turns. Using the coarse coil above described as primary at 110 or 55 volts, a secondary giving 5.5 volts may be made of 1¾ turns of copper strip 3¼ ins. wide and 1-16 or 3-32 in. thick on each leg. Two strips of this should be cut, each 31 ins. long. To one end of each solder a strip of the same material 2 ins. by 10 ins., making an L-shaped arrangement, as shown in Fig. 7. This end piece is for the terminal connection. Start the winding on the side of a coil facing the end of the apparatus and take one complete turn. Then paste on a sheet of shellacked paper and take another turn with the copper strip, so that the end is left pointing toward the other coil at the back of the transformer. Do the same thing in reverse order on the other coil, and sweat together the two ends that are left. With a current of 110 volts and 7 amps. in the primary, this arrangement will give about 140 amps. at 5.5 volts in the secondary.

The uses to which such a transformer may be applied are numerous and will readily suggest themselves. Wound for about 30 volts in the secondary the size given is large enough to feed a small electric furnace. With the copper strip secondary electric welding of small objects may be done. With the oil insulated type insulators may be tested and the remarkable phenomena of high tension alternating arcs shown.

ERECTING A HIGH VOLTAGE TRANSMISSION LINE—II.

BY S. H. DAILEY.

In this article it is supposed now that the poles are all delivered at the proper places, and that the gains are cut on a sufficient number to permit going ahead with the digging and raising.

The proper way to proceed at this point is to dig as many holes in the first part of the day as there can be poles raised in the last part, thus finishing the raising and setting of the poles as far as the work goes for each day complete, leaving nothing to do but string the wire to finish the line.

In consideration that the average length of poles in this case is 36 ft., it will require at least six men to raise the same, and for a gang of this size five sets of digging tools should be provided. On an average one man can dig eight holes 5 ft. deep a day of 10 hours, or one hole in 1 hour 15 minutes. Thus, with five sets of tools, there should be twenty holes dug in a half day, and the same number of poles can be raised and set during the afternoon of the same day.

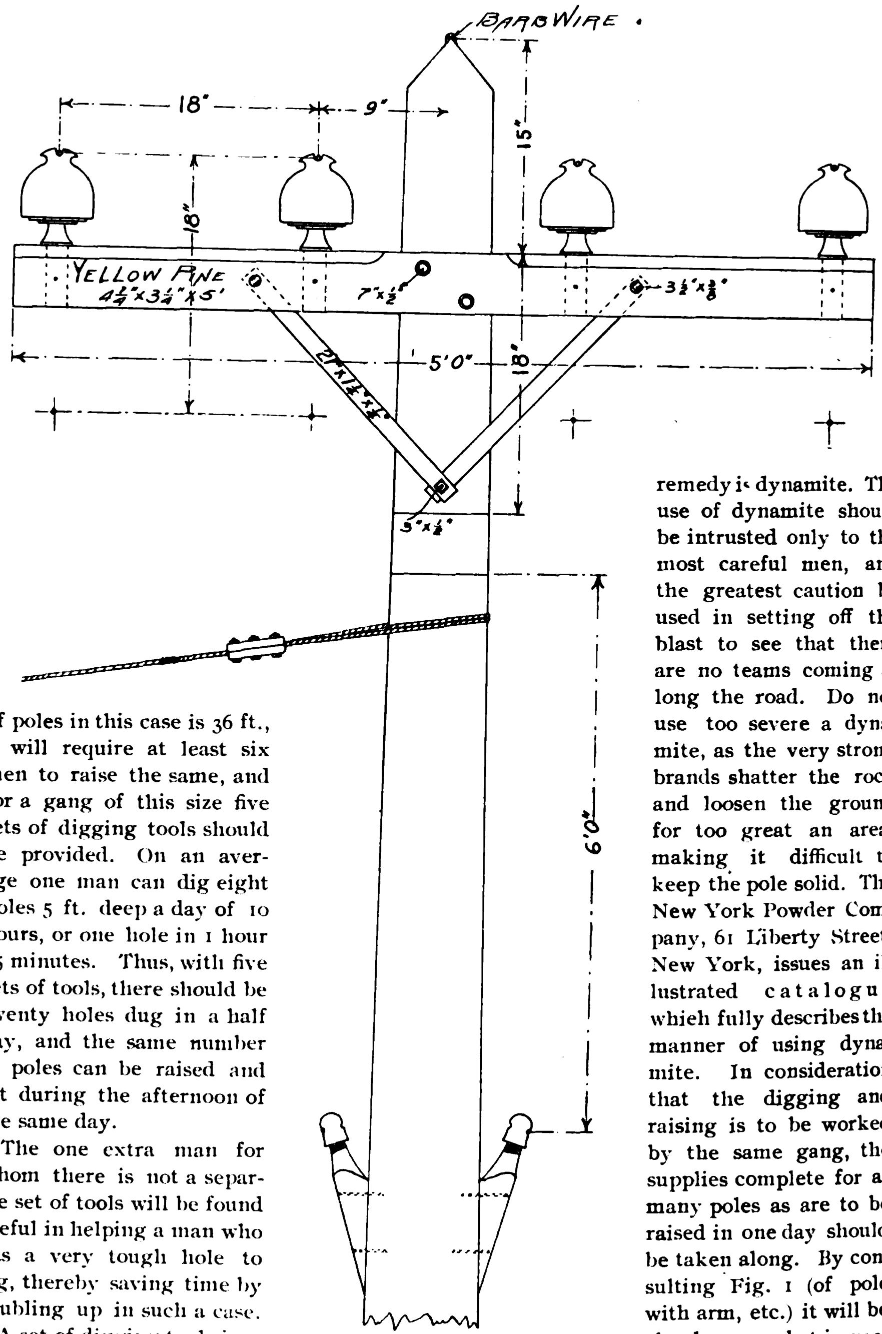

FIG. 1.—POLE WITH ARMS AND INSULATORS.

The one extra man for whom there is not a separate set of tools will be found useful in helping a man who has a very tough hole to dig, thereby saving time by doubling up in such a case.

A set of digging tools is as follows: One spoon shovel, 7 ft. handle; one round-point shovel, 7-ft. handle; one digging iron, 8 ft. long. The shovels may be purchased from an electrical supply house, but the digging iron can be made by a blacksmith. It should be 8 ft. long, of octagonal steel 1⅛ ins. diameter on sides, and will weigh about 28½ lbs. One end should be flattened and the other pointed. The sharp corners may be taken off with a rough file, making it easier on the hands.

When commencing a hole use the peg as the center and do not make the hole too large, governing the size by the pole to be set in it. Be careful to keep the hole of a uniform size during the digging—a caution necessary, as the most natural tendency is for it to become small at the bottom; this may make trouble in erecting, as the butt of the pole may bind and cannot be turned so as to line as easily as if it had a little play; at least 2 or 3 ins. around the pole should be allowed for tamping.

If rock interferes with digging, the only remedy is dynamite. The use of dynamite should be intrusted only to the most careful men, and the greatest caution be used in setting off the blast to see that there are no teams coming along the road. Do not use too severe a dynamite, as the very strong brands shatter the rock and loosen the ground for too great an area, making it difficult to keep the pole solid. The New York Powder Company, 61 Liberty Street, New York, issues an illustrated catalogue which fully describes the manner of using dynamite. In consideration that the digging and raising is to be worked by the same gang, the supplies complete for as many poles as are to be raised in one day should be taken along. By consulting Fig. 1 (of pole with arm, etc.) it will be clearly seen what is necessary for each pole, which will be as follows:

One cross arm, 4 pins and nails; 4 insulators, high-voltage line; 2 insulators, telephone line; 2 brackets and nails, telephone line; 2 7-in. x ½-in. lag bolts and washers; 2 braces; 2 3½-in. x ⅜-in. carriage bolts and washers; 1 3-in. x ½-in. lag bolt.

To save time, the pins should be put in the arms before being taken to the work. They should be dipped in paint up to the thread, and after being driven in the cross-arm, secured there by a wire nail.

A wagon large enough to hold all the supplies and tools needed for one day's work should be used.

It will be found convenient to have a set of 4-in. block double sheave, with ⅝-in. diameter rope about 300 ft. long, with the supply wagon, which can often be used in pulling poles around or up the side of a bank.

As the poles to be raised are not more than 36 ft. on the average, it will be found just as easy to erect them with the cross-arms on, thereby saving time, as the work of putting on an arm when the pole is set is at the best a long job; and with the arm on the pole it will be easier to line it up. So let two of the men go ahead of the gang and begin to put the arms on. After the raising is commenced, this should be done while the last pole set is being tamped.

In putting the arm on, notice that it sets square to the center line of the pole before tightening up the 7-in. bolts and 3-in. brace toe bolt. The arms should be set on the pole, and after starting the bolts with the hand axe they should be drawn up with a wrench, not driven all the way.

◆

INTERIOR WIRING.

CONTROL OF LIGHTS AND BRANCHING.

BY CHARLES F. KNOX.

But little now remains to be considered in regard to laying out the branch circuit work. We have already discussed the questions of locating the distributing center with regard to the branch circuit wiring, limiting length of circuits, the number of outlets and lights that may be wired on any circuit, the loss that may be allowed in the branch circuits, the method of determining the loss, and the question of local control. We will now consider the questions of controlling the lights in large groups and of "branching out" at outlets, and then pass on to the feeders and mains.

Of course it very frequently happens in a large room, such as a ballroom, for example, that a switch controlling only one or two circuits is undesirable. The reason for this is that in a ballroom there are usually a great number of lights, and consequently a large number of branch circuits, and if any of the lights are used at all they are generally all used; it would be useless to control each branch circuit when they might better be controlled in groups. Besides, it would increase the cost without any corresponding advantage gained, unless it be an advantage (and apparently that is what some people strive for) to raise the amount of the contract.

In such cases as these, push button or snap switches are rarely adapted for carrying currents exceeding 15 amps., and as knife switches should be located in the cabinet containing the cutouts, the distributing center should be located with reference to the lights controlled, and the lights may be then controlled by knife switches in any manner of grouping. As a rule, in private houses this distributing center or subsidiary switchboard is located in the butler's pantry. In hotels it is generally located in one of the halls in the service department. If it is essential, however, that the lights be controlled locally in large groups, automatic switches may be used, as suggested in the last number.

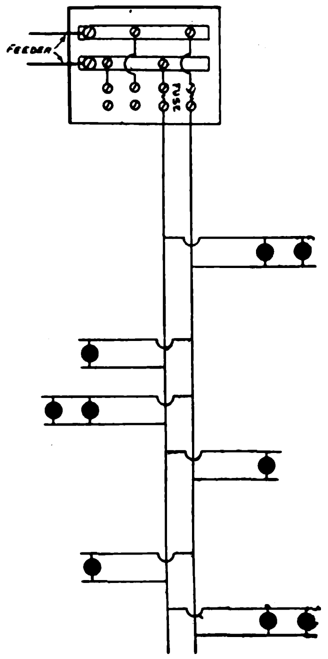

FIG. 1.—TOP OR BRANCH WIRING (EXPOSED).

It very frequently happens that owing to the length of the branch circuits it is impossible to run them from the point of control. In this event the mains controlled by the switches are extended to centers of distribution located near the lights supplied, the branch circuits being supplied from these centers.

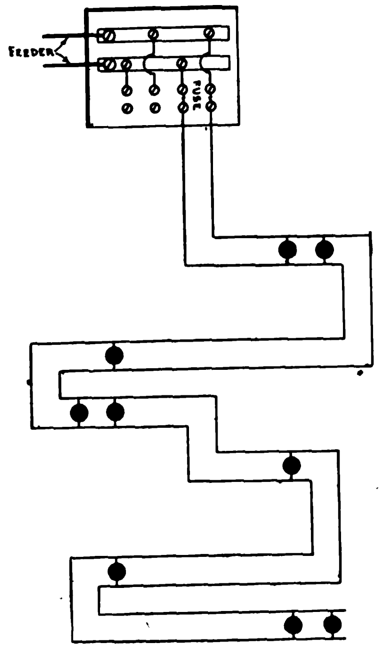

FIG. 2.—LOOP WIRING.

Now as to "branching" little need be said. By "branching" is meant the subdivision of one circuit at any outlet into two or more branches. Formerly it was the universal practice, where the wiring was exposed, to run a circuit of No. 8 or 10 wire down a room or along the hall and then to take or branch off wherever one or two lights were needed (see Fig. 1). Now, however, it is almost the universal practice to run the circuit work on the "loop" system; i. e., the circuit is run from the distributing center to the first outlet, thence to the second outlet, and so on, taking each outlet in turn (see Fig. 2).

The disadvantages of the "tap" or "branch" method of wiring are that it increases the number of joints or connections, and makes it harder to trace the course of the circuit; in concealed work it also has the disadvantage of increasing the number of conduits at a given outlet, and if outlet boxes are not used and a single wire run in each tube this last disadvantage is enough to entirely offset the slight gain in economy which it has over the loop system. In the days of brass armored conduit and before outlet boxes were used, if a branch were made at an outlet, it required a 5-in. and frequently a 6-in. canopy on the fixture to cover the conduit ends.

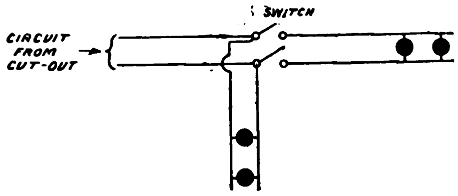

FIG. 3.—BRANCH AT SWITCH TO LIGHT OUTLET.

It happens quite often, however, that it is essential to sub-divide the circuit into two or more branches. For example, in the case of a local switch controlling only a few lights it is the general practice to subdivide the circuit at the switch, one branch of the circuit supplying the lights controlled, the other branch taken from the rear (or uncontrolled) side of the switch, supplying lights not controlled by that switch (see Fig. 3). If this were not done it would always be necessary to place the switch and the lights it controlled on the end of a circuit, and where there were a large number of local switches, each controlling a few lights only, the number of circuits would have to be equal to the number of local switches; otherwise there would not be enough ends to "go around"; it would frequently happen, then, that there would be only three or four lights on some of the branch circuits, and this would be uneconomical; the length of the branch circuits would also be considerably increased, as we would have to supply all

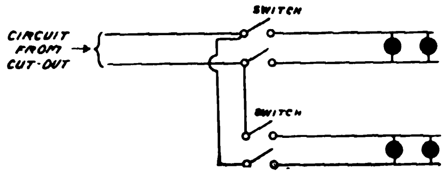

FIG. 4.—BRANCH AT SWITCH TO ANOTHER SWITCH.

the other lights on the circuit first and then run to the switch.

For these reasons it is, therefore, frequently desirable and necessary to "branch" at a switch. Where two switches are placed together and the number of lights which they control is not greater than twelve (Fire Underwriters' limit for one fuse) they may be fed on one branch circuit, supplying one switch and then branching to supply the other (see Fig. 4).

Sometimes it is even allowable to "branch" at an outlet other than a switch (see Fig. 5). As a rule, however, there is less necessity for doing this than there is for branching at a switch and the disadvantages are greater. It is, therefore, to be avoided except where necessary.

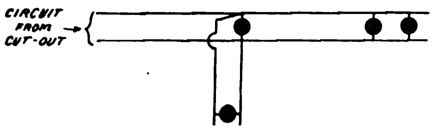

FIG. 5.—BRANCH AT OUTLET TO ANOTHER OUTLET.

Where a switch located at the distributing center controls two branch circuits, it is best to run one circuit to the switch and then sub-divide into two circuits, provided the current on the two switches does not exceed 6 amps., which is the limit allowed to be fed through a branch circuit fust.

AMERICAN TELEPHONE PRACTICE.

SELF-RESTORING SWITCHBOARD DROPS

KEMPSTER B. MILLER.

The drop and jack of the Western Telephone Construction Company was the first of this type to come into extended use. It is shown in Figs. 1 and 2, Fig. 1 showing the shutter in its normal position, and Fig. 2 showing it after it has been thrown down by an incoming call. In these figures the arrangements are such that the spring jack J of a line lies directly in front of the actuating coil E, belonging to that line, and the shutter C so arranged as to fall directly in front of the jack when released by the armature F. The combined jack and drop are mounted on a base of hard rubber A. The armature F is pivoted in the front head H of the electromagnet by the pivot screw P, and has a forwardly extending arm adapted to support the shutter C in a horizontal position. A small leaf spring S normally holds the rear end of the armature away from the rear head H of the coil and in a position to be attracted by that head when a calling current is sent through the coil. The attraction of the rear end of the armature causes its front end to move sidewise and release the shutter, thus allowing it to fall into a vertical position and display itself to the view of the operator, as shown in Fig 2.

In order to make a connection with the line the operator inserts her plug directly against the shutter, which is down, and in so doing restores the shutter to its normal horizontal position by a positive mechanical movement. The plug is guided into its jack by the shield or guide-plate K. In entering the jack the spring J is lifted off of the anvil I by the sleeve of the plug, thus breaking the connection through the coil of the drop. The spring J makes contact with the sleeve of the plug, while the spring shown on the under side of the jack makes contact with the tip of the plug, thus continuing the tip and sleeve sides of the line to the two strands of the plug cord.

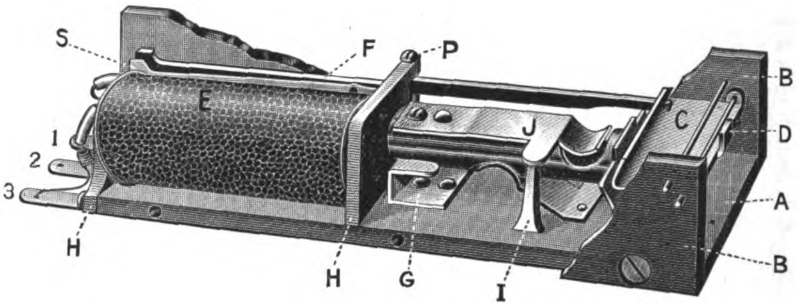

FIG. 1.--WESTERN TELEPHONE CONSTRUCTION JACK, UP.

These drops and jacks are mounted into a sort of an "egg case" composed of the bases A and the hard rubber side pieces B B. These egg cases usually contain one hundred compartments, ten wide and ten high; 1⅛ inches is allowed in each direction between the centers of the jacks. The wires on which the shutters are hung are common to each horizontal row of ten, and the other wire shown is also common to each row of ten. These two wires form the terminals of the night alarm circuit, and when a shutter is down the lug D on the shutter strikes against the rear wire, thus making connection between the two and causing the night bell to ring.

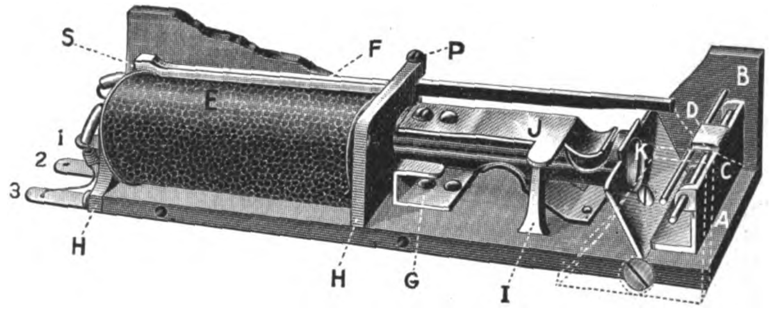

FIG. 2.—WESTERN TELEPHONE CONSTRUCTION JACK, DOWN.

This combined jack and drop has given good satisfaction in practice, and possesses advantages not to be found in the electrically restoring type of drops. In the first place, all the additional coils on the drops, and the additional contacts on the spring jacks and the additional wiring between the two, is entirely done away with. The action of restoring the drop by direct contact with the plug is so positive that it cannot fail. Another advantage, and one that is usually overlooked, is that when the drop falls the eye of the operator is attracted directly to the point into which she must insert her plug; while in the forms where the jacks and the drops are entirely removed from each other the operator must first look at the drop, ascertain its number, and then look for the corresponding number of jack on the board below. This very materially increases the ease of operation, and consequently tends in itself to give more rapid service.

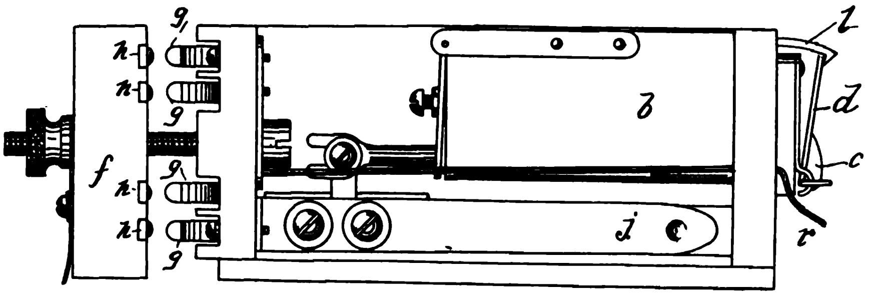

FIG 3.—ELEVATION OF AMERICAN ELECTRIC JACK.

The other form of mechanically self-restoring drop is that now manufactured by the American Electric Telephone Company. In this drop, which is shown in Figs. 3, 4 and 5, the actuating coil a is mounted directly above the spring jack j. The coil is incased on all sides except the top in a sheet iron shield or box b for lessening the amount of induction between adjacent drops. The armature of the magnet is pivoted at the rear of this shield and carries a forwardly projecting lever l, which in turn carries on its forward end a catch for holding the shutter d in its vertical position. On the shutter is placed a cam c, which when the shutter is down lies in front of the opening o of the jack. The plug shown in Fig. 11 carries an enlargement or collar k, which collar engages the cam c on the shutter when the plug is inserted into the jack, and forces the shutter into its normal position.

No cut-out is provided for the coil,

which is therefore left in series in the line during a conversation. The coil therefore serves as a clearing out drop, and when so actuated the cam on the shutter falls in front of the collar on the plug. When, therefore, the plug is withdrawn from the jack, after the clearing out signal has been sent, the cam again engages the collar on the plug and the shutter is restored again to its vertical position.

Another feature of this device is that when the plug is pushed to its fullest extremity into the jack the collar on the plug comes into contact with the front of the board and is depressed backward against the tension of a coil spring carried in the plug. This action wedges the line spring in the jack against a generator contact located in proximity thereto, and thus sends ringing currents out over the line. When the pressure on the plug is released the coiled spring forces it out of the jack to a slight extent, and thus restores the contact between the line spring and the contact of the plug.

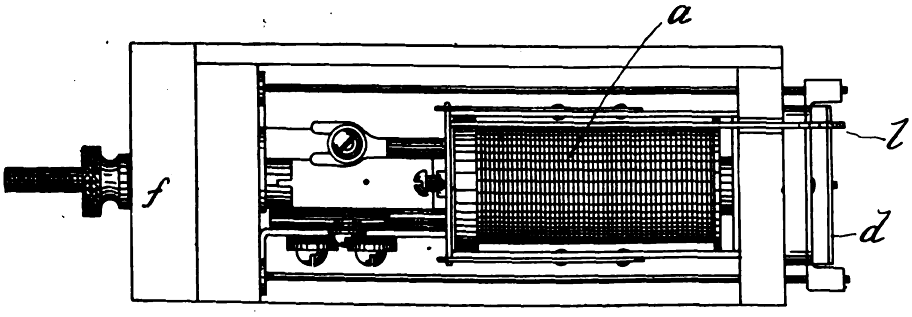

FIG. 4.—PLAN VIEW OF JACK.

The entire structure of the combined drop and jack is removable from the board by taking off the thumbscrew shown in the rear. This screw passes through the board forming the frame of the switchboard, and serves not only to hold the jack and drop in place, but to establish a connection between the line wire and the line spring of the jack. Small springs on the back of the jack register with corresponding contacts on the front side of the backboard, thus serving to extend the night alarm and generator circuits from the jacks to the other parts of the switchboard. By this means the proper connections are automatically made when the jack is slipped in place.

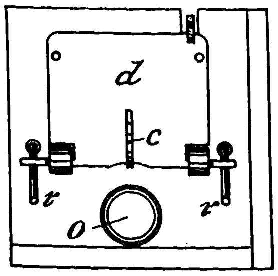

FIG. 5.—FRONT VIEW OF JACK.

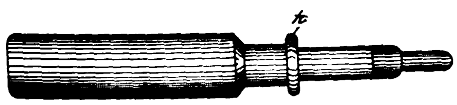

FIG. 6.—JACK PLUG.

Many other forms of mechanically self-restoring drops have been devised, but the two types here described have come into by far the most general use.

As an illustration of the saving which the self-restoring drops bring about in the operation of switchboards, certain boards have been devised and put into use where the drops are of the ordinary hand-restoring type, placed in series in the line and not cut out by the insertion of the plug. In the establishing and disestablishing of a connection between two subscribers the operator was required to restore a switchboard drop four different times. First she restored the drop of the line of the calling subscriber, next when she sent a calling current to the line of the called subscriber this current passed through the drop of that line, causing it to fall. This she also restored by hand, and lastly when one or both of the subscribers rung off the drops of each line fell and were restored by hand, thus making four in all. Such switchboards are, of course, necessarily slow. Moreover, they are almost invariably much larger and more cumbersome than the more modern types, but even these great drawbacks have not interfered with their giving fairly satisfactory service in some cases in small exchanges.

SOME STEAM PACKING.

BY JAMES F. HOBART.

It is well for every engineer to spend a few hours in the study of packing of different kinds. I believe there are several hundred varieties in the market, and they are made of all sorts of material.

They may be divided into metallic and textile. The metallic packings are usually made of Babbit or some other soft metal. I have seen metallic packing made of ordinary solder, such as is used by plumbers. It worked very well. In selecting a metallic packing it must be borne in mind that steam pressure sets the packing tight against the rod. Therefore great care should be exercised in screwing up the gland to make sure that no excessive pressure is put upon the packing.

All kinds of metallic packing should be made so as to approximate any shape of the conventional ball and socket so frequently used in mechanics. In applying this principle to metallic packing it is sufficient to make it into two parts, one fitting within the other and made concave and convex. The outer faces of the parts are flat and bear against the gland and packing box respectively.

This allows the packing to follow the rod, no matter whether the gland be screwed down evenly or not. It is important in this class of packing to make the faces or ends of the packing parallel, and give them a considerable space sidewise in the packing box. When this is done the packing can follow the rod laterally to a considerable extent, which enables the packing to follow the rod and keep it steam tight, even when it is considerably out of alignment.

Of the thousand and one varieties of textile packings, I will write at this time only of the asbestos variety. Asbestos works well in heat as long as the heat is dry, therefore for packing valves or rods which are only to be exposed to dry steam, asbestos leaves nothing to be desired. Unfortunately it is never safe to assume that the packing on any steam system will not at some time come in contact with water or moisture. In fact, the reverse is to be expected.

Water is a natural enemy to asbestos; nothing will destroy the working qualities of asbestos as quickly as contact with water. For this reason valves or rods should not be packed with that mineral and exposed to the action of water or wet steam.

The asbestos, even if it does not go to pieces, seems to "lose its grip" and becomes little better than so much dirt in the packing box. To remedy this defect a great many schemes have been tried, such as mixing the asbestos with rubber, with plumbago, and with soapstone. All these help the trouble, but none seem to cure it.

We frequently buy in the market a kind of packing which seems to be composed of alternate layers of asbestos and rubber. This packing is made by braiding asbestos threads around a core, which is also formed of asbestos. The braided rope is then passed through a solution of rubber and a portion adheres. After the coating thus applied has become dry to a certain extent, another layer of asbestos is put on. This operation is continued until the desired size of packing is reached.

Sometimes plumbago is substituted for the rubber or even mixed with a certain proportion thereof. In this case only sufficient rubber is used to hold the plumbago in place. Soapstone is also used considerably in asbestos, and also in other forms of packing. Ordinary asbestos wick packing I have seen loaded with 50 per cent of its weight of powdered soapstone. This is probably a benefit, for I think soapstone a much better packing than asbestos under all circumstances; provided it can be placed where it is wanted and kept there while the work is being done. Its structure is, however, not of a fibrous nature, and it must therefore be securely supported by some fibrous material.

The asbestos which comes in a square form often gives the outsider a good deal of trouble in guessing how it is made.

For the benefit of those interested, I will state that it is first braided up in the round form, then run through one or more sets of rollers and rolled in the desired shape, precisely as iron or other metal is rolled into bars either flat or square.

In using square asbestos packing be careful not to place too great a pressure upon it, for owing to the suction, this packing fills the gland completely full and when pressure is applied becomes very solid; thus when excessive pressure is applied to the stuffing box the packing becomes as hard as iron, with no elasticity. This does not happen to so great an extent when round packing is used. The shape leaves spaces between the layers of packing into which it can expand slightly when undue pressure is applied.

LESSONS IN PRACTICAL ELECTRICITY

HOW TO DESIGN A DYNAMO.

The reader who carefully peruses the following set of lessons must not expect to emerge from his study a perfected dynamo designer. All that is expected and hoped for is to give the student an idea of what must be taken into consideration in designing a machine and possibly to assist him in making moderately successful small bi-polar designs.

The formulæ and other data by the aid of which the dimensions of a direct current machine are determined are of a varying character. Some are magnetic, some electrical and some mechanical, and of all of these some are rational, that is, deduced from scientific laws, and others are empirical, that is to say, they are modeled to fit the facts as they are experimentally found and are the result of practical experience. Almost every designer has his own ideas as to the best empirical formulæ. By far the best way to understand how to design a machine is to follow through the methods employed in designing an actual machine taken for an example.

To this end we will assume that we are designing a 100-light dynamo of the high speed, belted, drum armature type. The machine is to be of the simple horseshoe form, with the armature uppermost. It is to operate at 110 volts and is to have a margin for compounding. The compounding is to be 10 volts. The prescribed speed of the dynamo is to be 1500 r.p.m. These are all ordinary commercial conditions and very easy to fulfill.

The first step is to calculate the total current output of the dynamo. An ordinary incandescent lamp takes an average of ½ amp., and the machine will, therefore, have a total current output of 50 amps., which must be available for the outside circuit. In addition to that we must have some current for the purpose of exciting the fields. In such machines as this it is found that the fields can be excited with about 6 per cent of the total output of the dynamo, that is to say, 3 amps. in this case, making the total available current 53 amps. If, therefore, we calculate a wire for a machine which can deliver 55 amps. we shall have an ample margin.

The machine is to be of the bi-polar type and consequently there are two circuits in the armature, each of which must carry half the total current, viz., 27½ amps. The first question therefore arises, how much must this wire be to carry the current without heating. In this case we must resort to practical considerations and note just what has been the results with other armatures. A single wire freely suspended in mid-air will carry much more current than if tightly wound into a bobbin. The following table, which has been prepared by a prominent designer, is a very safe criterion by which to go:

	Amps. per square inch.
Small high-speed armatures.......	2500 to 3500
Large " "	1500 " 2500
Small low-speed armatures	1500 " 2000
Large " "	1100 " 1600

However, heating is not the only consideration. We want an armature of low resistance, because there will be less drop in such an armature and the regulation will be better. Therefore, these figures represent the limits to which we may go and not necessarily the wire we shall choose. Consulting the table, we see that, as this is a small, high-speed armature we may safely assume a current density of 2500 amps. per square inch. If we are to deeply notch this armature with teeth and thereby bury the conductors in a confined space, we shall have to choose a lower density. Modern armatures are built in this way, and therefore we may select 2000 amps. per square inch as a suitable value to adopt in fixing the size of our armature wire.

The calculation is a simple proportion. The wire carries 27½ amps., and it is obvious, therefore, that its sectional area should be $\frac{27\frac{1}{2}}{2000}$ in., which is equal to .013625 sq. in. Here an economical consideration enters. It would not pay to have a special wire drawn for such a small machine as this and we must choose the nearest standard size. Consulting a wire table, we find that the nearest standard size is No. 8 Brown & Sharpe wire, the area of which is .012966. Then the question arises, How large must we make the armature core and how many of these wires shall be wound upon it?

The size of the armature core depends almost entirely upon the number of wires that it must carry. It must have sufficient circumference to hold them all and also to make room for teeth. To determine this we must make a preliminary calculation. The total e.m.f. which this armature must generate is 110 volts for the lamps, 10 volts for the drop in the line, and we must further add a percentage for the drop in the armature. If we choose 130 volts as the total voltage the machine must generate, we shall be on the safe side.

The voltage, speed, flux and number of conductors on a direct current bi-polar machine are related as indicated in the following formula:

$$E = \frac{NCr}{100,000,000}$$

in which E is the total e.m.f. of the machine, N is the total number of lines of force, C is the total number of conductors on the surface of the armature, and r the revolutions per second. Of these various factors, we know the following:

$E = 130.$

$r = 25.$

Substituting these in the formula, we find that the product NC must equal 520,000,000. We are now at liberty to choose any value of flux and number of conductors which will multiply to that product. Here we must refer to practical experience to find out what is suitable in such a case. The following table serves to show the total fluxes employed in dynamos of various capacities of the high-speed drum type.

Capacity in Kws.	Conductor Velocity. Feet per Second.	Average Useful Flux. Lines of Force.	Average Leakage Coefficient.
.1	25	200,000	2.00
.25	30	333,000	1.90
.6	32	550,000	1.80
1	34	880,000	1.75
2	36	1,530,000	1.70
3	40	1,875,000	1.65
5	45	2,550,000	1.60
10	50	4,000,000	1.55

Our machine can run 100 lights and is, therefore, a little over 5 k.w. capacity, and hence we may assume any number of conductors that gives us a flux in the neighborhood of from 2,000,000 to 3,000,000 lines. If we assume 3,000,000 lines as a flux, we shall find that we need:

$520,000,000 \div 3,000,000 = 173\frac{1}{3}$ conductors.

Of course, we cannot have a fractional number of conductors, but we can easily have any magnitude of flux we wish. Experience has shown that it is very convenient from a mechanical point of view to have the number of bars in the commutator and therefore the number of conductors on the armature a multiple of six. Hence we may select 168 conductors as a convenient compromise, and dividing this quantity into 520,000,000 we find for our total useful flux 3,095,240 lines of force, nearly.

We are now concerned about the size of the core upon whose surface these 168 No. 8 wires are to be placed. No. 8 double cotton-covered wires, laid side by side in a winding, run about 6.66 turns to the inch, and if we laid these wires side by side around the circumference of a smooth surface armature, it is obvious that the circircumference would be 168 ÷ 6.66 = 25.25 ins., giving us an armature some 8 ins. in diameter, which would be large for such a machine. It is evident that we must pile the wires one on top of the other in order to reduce the size of the armature. If we pile the wires two deep we would have an armature a little over 4 ins. in diameter, which would be small, but if we allow a tooth width equal to a slot width, we should be back at 8 ins. diameter. If we pile the wires four deep, the armature diameter would be 2 ins., but the teeth will add over 2 ins. more and the slot insulation will add still more. We may, therefore, make a preliminary calculation on this basis. Those who have read Prof. Rice's article will appreciate the fact that it is desirable to use two coils per slot. The reason for having the wire a multiple of six now appears, for we can arrange our coils without having an odd number of slots or segments. In such a small machine it is not advisable to have too many slots, as it adds to the expense. It is obvious that the wires in the slot must be a multiple of four. If we assume four wires per slot, we shall have four wires per coil, and forty-two slots and forty-two commutator bars. This is convenient, for we shall have twenty-four bars across 110 volts, which is a little over 5 volts per bar, and there are enough bars to avoid pulsating currents. Moreover, a bobbin of two turns is not very inductive, which conduces to sparkless running. The slots should be at least of the following width to make room for the various insulating materials:

No. 8 wire	128.5 mils.
Fuller board trough	70 mils.
Insulation	25 mils.
Giving a total slot width	223.5 mils.

As these should be straight slots, because the wire cannot be wound four deep conveniently in any other construction, the teeth will be wedge shaped, being broader at the circumference than at the root. Practice has shown that it is not wise to have the root of the tooth less than 60 per cent of the width of the slot. We then have the following items to make up the circumference of the armature: 42 slots at 223.5 mils. each, equal 9.387 ins.; 75 per cent more for teeth, 7.04.; giving a total circumference at the base of the slot of 16.427 ins. The depth of the slot is, of course, equal to:

Four thicknesses of No. 8 insulated wire equals	614.0 mils.
One thickness of paper insulating trough	35.0 "
3-64 of an inch for clearance and band wires	46.8 "
Total	695.8 mils.

It is obvious that, if we add double this distance to the diameter of the armature computed from the roots of the teeth, we shall have the diameter of the finished core disc. This quantity is 5.22 ins., to which we add 1.39 ins., giving us 6.61 ins. as the core disc diameter. We will find it better to choose 6½ ins., because that is a standard size. The difference will be a slight narrowing in the thickness of the teeth at the roots, but it will not reduce them to less than 60 per cent of the width of the slot.

Having computed the diameter of the core disc, we must determine the length of the armature, approximately. This is determined by the density of flux per sq. in. which it is wise to carry. In armatures of this type it can be safely advanced to 70,000 lines per sq. in. We have approximately 3,000,000 lines, which means that the fluxed area of our armature must be at least 43 sq. ins. The effective flux carrying diameter of the armature, as we have computed, is about 5¼ ins. From this we must subtract 1¼ ins. to allow for a shaft, leaving us an effective iron diameter of 4 ins. Dividing this into 43, we obtain a length of 11 ins. for the assembled core discs. Having thus computed the general dimensions of the armature it is necessary to make some calculations to see whether or no it will overheat. These will be considered in the next lesson.

Letters on Practical Subjects

Oil Economy.

To the Editor of American Electrician:

I happened to be in a shop where they made electrical work, and was impressed with the amount of oil wasted on the screw cutting machines, and especially on the various drilling machines used on heavy work. Oil was simply used by the quart and no one seemed to think of catching any of the oil again, at least as long as the chips from the cutting tool would take up and hold all the oil that was ladled upon the tool.

I want to compare the above noted shop with another where not one-tenth the oil is wasted that is got away with in the first mentioned shop. There oil is used as freely and the quality is as good, if not better. Under each machine is a concern which looks a good deal like an ordinary cuspidore. The top is made funnel shaped, and the bottom dish in which the flaring top sets is about 6 ins. deep and 10 ins. in diameter.

The flaring top is made of sheet iron 1-16 in. thick, and drilled full of ⅛ in. holes. A double flaring shape is then cut out, bent in the form of a cone, and riveted. This forms the perforated funnel which appears in the top of each oil dish, and which catches 99 per cent of the chips, which either fall or are thrown into the funnel. All chips and borings from the oil-using cutting machines are placed in one of these cones, and allowed to drain thoroughly before they are removed from the machine, or from beneath it. Then the cones are dumped into one made on a much larger scale, but built in a steel cylinder, around the inside of which is a coil of steam pipe. Here, about all the rest of the oil is "tried out" and the entire quantity is then filtered and used again. But considerable of the oil from the first strainer box, or filters, is put right back in the machine by the operator.

SAMUEL SWEET.

Providence, R. I.

Motor Action.

To the Editor of American Electrician:

Some time ago I wrote you about the action of a motor (direct current), as to whether it was ferric attraction between the pole pieces and the armature core, or if it was the thrust which lines of force give to a conductor carrying a current. You recommended me to look up "American Electrician," July, '96, wherein is an article by Mr. Townsend Wolcott, in which he explains that the first is the case in a slotted armature and the latter in a smooth core.

Now here is an incident which, I believe, fully confirms the first part of the problem, viz., that of a smooth core armature. The shop I work in recently had to repair a direct current bi-polar shunt motor. The owner complained that upon the throwing of the main switch and operating the starting box, the wire and commutator turned around while the shaft and pulley stood still. The armature is an old style one, in which the coils are wound between driving pegs; the armature is then banded and the pegs pulled out so that its own friction is all that holds the wire to the core. The commutator also is held to the shaft by friction, and the motor being about fifteen years old, it had become loose enough to turn with the wire, which was lucky for the armature connections. The only explanation that I can see is that of Mr. Townsend Wolcott, as above noted.

Yours very truly,

A. K. B.

Hamilton, Ohio.

How They Will Behave.

To the Editor American Electrician:

Will any of your readers who may have had experience with similar magnets, kindly inform me of the probable behavior of the pair described herewith? Each one of the pair is designed to pull 450 lbs. at a distance of 0.5 in. The core of each magnet is made of the best and softest iron to be procured, and is 1 in. thick, 12 ins. wide and 24 ins. long from extreme end of pole-piece to junction with yoke. The magnet is of the ironclad type, the case or shell inclosing the core and the winding being used to form the other pole of the magnet. The shell or case is made of "50 carbon cast steel" and is consequently pretty hard, and capable of retaining permanently more or less of the magnetism imparted to it by the coil.

The winding is of copper wire, .036 in. diameter (about No. 19) and is put on .25 in. thick, and carries a current density of 4000 amps. per sq. in. The case is made (cast and machined inside) 14½ ins. wide, 26 ins. long and 3¾ ins. thick, the hole inside being large enough to receive the soft iron core with the winding on it, ¼ in. thick, as stated.

The winding is to be absolutely water tight, and this is secured by rabbetting the core 1-16 in., and counterboring the end of case the same amount; then a phosphor bronze washer is forced into the channel thus made, and both the case and the core carefully riveted down on to the bronze. The wire enters the case through a stuffing box and is grounded on the magnet core. The wire cavity is therefore sealed perfectly air and water tight. What will be the effect of prolonged passage of current through the apparatus just described, the rise of temperature figuring 50 degs. above the temperature of the surrounding atmosphere?

Another point. Two of these magnets are to be set up opposite each other, the armature upon which they are to act alternately being ½ in. less in width than the distance between the poles of the magnets. It is proposed that the residual magnetism of the steel magnet case shall hold the armature against the poles of the magnet last energized until current is sent through the opposite magnet. Then, the two being connected together, iron and iron, the wiring of the one magnet shall be so connected that the act of energizing shall destroy the residual magnetism in the other magnet, thus releasing the "electric lock" and permitting the opposite magnet to attract and pull over the armature, where again it is in turn held by the residual magnetism as before.

The magnets are fastened to a considerable piece of steel of the same composition as the magnet cases, which are made ironclad form to prevent their magnetism from being absorbed by the body of metal instead of by the armature. How will this scheme work?

James L. Francis.

Brooklyn, N. Y.

Electrical Coffeepot.

To the Editor of American Electrician:

For several months my business took me to an office in a part of the city where there were no restaurants, and the problem of a warm lunch at noon became a serious one. It was finally solved by the setting up of an electrical cooking bench in the office and the construction of two or three electrically heated utensils.

The coffee pot was first made, then other dishes were added. An ordinary two quart agate coffee pot was procured and a piece of asbestos paper was fastened around it, close to the bottom, and extending up about five inches. For the resistance wire, some of the German iron wire used by some makers in electric car heaters was procured, sometimes called "Krupp iron" wire.

About 40 ft. were necessary to give a resistance of about 27½ ohms. This wire was bare—it did not come insulated—and a coil was wound on the lower part of the coffee pot, the convolutions being kept about one-half inch apart. Then the wire was held very tight, and some hot asphalt was daubed on. Then another piece of asbestos paper was put in place, and the winding continued until all the wire was on. Then another daub of asphalt, and another layer of paper finished the pot.

A flush wall socket was let into the plaster of the office, and the coffee pot wiring was carefully connected to the plug by means of some extra heavy flexible lamp wire. This finished the pot, and it boiled water in thirty minutes. Next a "cooking mat" was made by weaving the same amount of wire back and forth across a surface 6 ins. long, making a mat about ten inches long. The wires were fixed by placing short pieces of asbestos twine between them, painting the whole with asphaltum, and then the whole was stitched in a sewing machine, a number of seams being run about 1 in. apart, all across the body of the mat, which, I should have stated, was built up on a foundation of asbestos cloth, and covered on top with the same material.

By placing a dish flat on this mat, cooking could be done very quickly. The coffee pot, with its own coil, if placed on the mat, would come to time in a hurry. Next we made what for the want of a better name we called a "boiler." Forty feet more of the resistance wire was put on a braiding machine and carefully insulated with asbestos thread. A nickel plated brass tube, 3 ft. long and ½ in. internal diameter, was obtained, and the wire doubled into twenty lengths of 2 ft. each, was drawn into the middle of the tube. After testing for short circuits and grounds, the tube was coiled up into a double circle a little over 3 ins. in diameter.

The ends of the tube were turned up at right angles, so as to project above the liquid when the coil was in use inside of a can or other dish. After plugging the ends of the tube, we had a machine which could be put right into any dish, and water boiled—a quart or so—in five or six minutes.

A separate plug connection is necessary for each of these cookers, and be sure to have the city inspector look them over before you use them. I know of hardly anything which will so thoroughly demoralize an insurance policy as the unauthorized use of electric cooking connections. Above all, never connect any appliance of this kind to a lamp socket. That is forbidden under any circumstances.

George Eastlake.

New Brighton, Staten Island.

Some Electrical Sport.

To the Editor of American Electrician:

Since the last writing, I have been looking around the countrty in search of various things of interest, and incidentally have now and then come across bits of "Electrical Sport" which I have duly "salted down" for "The Electrician." One concern was troubled by the depredations of a certain very little dog which persisted in dodging into the station every chance it could get, and after nosing out a lunch belonging to one of the men, would bolt for the door, taking the lunch with him, to the great disgust of the man whose dinner it chanced to be. Many a time was this trick played by the dog, and no amount of hiding the packages, or placing them in inaccessible places, would discourage the persistent rascal.

For hours he would lie in the sun, apparently asleep, but waiting for all the conditions to be favorable for a visit to the lunch corner. When everybody was busy, and had forgotten dogs and lunches, he would steal in, and somebody's lunch was sure to go with him when he went out. Finally, a trap was laid, and he got caught. A nice juicy bone was procured and laid where the lunches usually were placed. A copper wire—No. 28—was wound around the meat, the insulation having been removed for a few feet at the end, so as to make a good contact with the meat. The wire was then coiled loosely, as it came from the reel, and laid on the floor near by, the other end of the coil being carried to the switchboard, and made fast to the lead of a live arc light circuit. The ground just outside of the station was kept well wet to get rid of the dust. The next time that dog came lunch hunting, he spied the meat bone the first thing, as even its odor was plainly visible with one's eyes shut. He grabbed the bone, and made a bolt for the door, the wire uncoiling as he ran. Just as he got out of doors, the fun commenced. There was a good deal of static charge accumulated on the arc line, and the dog got the benefit of that, also all of the leakage caused by grounds and poor insulation. At any rate, the dog went into the air with a yelp, and as he came down again, and the current cramped his jaws more closely to the meat, he cut capers and did stunts with himself all over the sidewalk.

Finally, with a grand effort, he leaped into the air, broke the wire, dropped the bone, and fled. And never, as long as I knew the place, could that dog be induced to set foot in the station again. The lunches were safe.

George Eastlake.

New Brighton, Staten Island.

ELECTRICA CATECHIS

230. How can one tell whether a wire will be attracted or repelled in a given case?

The general rule is that (a) the lines of force are considered as coming from the North pole and going into the South pole, (b) the lines of force around the current are in the direction of motion of the hands of a clock when one looks in the direction in which the current is considered as flowing, and (c) the effect of bringing two magnetic forces together is to strengthen the field where the two forces are in the same direction and to weaken it where they are in opposite directions, and (d) that the lines tend to separate so as to make the field of uniform strength. It is easier for some to remember the "rule of thumb" for the motor or dynamo.

231. What is a rule of thumb for remembering the direction of pull on a wire?

It is similar to that for the e.m.f. of a dynamo, except that the left hand is taken instead of the right hand. Spread out the thumb and first and second fingers, so that all stand at right angles to one another. Let the forefinger represent the direction of the lines of force, the center finger the direction of the current and the thumb the

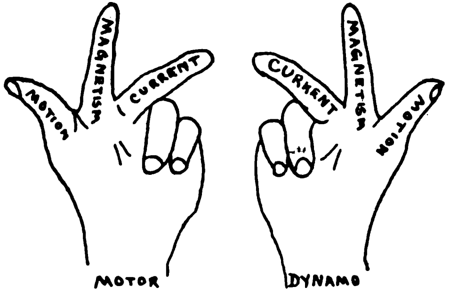

FIG. 1.—RULE OF THUMB.

direction of the motion. Then, if one knows any two, he can easily get the direction of the other. The fingers of the right hand may be remembered as for the dynamo and the left for the motor, since the right hand usually comes before the left and the dynamo must work before the motor will start. Fig. 1 shows it all.

232. What instruments are developed from the force between a current and a magnetic field?

The large class of instruments using permanent magnets, also many using electro-magnets. Many of these are simply portable forms of d'Arsonval galvanometers.

233. What is the d'Arsonval galvanometer?

It consists of a coil suspended between the poles of a magnet so that it may rotate through a small angle when current passes. Fig. 2 shows a simple form arranged for fastening to a wall. The coil is suspended by a small flat wire which forms one terminal of the coil, the connection with the other terminal being made through a very weak spiral spring below. The coil carries a pointer that moves across the scale for reading large deflections. A mirror also fastened to the coil allows the use of a telescope and scale for reading very small deflections of the coil caused by correspondingly small currents. The cylindrical piece of iron in the center of the coil is stationary, and simply serves to better the magnetic circuit, and so make the field stronger than it would be if the whole space between the poles consisted of non-magnetic material, such as air.

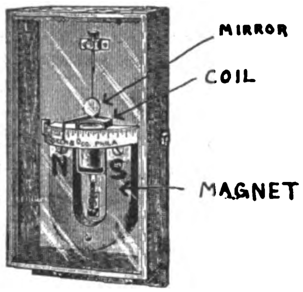

FIG. 2.—D'ARSONVAL GALVANOMETER.

234. What instruments are developments of the d'Arsonval galvanometer?

Those best known are the Weston ammeters and voltmeters, in which the moving coil is supported between jeweled bearings, the current being taken into and out of the coil by means of delicate hair springs, which also serve as controlling springs to balance the deflecting force of the current in the coil. The "heart" of the instrument is shown in Fig. 3, in which parts of the magnet and polepiece are cut away to show the moving coil, the central soft iron core, the two springs and the pivots.

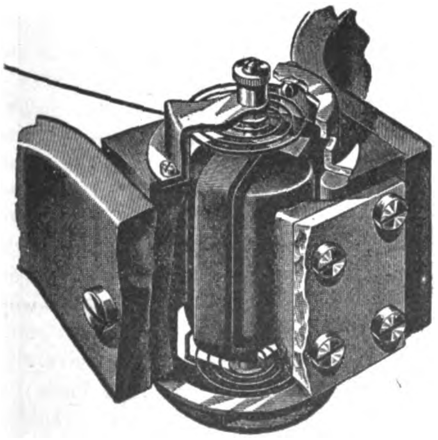

FIG. 3.—WESTON MECHANISM.

235. Do not the currents in the two sides of the coil go in opposite directions and so oppose each other?

The currents are in opposite directions, going up on one side and down on the other. The result is that one side is pulled toward the observer, while the other is pushed away. But both pull and push tend to rotate the coil in the same direction about its center, and so work together to give the deflection.

QUERIES AND ANSWERS

Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied. The privilege of this department only extends to subscribers, and queries must be accompanied by name and address to secure attention.

How may a commutator be repaired in which the insulation between the segments has been partially destroyed near the surface?—E. P. H.

Clean the burnt portion carefully of all copper and carbon dust, and then fill with a mixture of finely powdered mica and melted sealing wax, using as little sealing wax as will make a solid mixture.

Can I run a 125-cycle fan motor on a 60-cycle circuit? If so, how?—T. L. D.

The motor will not run satisfactorily on a 60-cycle circuit. It may be made to operate after a fashion by means of a choke coil in series with the motor. Without the choke coil, it will probably burn out.

Can compound machines be operated in multiple with shunt machines? If so, how? —J. R. L.

They cannot. It may be possible to run them for a short time on a steady load, but it will be in the nature of a feat. The voltage of the compound machine rises as the load comes on; the voltage of the shunt machine falls, and this tends to make the former motor the latter, unless rheostats are narrowly watched. The best way is to cut out the compound coils and run all the machines as simple shunt dynamos.

I have an induction coil which works in a satisfactory manner when the regulating tube is clear in the coil, but as the tube is drawn out the vibrator weakens, and when it is almost out the vibrator stops.—L. F.

The tube acts as a closed secondary coil and allows more magnetizing current to flow in the primary circuit, thus causing the vibrator to operate. When it is withdrawn the magnetizing current weakens and the vibrator fails. A stronger battery is the remedy.

1. What is the meaning of the term "charcoal iron?" How is it made, and how does the term originate? 2. Does it make any difference whether wrought or cast iron is used in the construction of field magnets?—H. C. B. and A. V.

Charcoal iron is simply wrought iron made with charcoal for fuel. It is specified in many cases where the quality of the iron would be damaged for the purpose in hand by absorbing impurities contained in other fuels. If wrought iron is used in a field magnet, about one-half the sectional area will be required that is necessary if cast iron be used.

I am having trouble with a Westinghouse shunt box system, working on 1100 volts, with 20 and 55-volt lamps on one circuit. Lamps in certain localities keep burning out, while other similar circuits give us no trouble. We have renewed the lamps, and even the shunt box in the troublesome localities, but that seems to do no good. The lamps that burn out burn very brilliantly while they last.—V. M.

The trouble is probably not in the lamp or shunt box which burned out, but in the other shunt boxes on the same circuit. The effect of a disabled shunt box would be to dim the lamp with which it is in multiple and to make other lamps on the same circuit extraordinarily bright.

I have three gravity cells in series, operating a closed circuit burglar alarm. They last about four months. If I were to add three similar cells to the system, would the whole set last longer? How should they be connected?—H. B. Q.

If the voltage of three cells is sufficient to operate your burglar alarm, the proper way to add cells to the system is to connect them in multiple. If more cells are added connected in series, the current in the system will be stronger and the cells will run down even quicker than before. Six cells will, of course, last longer than three, though not necessarily twice as long.

What is the method of movement for finding the combined weight of lengths of bare wire of different gages? C. H. K.

Multiply each length by the circular mils, add the product, and divide the sum by the circular mils of a wire whose weight per foot is known. For example, suppose there are 500 ft. of No. 1, 820 ft. of No. 4, 325 ft. of No. 8 and 1620 ft. of No. 14. The aggregate feet-circular mils will be found to be 87,910,590. The circular mils of No. 0000 wire are 211,600, so that the above is equivalent to 415 ft. of this wire, which, at .64 lbs. per ft., will weigh 265 lbs.

We are using a test circuit in our construction department, which consists of two leads from 250-volt mains, including in series four 50-volt 16 c. p. incandescent lamps. What is the voltage between the free ends of the circuit?—H. B.

The voltage between the free ends depends upon the resistance in the circuit across them. If the resistance is very high, such as a voltmeter or the human body, the potential difference will be practically the full 250 volts. As resistance between the ends is diminished the lamps take up more and more of the potential difference until finally, when the two ends are short circuited, there is no voltage between them and 250 volts on the lamps.

1. Is there a process by which the carbons of a simple battery—for instance, the Laclede—can be renewed after being polarized by use?

2. Is there a practical way of refilling or renewing the porous cup of a Le Clanche battery?—W. L. B.

1. The simple carbon is practically indestructible when used for the positive electrode of the battery. If polarized, give it a thorough scalding in boiling water and dry it in the hot sun or by strong artificial heat.

2. The mixture in the porous cups of sal ammoniac cells is frequently composed of equal parts of pounded carbon and black oxide of manganese. Melt the pitch off from the top of the porous cup, pull out the center carbon, empty out the old mixture, repack with new and reseal.

In the operation of shutting down an arc machine, why does not the armature burn out when short circuited?—P. H. P.

The arc machine has its fields connected in series with its armature, and if the latter is short circuited the current is practically cut out of the fields, thus preventing currents of any magnitude being generated in the armature. Some arc machines shut down by short circuiting the field. Short circuiting the armature, however, more promptly deprives the machine of its voltage, for the reason that a momentary flush of current in the armature tends to rapidly demagnetize the field. Either method is good.

What length of No. 22 German silver wire, carrying about five amps., will be required to heat an electric soldering iron on a 500-volt circuit? Would it be better to connect two or three irons in series?—F. D.

The amount of current necessarily depends upon the size of the iron. One to two hundred watts will heat an iron weighing three-fourths of a pound. If you wish to use No. 22 German silver wire and a voltage of 500, you will need about 1250 ohms, which will be in the neighborhood of 3000 ft., according to the specific resistance of the wire you use. No. 22 wire would be too large for such a voltage, as the coil would be bulky and weigh considerably over 4 lbs. One thousand feet of No. 27 would give the same heat and weigh much less. It is not convenient to connect the irons in series, as all of them would be heated when perhaps but one was to be used.

1. Can I wind a one-quarter h.p. 110-volt direct current motor as a rotary transformer to give 7200 alternations per minute?

2. Could I get a storage battery of six volts and 1250 or 625 amp. hours in 6 sq. ft. of floor space?

3. What resistance has a series wound, 110-volt, 1 h.p. motor, and what size wire is it wound with?—F. B. D.

1. Any direct current, constant potential dynamo frame can be wound as a rotary transformer. In your case, however, the motor is probably bi-polar and has to make one complete revolution per cycle or 7200 per minute, which is a dangerous speed for such a machine.

2. No.

3. Such a motor would probably have a resistance of about three ohms. It would probably be wound with about No. 18 wire on the field magnets and No. 21 wire on the armature, but that would be determined by the design of the machine.

What is the actual candle-power of a 2000-c.p. (nominal) arc lamp? J. K.

A test made at the Antwerp Electrical Exhibition on a lamp using 10 amps. and having 45.5 volts between its terminals showed a maximum c.p. of 2070, which corresponds to the nominal rating; a horizontal c.p. of 421; a lower hemispherical mean c.p. of 640, and an upper hemispherical mean c.p. of 102. The total mean or actual c.p. was thus 742, and the useful c.p. 640. Other tests have given a lower figure for the mean or actual c.p.; the quality of carbon, length of arc and shape of crater influenclength of arc and shape of crater influencing the same. The National Electric Light Association has defined a nominal 2000-c.p. lamp as one consuming 450 watts between terminals.

Can a magnet be made with a hollow iron core, which will sustain an iron rod on the inside weighing about 4 or 5 lbs.? What should be the size and weight of the iron core, and how much wire should it be wound with for 100 volts?—W. L. T.

If the magnet be made with a hollow iron core, there will be little if any magnetic pull in the interior of the tube, if the latter is at all thick, although the ends of the tube would probably be strongly magnetic. The better way is to encase the outer parts of the coil with iron and use a brass tube for the center. For a hundred volt circuit the coil should be wound with No. 30 wire, B & S, and each coil should contain at least 1½ lbs. If properly designed, such a coil may be made to hold a weight of 15 to 20 lbs. attached to its plunger. The diameter of the inner tube may be three-fourths of an in.; its length about 5 ins.; the outer iron casing can be conveniently made of 2½-in. gas pipe, and the heads can be made of cast iron.

1. I am having trouble with a double motor equipment. One of the commutators blisters badly, and sometimes connects the segments all together, thereby short circuiting them. I first laid the trouble to weak fields, but find that even with new field coils it still persists.

2. What are the dimensions on a spark coil for gas lighting?—E. P. H.

1. The reason probably exists in the fact that the load divides unequally between the motors. It is easily possible for a field to be weak and yet the field coils be in perfect condition, either by reason of a difference in the quality of the steel of which the casing is made or because the casing is not tightly closed. An ammeter placed in the circuit of each motor will detect this trouble, if it exists; and its magnitude. If there was trouble with the resistance coils on the car it would affect both motors. It is possible also that you have armatures which look alike, but in reality are differently wound. Very frequently manufacturers supply railway motors with different numbers of turns per bobbin on the armature, according to the work that they have to perform, and in other respects the machines will be identical.

2. Core 8 ins. long; ¾ in. in diameter. Outside diameter of finished coil, 2¼ ins. Wind with No. 18 annunciator wire.

1. Is it necessary to use lead for the negative grids of a storage battery? Might not some light metal be used?

2. What is the average life of a storage battery and the deterioration percentage each year?

3. What prevents the battery reacting upon the charging current when the voltage of the latter is reduced? Directions have been given by storage battery people, saying: "The initial charge should be about one-third of the normal rating for four hours, then increase to normal current, which should continue for twenty consecutive hours, or until the positive plates are of a dark brown color and the voltage is 2.6 volts per cell. Drop the charging current gradually to one-fourth and continue until 2.6 volts is reached."

Will not a storage battery discharge through charging circuit as soon as the voltage is reduced to one-third that of the rated voltage of the storage cell?

4. Why is there a loss of at least 25 per cent in a quick discharge of a storage battery?

6. What would be the effect on a battery if the charging voltage was more than two and one-half?—C. H.

1. It is not necessary to have lead grids. Several other materials have been used, both in this country and in Europe; mostly alloys of lead. The main reason for the universal use of lead is that no other metal except gold will withstand the action of the electrolyte during the charge, and gold, even if cheap, is much heavier than lead. Common metals are out of the question, as their presence in solution in the electrolyte is injurious and their structure is soon destroyed. Aluminum on a negative grid may endure for a considerable time, but in the positive grid a few hours' charging will frequently serve to completely dissolve it. Non-metallic grids have been used, simply supporting active material in intimate contact with the conductor, which need only be sufficiently heavy to convey the current properly.

2. This depends entirely upon the service the cell performs and upon the type of cell. The yearly depreciation is as high as 10 per cent in some classes of work.

3. You have confused current and voltage. It is the current that should be reduced to one-third of the normal rating for four hours and then increased as per directions, and the charging voltage should be adjusted so as to give the current the proper values. The battery will certainly discharge into the charging circuit if the voltage of the latter falls below that of the batteries.

4. It takes time for the electrolyte to become diffused through the active material and, as the chemical action goes on in the interior of the active material, it is necessary to supply fresh fluid at the points where the action is taking place. A cell that has been exhausted at a high rate of discharge, after resting for a while, will give a considerable current at a low rate.

5. If the voltage was raised above 2.5, the charging current would be likely to become excessive, liberating gases rapidly within the plates and causing them to warp and buckle. The charging voltage must be manipulated very carefully. A very slight increase frequently largely alters the charging current.

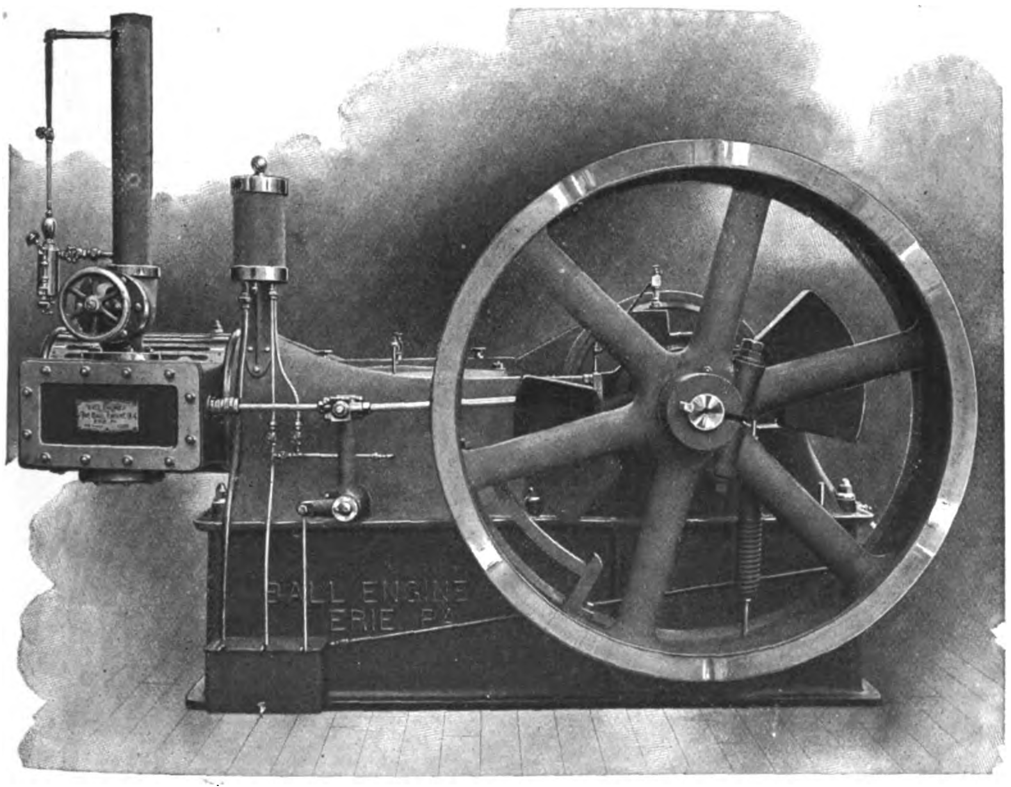
Apparatus AND Appliances

IMPROVEMENTS IN HIGH SPEED ENGINES.

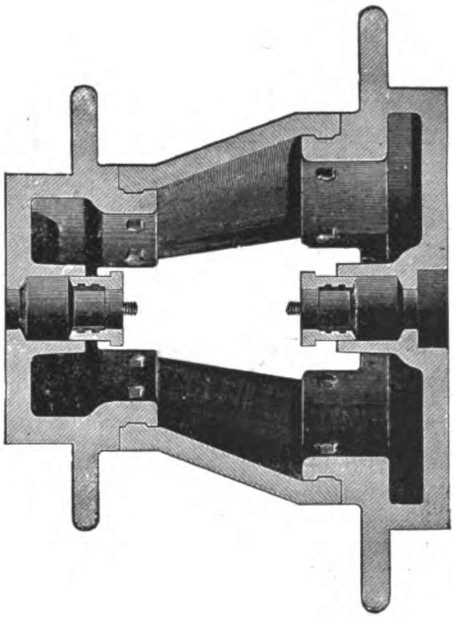
One of the most recent improvements in the engines of the Ball Engine Company, Erie, Pa., is their new oiling system, which is worthy of special note. The ordinary arrangement of sight feed oil cups, though still preferred by many engineers, is growing out of date, the present plan being to have a common reservoir, which feeds all of the sight drips. In order to make such a system as this entirely automatic the manufacturers have provided two reservoirs, one near the base of the engine, and the other mounted on a suitable pedestal, as shown in the illustration. A lever pivoted to the adjacent rocker arm operates a small pump, which pumps the oil from the drip tank up into the reservoir tank and makes the circulation continuous. A new inertia governor, which was introduced a short time ago, is still being used and has proved a great success.

Another arrangement shown in the illustration is a divided head between the high and low pressure cylinders in tandem compound engines. By means of removing this head access can be had to the low pressure without removing the high pressure cylinder, a distinct advantage in such types. A further advantage in this form of head is that the stresses exerted by the cylinders are taken up by the grooved joints and not by the bolts that hold the head in position.



AUTOMATIC LUBRICATOR FOR HIGH SPEED ENGINE.

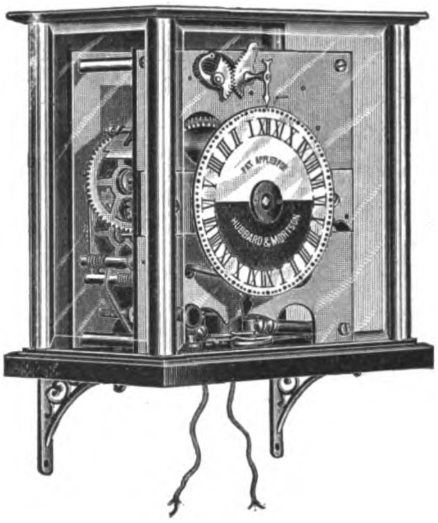
The vertical engines of the company, which a few years ago were comparatively new and untried, have met with great success and are now being extensively advertised and sold. The company's new catalogue contains much interesting technical information concerning the construction of their engines, and those who are interested will do well to write for it, as it is supplied on application.



DIVIDED HEAD BETWEEN CYLINDERS.

AN AUTOMATIC TIME SWITCH.

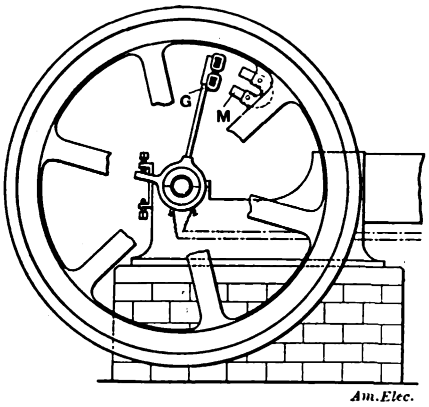
The accompanying illustration depicts an automatic time switch, which will switch on and switch off an electric current at any desired hours. As is shown it is attractive in appearance and an ornament wherever it may be installed. It consists of a powerful train of wheels actuated by a spring and automatically controlled by a clock movement. A twenty-four-hour dial which makes one revolution every day revolves under a fixed pointer at the top of the apparatus, and behind this dial are two movable pointers which are held in position with sufficient friction by the action of a spring disc. These pointers may be set at any time of the day or night, and when set, are fixed rigidly in position by pins which engage in a row of holes parallel with the circumference of the disc. When the first pointer reaches the reading point at the top, the other end trips an alarm wire, which sets in motion the train of gears and turns the switch. After the set time has elapsed, the second pointer approaches the point of reading and sets the train in motion again, turning off the switch. The only attention the switch requires is winding once a week. The installation is very simple, the circuits to be controlled being connected the same as with an ordinary jack-knife switch. Different sizes of switches are put into the clock in accordance with the strength of current it is required to handle. The switch is arranged on a slate base and meets all the requirements of the boards of underwriters in the different States. It is manufactured by the Hubbard & Mortson factory, located at 42 Union Place, Hartford, Conn.



AUTOMATIC TIME SWITCH.

NEW ELECTRIC IGNITER FOR GAS ENGINES.

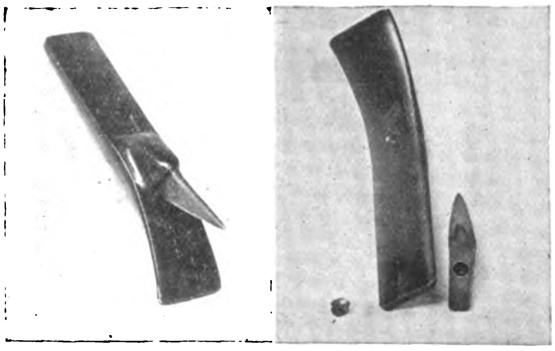
The problem of electric ignition for gas engines has met with a very pretty solution at the hands of the McInnerny Manufacturing Company, Omaha, Neb. The accompanying drawing suffices to show the principle, which is exceedingly ingenious. A generating coil G, suitably provided with a magnetic core, is fastened to an arm which can be varied in its angular position relatively to the fly wheel. The fly wheel carries a powerful magnet, which passes across the face of this coil once every revolution and induces therein a pulse of e.m.f. The arm carrying the generating coil is so set that this pulse occurs coincidentally with the breaking of the contacts in the explosion chamber. The weight of the magnet is 3¼ lbs. and that of the generating coil, including the core, 8 lbs. It will be seen at once that there is no wearing to the generator and there is no reason why it should not outlast the engine. It is said that simply turning the fly wheel over by hand gives sufficient e.m.f. to make a spark that will ignite the charge. The problem of a good electric igniter for gas engines has been a puzzler for electricians of all grades and has been more than once given up in despair. For this reason the device shown and described herewith will prove more than exceptionally interesting for those who have to do with gas engines.



ELECTRIC IGNITER FOR GAS ENGINES.

CLIMBER FOR LINEMEN.

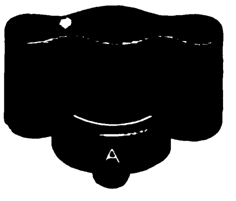
The accompanying illustrations show a new climber recently placed on the market by the Electrical Supply Company of Madison, Wis. The advantage of this climber is the detachable and renewable spur. The frame of the climber is drawn out the proper thickness from either direction of the spur socket, leaving the metal at that locality of the original thickness of the iron. The spur is made of the very best tempered steel by experienced toolmakers and is secured in place by a small set screw, which has no other duty to perform. Linemen will appreciate this specialty, because, in the first place, it ensures a spur of the very best material, and, in the second place, this most destructible part of a pair of climbers is by means of this device readily renewed. A lineman gets accustomed to a certain set of climbers and the breaking in of a new pair is very troublesome, a difficulty which is avoided in the climbers shown.



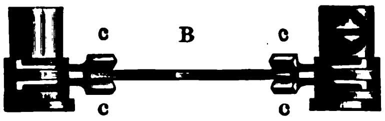
RENEWABLE SPUR FOR CLIMBER.

IEPROVEMENTS IN SNAP SWITCHES.

The Hart & Hegeman Company, Hartford. Conn., call attention to the recent improvements made in their switches, some of which are illustrated here.

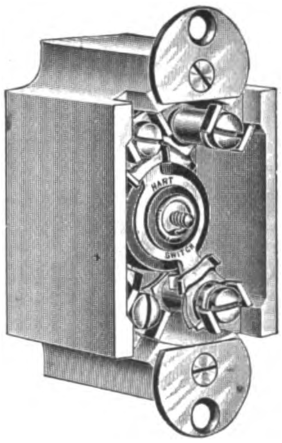


HANDLE WITH SPRING WASHER.



JACK-KNIFE SWITCH JAWS.

A snap switch is capable of being one of the most unsubstantially made articles on the market, although it may for a time perform the work that it has to do, and the thorough construction of the Hart switch will, therefore, be appreciated. The contacts are on the jack-knife plan, as shown in the figure, the connecting plate being forced between plates in precisely the same way as a station knife switch, although on a smaller scale. Another feature obtains in the self-adjusting handle, also illustrated. The collar, A, is movable vertically and is pressed downward by a spring between the body of the handle and the collar itself. When the handle is screwed on the switch, the collar holds the cover in place and the handle can be manipulated without unnecessary friction. The spring is incased within the collar and is invisible. The Hart switches are made in many different forms, one of the most popular being the flush switch, shown in the accompanying figure. These switches are made in many types, but this particular one is very suitable for use in confined quarters, as its dimensions are only 2 13-16 x 1 11-16, the depth being 1½ ins. The switches are all indicating, showing at a glance whether they are on or off.



COMPACT FLUSH SWITCH.

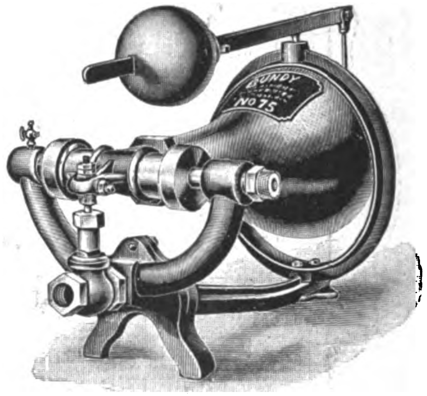
Electricians will be interested to know that the Hart & Hegeman Company is prepared to supply these switches in three and four point types, which are exceedingly useful in many cases and often indispensable. It is hardly necessary to mention that the switches are also supplied in gangs of any number with a single cover plate. These gang switches are of the flush type and frequently do away with the troublesome necessity of a cabinet. Special finishes will be furnished when required.

The company also announces the production of a 500-volt switch, which they claim to be fully equal to the severe requirements of the 500-volt service. This information will be of interest to railway officials, who frequently have to use power-house currents in lighting car barns and stations.

The reputation of Hart & Hegeman goods is well and favorably known, and it is to be assumed that these specialties will be received with the same favor that has been accorded the goods they have been previously making.

AN IMPROVED STEAM TRAP.

The high pressure tank steam trap, known as the Bundy, and illustrated herewith, is designed for draining receivers, reheating coils, cylinder jackets on compound engines, separators and the like—in fact, any apparatus working under extremely high pressure. It is constructed for use under as high a pressure as 250 lbs. to the sq. in. The valves are fitted with specially devised discs, and their opening and closing is independent of the pressure. The trunnion stuffing boxes are packed with a specially prepared spiral packing, and if the pressure on this packing is adjusted while the trap is hot it will not leak under any pressure. The actuating power of the trap is gravity. The bulb shaped tank fills with condensation, and the added weight causes it to fall, which opens the valves and allows the tank to empty. The weight of the top of the trap is heavier and lifts the tank, thereby actuating the valves again and reconnecting it to the high pressure system. The trap is tested by 300 lbs. of live steam pressure. Its

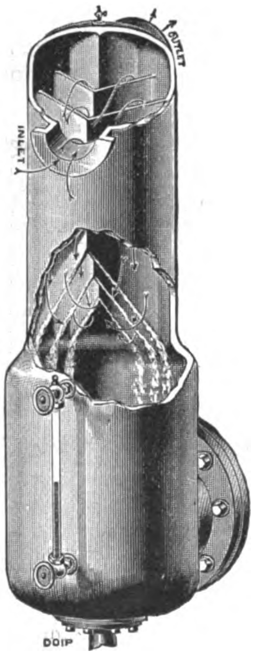


STEAM TRAP.

principle is simple and its makers have aimed to make its construction such that it will be classed among the highest grade of steam specialties. This trap is manufactured by the A. A. Griffing Iron Company, Jersey City, N. J.

A STEAM SEPARATOR.

The Curtis separator herewith described is unique in the fact that it combines a steam separator and steam trap. The principle upon which the separator operates is the well known method of causing the steam to quickly turn a sharp corner in a suitable receptacle and the entrained water is thrown off and projected against the inclined faces of a deflector. The particles gather together in a stream against the back of the separator and flow downward toward the base. The deflector plates are so arranged that the drops and streams of water and grease cling to the plate until they reach a point of contact with the shell, and in that position, as they are entirely out of the steam current, they flow quietly to the bottom of the separator. The steam passes through this operation twice, and thus any entrained matter which has escaped the separating action of the first turn is thrown out in the second and showers down as a fine spray against the sides of the shell. The water in the base is removed by the Curtis patent balanced float trap. The valve is double seated and balanced and therefore independent of pressure. The float is made of composition and is perfectly rounded and guaranteed up to 150 lbs. pressure. A by-pass valve is provided whereby the entire contents of the separator can be blown out at will. A grease cock is placed just below the water line of the trap and the grease, which is lighter than water, is drawn off at intervals. The water itself is trapped off and the sediment which sinks to the bottom of the apparatus can be occasionally removed as it accumulates by taking off the cover, which removes the float and exposes the interior for inspection. This apparatus is manufactured by the D'Este & Seeley Company, Boston, Mass.



STEAM SEPARATOR.

A NEW BELT DRESSING.

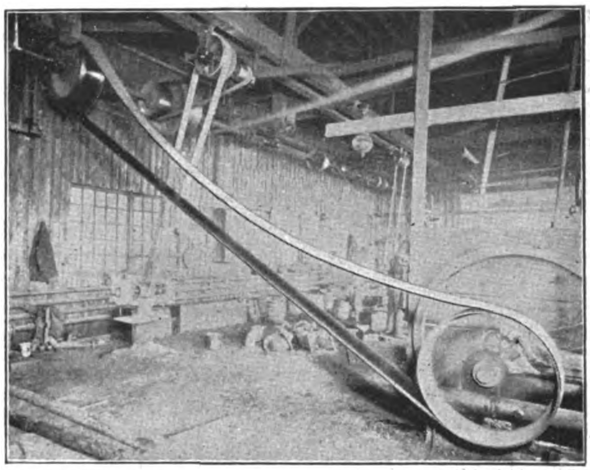
Many station managers derive excellent results from the use of belt dressings, one of the latest of which to be placed on the market is that known as "Cling-Surface," manufactured by the Cling-Surface Manufacturing Company, Buffalo, N. Y. The theory upon which this dressing derives its efficacy is as follows: Leather, which constitutes two-thirds of the belting material, is composed of interlacing fibres which are commonly dry. As the belt in use bends over the pulley these fibres are constantly rubbing together, producing friction that after a time wears out some of the fibres. The leather becomes weakened in spots and the belt cracks. Again, the belt is stiff and hard, its wearing surface becomes polished, and, as it does not conform to the pulley face, it slips. To "save time" it is often taken up as short as possible, which increases the strain on the belt, the friction on the bearings, and also wears the metal.

The same is believed to hold good in a measure with a cotton belt. In a rope drive the friction is between the strands, augmented by the fact that they are hard twisted.

A good rubber belt ought to cling, but in some instances it is found that it clings for a short time only, when the belt takes on a gloss and requires something to make it pull.

The stitched and painted cotton belts are good drivers for a time, but is stated that they also take on polish and slip. As the result of repeated tests it is claimed that a patent leather belt will transmit the most power, for the reason that it is thin and soft and conforms to the pulley; that the surface being perfectly smooth and dry, no dust adheres to it and consequently it lies flat, with no air between it and the pulley face; also that the patent leather surface clings to the face of the pulley without sticking.

In Cling-Surface the inventor claims he has a material that will produce and retain this patent leather effect, and more, on a new or an old leather belt, on cotton, on rope, or on a rubber belt. He states that when this dressing is applied to a leather belt it should be melted and a very thin coating laid on with a brush every day or two until the belt is full; that as a result of this process the fibrous leather becomes filled with a neutral hydro-carbon that will not oxidize like a grease or evaporate like an oil; consequently it will remain in the belt surrounding and lubricating the fibers as if they were resting in an oil bearing.



BELT USING "CLING SURFACE" DRESSING.

The manufacturers of the dressing claim that a belt treated in this way cannot crack, and that it will last almost a lifetime; that it is as soft almost as a piece of cloth, and yet it will not stretch; that the soft, spongy portions of the belt are filled and become solid and firm, yet flexible; that it is absolutely waterproof, and if immersed in water for two years it will not become hard; also that it is oil proof, for if an oily belt is treated on the inner side with this dressing the oil will be driven out and can be wiped off, while the Cling-Surface will take its place.

It is stated that while this transformation is taking place in the belt, a clinging surface is being produced on its surface, so much like the patent leather surface as it is possible to produce and retain on an oily background. This surface is smooth and even. It is neither sticky nor smeary, and yet it is very clinging; so much so that slipping is impossible with such a belt, and it can run slack as shown in the illustration herewith of one of the company's bells, which, it is said, had no dressing on it for two months previous to the taking of the photograph.

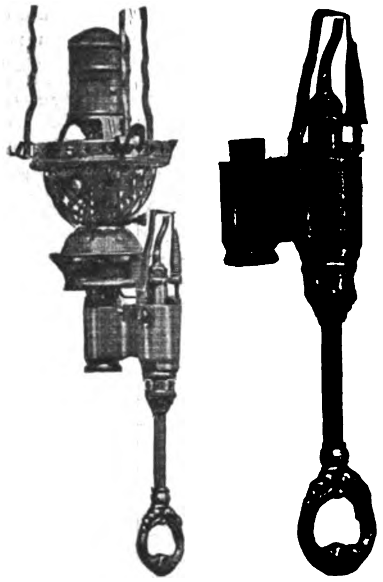
When a belt is full of the dressing it can hold no more, so that only enough is necessary thereafter to keep the surface from getting dry.

The company states that cotton belts and rope drives are treated in the same manner, but as this inner treatment is not necessary with a rubber belt, the Cling-Surface on the latter must be laid on thinly and not so often applied.

The Cling-Surface Company states that the assistant superintendent of the Erie Railway Dry Dock says that by the use of this dressing "We believe we have saved the cost of taking up 500 belts in the past two and a half years."

ELECTRIC GAS LIGHTING ATTACHMENT.

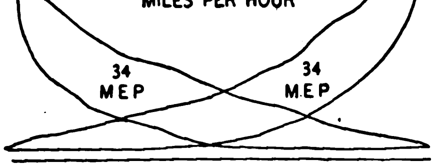
We illustrate herewith one of the specialties known as the American gas lighting attachments for Welsbach burners, manufactured by the Bibber-White Company, of Boston, which has recently purchased the business of the American Electric Company of that city. These attachments are claimed to be of exceptionally good design, and none but the best material and workmanship are employed in their construction, which guarantees good results to the users. The company will continue to produce the various specialties manufactured by the American Company, including the New Era and Victor burners, so favorably known to the trade.



GAS LIGHTING ATTACHMENTS.

AN INTERESTING INDICATOR CARD.

The accompanying cut shows an indicator card taken from a locomotive traveling at the rate of seventy-eight miles per hour. It speaks well for the indicator which took the diagram, for the conditions at the top of a locomotive cylinder running at that speed are particularly arduous.

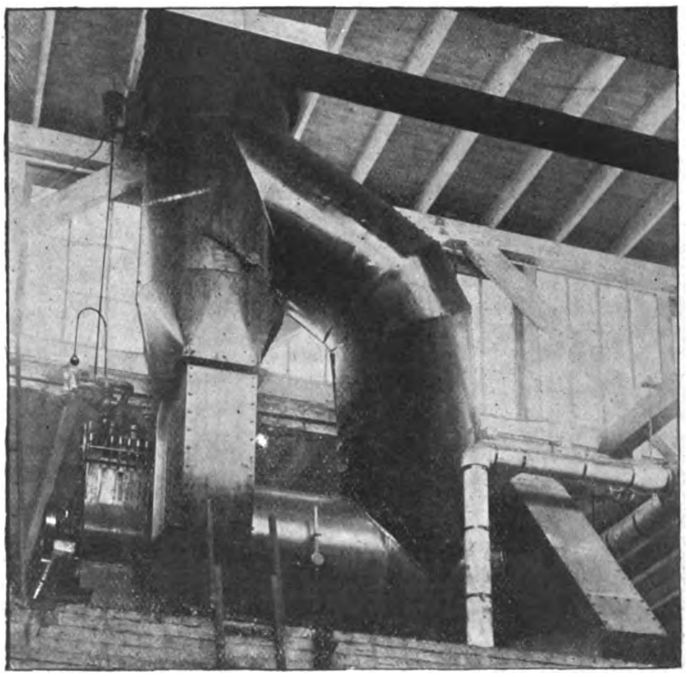


INDICATOR CARD.

The fierce wind, the flapping of the indicator cord and the vibrations all tend to make the diagrams exceedingly irregular, and these appear remarkably smooth. These diagrams were taken by a Robertson-Thompson indicator, made by the Robertson Manufacturing Company, New York. Part of the secret of the easy management of this indicator is in the detent arrangement on the drum, which enables the indicator to be started and stopped without unhooking the string on the reducing motion, which is inconvenient at all times and frequently in the nature of a feat with high speed engines. The company also supplies a reducing motion known as the Victor reducing wheel, which has been successfully operated on engines running at 580 r.p.m.

FORCED DRAFT APPARATUS.

In the accompanying illustration is shown a Sturtevant engine and blower as applied to the boiler plant of B. F. Sturtevant & Company, Boston, Mass., the object being to produce forced draft and do away with the necessity of a tall and expensive chimney. The outfit shown is mounted on top of the boilers and supplies a draft for a plant of three boilers having a nominal rating of 260 h.p. The engine is a double upright affair with cylinders 5 x 4, and the fan is a special 90-in. Sturtevant exhauster. The speed of the engine and consequently the intensity of the draft is regulated by a special device, which serves to increase the steam supplied in proportion as the pressure is reduced. It is so adjusted that a decrease of about 1 lb. of the steam pressure varies and changes the speed from minimum to maximum, or vice versa. The boilers use a half and half mixture of Cumberland coal and yard screening, and by means of the fan have been operated at as high a rate of combustion as 21.5 lbs. of coal per sq. ft. of grate surface per hour, and an evaporation of over 11 lbs. of water from and at 212 degs. per pound of combustible has been obtained. Although no economizer was used, the temperature of the gases at the inlet of the fan, when evaporating this amount of water, was only 222.5 degs. These figures are furnished by the Sturtevant Company, who installed the apparatus, and they make very interesting food for reflection as to the advisability of large chimneys in connection with manufacturing plants. Tall chimneys are expensive constructions, and frequently utilize much valuable space, and a little forced draft equipment, such as is shown, occupies much less space and consumes very little power, frequently so little that the interest on the added investment of an equivalent chimney would pay for it.



ENGINE AND BLOWER MOUNTED ON BOILER.

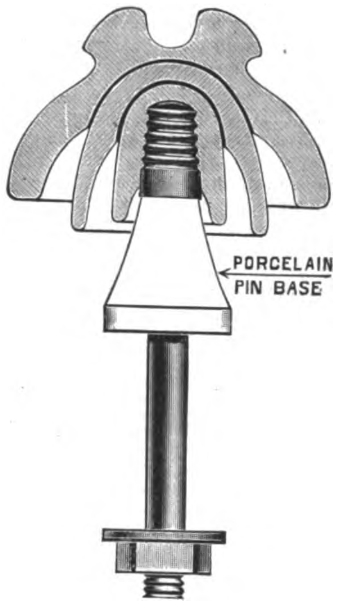
This, however, is not the important engineering feature, which consists in the fact that having the intensity of the draft under complete control, the fireman can admit exactly the right amount of air to secure the best combustion, and can efficiently use cheap fuel in cases where with the ordinary chimney the results would fall short of the requirements. In the plant illustrated, the stack does not extend above the level of the surrounding buildings, and it is stated that no inconvenience has resulted therefrom, that in fact smoke is scarcely ever visible, and then only for an instant, due to the more perfect combustion obtained by means of accurate regulation of the forced draft. It is, further, a well known fact that in order that a chimney must draw well its flue gases must have a reasonably high temperature. It is easy to see that the forced draft is independent of the temperature of the flue gases, and therefore all the heat that they contain could be withdrawn for useful purposes by suitable economizers without in any way interfering with the intensity of the draft.

A MARINE LIGHTING SET.

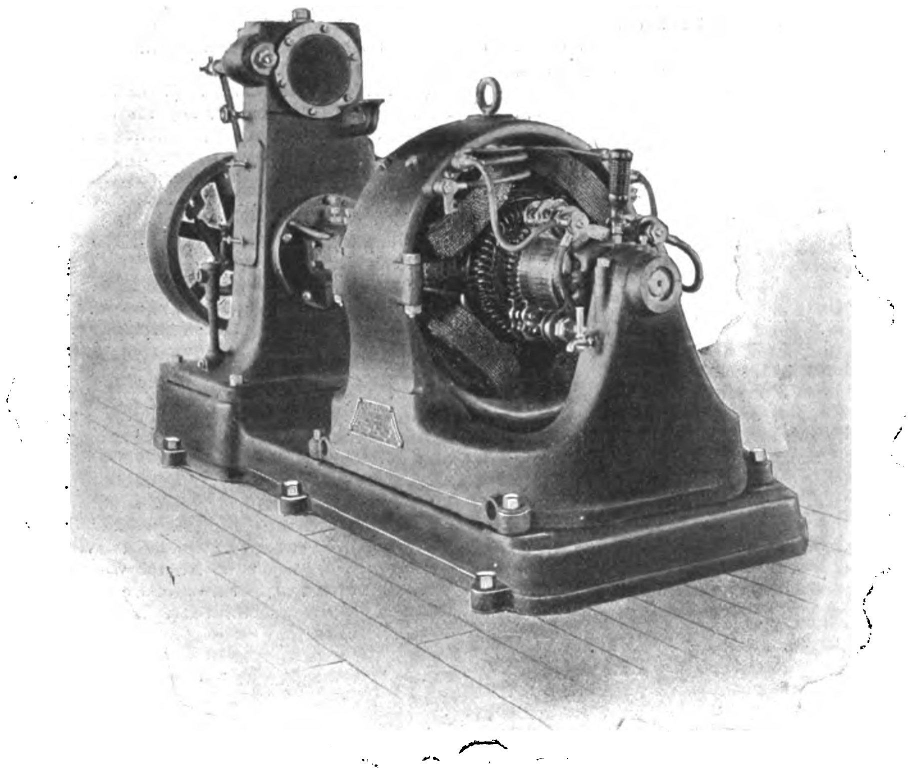
In the accompanying cut is illustrated a Case engine and Keystone dynamo, adapted for a marine outfit. The two machines operate very prettily together and the plant can be placed in many situations where a belted machine would be inadmissable. The outfit illustrated was installed upon a steamer from San Francisco. It is a well-known fact that there are but comparatively few small good upright engines, and also small dynamos are apt to be of poor quality, because they can be made with moderate facilities and small outlay. The apparatus illustrated, however, is an exception to this class. It is strictly high grade throughout. It is particularly adaptable for shipboard work, because of its complete reliability. A breakdown of the lighting plant on shipboard is frequently a serious matter and reliability rather than first cost should be the primal consideration. The engine of this set is manufactured by the New Britain Machine Company, New Britain, Conn., and the dynamo by the Keystone Electric Company, Erie, Pa.

HIGH VOLTAGE LINE INSULATOR.

Illustrated herewith is still another type of insulator, manufactured by Fred M. Locke, of Victor, N. Y., which is intended for high voltage work and is made for potentials from 5000 to 50,000 volts. It consists of three shells of vitrified china fastened together with glaze. The whole is mounted on a steel pin with a porcelain base. There is nothing combustible about either the insulator or the pin and it is impossible, therefore, to burn off the latter by static discharge. A double petticoat insulator of this type was illustrated in the last number of the "American Electrician," but this insulator is adapted for higher voltage and even more arduous duty.



HIGH VOLTAGE LINE INSULATOR.

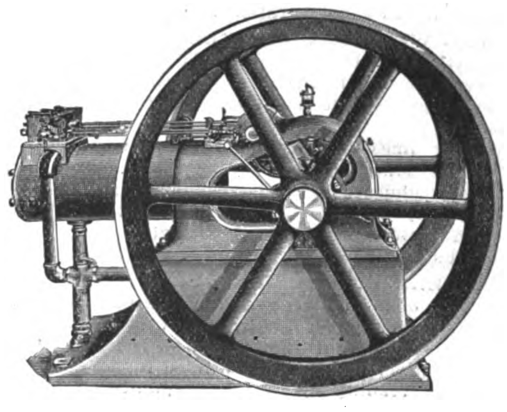


MARINE LIGHTING SET.

AN IMPROVED GAS ENGINE.

The gas and gasoline engine illustrated herewith, possesses a number of features which are worthy of inspection and should meet with approval. The engine shown is a simple, double stroke, four cycle engine. The valve mechanism, as will be noted, is all on top of the engine where it can be easily gotten at. There are three valve rods, two of which are actuated by a cam mounted on a shaft, which is driven by the main shaft in the ratio of 2 to 1. The third rod, which controls the admission of combustible, is actuated by a movement controlled by the governor. The valves are of the mushroom or poppet type and are securely closed by springs.

The manufacturers claim a great deal for their electric igniter. There is no question that the electric igniter is a much superior device, provided that it can be kept in order and always relied upon, for it explodes the charge at the right moment, and without waste of fuel. In many engines, ignited on the hot tube plan, it frequently requires nearly as much gas to run the igniter as to run the engine. The manufacturers have, they state, an automatic arrangement for cleaning the contact points of the igniter temporarily without stopping the engine, thereby obviating the troubles which are certain to ensue from incrusted electrodes, and which have effectually relegated many igniters to the domain of partially successful experiment.



GAS ENGINE.

The engine is adapted to burn any kind of gas without special devices and is provided with an automatic starting device, which saves a great deal of annoyance and enables one man to readily start a 50-h.p. engine.

Another valuable feature of this engine is the fact that it can use as a fuel natural gas, producer gas, manufactured gas or gasolene without any special attachment, and change can be made from one fuel to another without stopping the engine.

The engine is manufactured by the Dayton Globe Iron Works Company, Dayton, Ohio, in whose catalogue are set forth some very flattering tests showing the voltage of dynamo driven by one of their engines on various loads. The catalogue also describes the construction of the engine, and will be sent on application.

◆

TRADE PUBLICATIONS.

THE ELECTRIC APPLIANCE COMPANY, of Chicago, has issued a very neat circular of electrical house goods specialties for which they are general Western agents, giving particular attention to the Noxall annunciator, showing in detail the construction and operation of the machine, etc. The company will be pleased to send a copy of this special circular and price list to any of the trade who have not received the same.

THE BABCOCK & WILCOX COMPANY, New York, has just issued the thirtieth edition of its book entitled "Steam." This book has been for years one of the standard works on water tube steam boilers and on boiler practice generally. The present edition contains much new matter. It is beautifully printed and illustrated and substantially bound, and is sent free to anyone in any way interested in the generation of steam.

THE WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY has issued a very neatly illustrated trade catalogue on the subject of the advantages that may be secured by using an electric current instead of long lines of shafting and connecting belts for the transmission of power. The little brochure is carefully compiled and interestingly written. It is replete with excellent half tones of the Westinghouse apparatus and methods.

MODERN ENGINEERING PRACTICE is the title of a circular issued by the Famous Filter Company, St. Louis, Mo., which contains some original information on renewing waste lubricating oil, and will be found interesting reading by all power plant engineers.

MR. WILLIAM ROCHE, the maker of new standard batteries and various other electrical specialties, located at 250 Greenwich Street, New York, has issued a little booklet on his new standard dry battery. As he claims to have made over 1,250,000 cells, he certainly should know something about the business.

EUGENE MUNSELL & COMPANY, Chicago, Ill., are sending to their Western customers a very neat blotter, on which is embossed the Cuban and American flags, under which are the words, "Victorious on Sea and Land!" The printed matter beneath these words refers to the rapid development of the company's business and to the superiority of their "Mica" insulation.

JOHN A. ROEBLING'S SONS COMPANY, Trenton, N. J., who are well and widely known as manufacturers of wire and cables of all kinds, have issued an extensive catalogue of their goods, which exhaustively describes their various products and is supplemented with many valuable tables of data concerning them. The front of the catalogue is devoted to an interestingly written introduction discussing their facilities and the growth thereof. Following this are descriptions of the famous Roebling suspension bridges, among which may be mentioned the Niagara Suspension Bridge, the Allegheny Suspension Bridge, the Ohio Bridge and the well-known Brooklyn Bridge. In this particular field the Roebling Company seems to have been almost without a competitor. The catalogue is handsomely and substantially gotten up and is certainly worthy of the efforts of any interested party to secure it.

◆

BUSINESS NEWS.

MR. H. A. WAGNER, of the Wagner Electric Manufacturing Company, St. Louis, Mo., has been staying at Asbury Park for some time and transacting a large amount of business between whiles.

THE VULCANIZED FIBRE COMPANY, Wilmington, Del., is sending to its customers samples of its product in the shape of tubes, washers and sheets. This fibre is exceedingly tough and close grained. It is a well-known and valuable material in electrical construction of all kinds.

MR. JOHN A. BRILL, Philadelphia, advises us that, owing to extreme rush of business, he is kept so closely confined to business as to be unable to serve as a director in the General Electric Automobile Company, as was generally given out at the starting of that organization.

THE CUTLER-HAMMER MANUFACTURING COMPANY, of Chicago, since its consolidation with the American Rheostat Company, has been working overtime in order to fill orders promptly, and has more men in its employ than ever before. It has received large foreign orders, and states that if the increase in business continues it will be obliged to seek larger quarters.

MR. A. C. GARRISON, secretary of the Columbia Incandescent Lamp Company, of St. Louis, states that the demand for the Columbia lamps has increased to such an extent during the past year that his company will be obliged to enlarge its factory during August. Orders should be sent to them as early as possible, and thus insure prompt shipment during the next sixty days.

THE OHIO ELECTRIC SPECIALTY MANUFACTURING COMPANY, Troy, Ohio, which has long made a specialty of dynamo and motor brushes, states that the Perfection brush manufactured by it is the result of the ideas of its own inventors and designers, and trust that the trade will avoid the purchase of "all cheap imitations of this type of brush placed on the market by parties claiming to be the designers."

McINTOSH, SEYMOUR & COMPANY, Auburn, N. Y., have recently secured contracts for two 700-h.p. horizontal cross compound engines for direct connection with two 452 k.w. General Electric generators, for trolley work in the City of Mexico. This company has also sold a 150 h.p. engine for use in the Kimberly mines of South Africa, where it will be direct connected to two 60 k.w. generators of the double end plan.

THE JOSEPH DIXON CRUCIBLE COMPANY, Jersey City, N. J., is now placing on the market a solid belt dressing in round bars, about 8 in. long and 2 in. in diameter. It makes a package convenient to the hand and easy to apply, even to fast running belts. The company does not claim that the solid dressing is as good a preservative of the life and elasticity of the leather as the Dixon paste, but it is quick to apply and quick to act, and that is what is wanted by the general run of belt users.

THE WARREN-MEDBERY COMPANY, Sandy Hill, N. Y., has practically completed the addition to its new works, and is now setting up some very heavy machinery, to be used in the construction of its inductor alternators. The company reports the sale of these machines is rapidly increasing, and the works are running to their utmost capacity. The line of knife switches which they are producing is very extensive, and the demand for same is rapidly improving.

THE CENTRAL ELECTRIC COMPANY, of Chicago, is carrying in stock large quantities of wooden and iron pins and brackets and glass insulators. They have considerably augmented their previously large stocks, and are prepared to take orders of any size. The company also has a large and well assorted stock of the celebrated Loricated Conduit for interior wiring, and complete lines of all sizes of circular loom conduit and plain brass and iron armored interior conduit and all fittings.

MR. EDWARD E. CLEMENT has resigned his position of assistant examiner of electricity in the Patent Office and has opened an office for the practice of patent law. He is located at the Magill Building, 908 G Street, Washington, D. C. Having been nearly seven years in the Patent Office, he is in close touch with the department and should experience but little difficulty in serving his clients. His specialty is the electrical field, but he is well qualified to operate in kindred branches.

THE PENBERTHY INJECTOR COMPANY, of Detroit, Mich., reports a very gratifying increase in the sale of injectors for the first half of '98, its sales having increased over 30 per cent during the past six months, and the outlook for a still greater increase before the end of the year is very bright. This gratifying increase in the volume of business is believed to be due to the high grade and excellent reputation of this company's product among steam users.

THE CLEVELAND ELECTRIC COMPANY has recently been organized for the purpose of manufacturing specialties in the way of electrical appliances, with offices at 14 Middle Street, Cleveland, Ohio. The company is fortunate in having secured for its general manager Mr. F. A. Rogers, for many years connected with the Card Electric Company, Mansfield, Ohio, whose many friends wish him every success in his new enterprise. The other officers of the company are W. J. Morgan, president; F. C. McMillin, vice-president; O. P. Fisher, treasurer, and N. C. Stevens, secretary.

THE W. H. ELLIOTT ELECTRIC COMPANY, Cleveland, Ohio, has entered the field of heavy repair work and has exceptional facilities for handling jobs of that character. The business of this company is that of rewinding armatures, fields, transformers; refilling commutators and making new ones; building armatures for all classes of machines and doing experimental work. It is doing an extensive business and has just shipped two large armatures to the Salem Consolidated Company, of Salem, Ore., and is also doing some work for Jacksonville, Fla., and in the meantime it is also securing a large volume of local business.

AN INGENIOUS LINE of fixed and portable pole steps has recently been brought out by Mr. D. B. McBride, of 132 Southwest Temple Street, Salt Lake City, Utah. The portable step is fixed in a socket which is securely screwed to the pole. The step can be detached from the socket and carried in the pocket of the linemen, and enables them to reach the permanent steps above. The sockets weigh eight ounces, each portable step six ounces and the permanent step nine ounces. The fixed step is not a spike, but a screw, and can be removed from the pole at any time and used elsewhere. It is intended to use four portable steps on each pole, and the lineman is supposed to carry the four steps with him. The sockets are rounded and afford no handhold for unauthorized persons to climb the pole.

THE MICA INSULATOR COMPANY, of New York and Chicago, reports a gratifying demand for "Micanite" segments for electric light and power generators, and that some heavy orders are being executed at the factory in Schenectady, N. Y. Many of the large generators now under construction have for their commutator insulation "Micanite," and the heavy increase in the company's business during the last few months is reported to be largely due to the improved process of manufacturing a perfect commutator segment. The company offers to send free to any machinery builder or electrical repair concern a set for any one of the smaller machines free of expense, and solicits correspondence from parties interested in the economical insulation of electrical machinery.

THE E. G. BERNARD COMPANY, Troy, N. Y., has recently completed a contract for wiring the State capitol. The installation was for about 7,000 lights, and was unique in many respects. All the wire was special size in both copper and lead covering, and dies had to be made to order. All of the cabinets, switches and cut-out centers were also from new and special designs. In one place in the construction there were sixty vertical holes drilled through Hallowell granite. These holes averaged from 19 to 17 feet long, and were met by horizontal holes from 4 to 8 feet long. These features show the difficulty in the construction and the thoroughness with which the work was accomplished. The E. G. Bernard Company has been highly complimented by the Superintendent of Public Works for the substantial way in which it carried out the contract.

VITAE BRUSHES, manufactured by the Le Valley Vitae Carbon Brush Company, 39-41 Cortlandt Street New York, are reported to be giving excellent satisfaction, especially to street railway companies for car motors. It is stated that many of the largest roads in the country are using.

these brushes. The company has on exhibition at its office brushes which are said to have run over 5700 miles on a car motor. The brushes were only worn down a quarter of an inch, and could have run on that same basis of wear many thousand miles more. The company states that the commutators on which these brushes were placed were not worn or scratched a particle during the entire length of run, and that in many cases their brushes have run from 8000 to 10,000 miles on car motors.

THE STOREY MOTOR AND TOOL COMPANY has moved its main office and factory from Philadelphia to 464 South Broad Street, Trenton, N. J., in a plant with the Trenton Iron Company. The company is well and favorably known on account of its entirely inclosed dust and moisture proof motors, the first of that style to be placed on the market. The increased demands which they receive for this apparatus have necessitated the removal. The motors are now issued to the trade in a much higher state of mechanical and electrical improvement than ever before. With increased facilities, the Storey Company will push on the market its open type machines for all classes of standard work, together with several other specialties which up to the present time they have been unable to present to the public.

MR. MAX LOWENTHAL has been recently added to the editorial staff of the "Electrical Engineer," and will hereafter hold the position of associate editor on that well-known weekly. Mr. Lowenthal is eminently fitted for the duties he will be called upon to perform, as he has studied extensively abroad and graduated at the head of his class at the Hebrew Technical Institute. He also holds the degree of E. E. from Columbia University. Mr. Lowenthal was for some time in the testing rooms of the Western Electric Company, and later had charge of the testing department of the Schuyler Electric Company at Middleton, Conn. He has been a frequent contributor to the electrical journals, is a member of the New York Electrical Society and associate member of the American Institute of Electrical Engineers. The "Electrical Engineer" is to be congratulated upon securing his services.

THE CLOOS ENGINEERING COMPANY, Milwaukee, Wis., has lately been organized and thoroughly equipped for doing a general electrical contracting business, and will make a specialty of complete electric light and power plants. This company controls exclusively the Cloos patents on high potential dynamo and feeder switches, single and double coupling boxes, alternating and direct junction boxes, etc. The company is exclusive selling agents in the Northwest for the apparatus manufactured by the Northern Electrical Manufacturing Company, consisting of both belted and direct-connected dynamos and motors of all sizes, and is prepared to make prompt delivery of switchboards, dynamos, motors, arc and incandescent lamps, etc. The officers of the company are Herman W. Falk, president; Jacob Cloos, vice-president and general manager; E. A. Wurster, secretary; C. R. Falk, assistant secretary; H. R. King, treasurer.

THE SOLAR CARBON & MANUFACTURING COMPANY, Pittsburg, Pa., has an interesting plant located at Mahoney, 62 miles up the Allegheny River from Pittsburg. This location was chosen because of its proximity to the natural gas fields, from which cheap fuel can be obtained for baking carbons. As the fuel constitutes one of the chief expenses of the process, this is an important consideration. The company has built six buildings, which occupy a tract of 100 acres. It has a complete plant for the manufacture of its product, and, furthermore, considerable special machinery, with calcining and baking furnaces, which are also of special construction. The company furnishes as its product electric light carbons, both solid and cored; brushes for generators, motors, battery cylinders, smelting rods, for electric furnaces; telephone parts; tubes and granules for telephone transmitters. A recent product of the company, and one in which it enjoys a monopoly, are carbon pencils of a particularly fine grade, being very smooth and homogeneous in construction. The composition of these conductors involves no acid constituents and, in consequence, they last four or five times as long as some of the foreign made carbons. Indeed, they are even being exported for use in chemical and refining plants abroad.

THE WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY has installed

I-T-E
CIRCUIT BREAKERS
CUTTER ELECTRICAL CO., PHILADELPHIA

Few electrical instruments have been received with the same favor throughout the entire world as has been accorded to the Circuit Breaker. The Cutter Electrical and Manufacturing Company, of Philadelphia, pioneers in this field, have, for some years past, devoted almost their entire attention to the important subject of protection to electric circuits and electrical apparatus. The Circuit Breakers are usually placed on the switchboard and, as their name implies, break the circuit automatically should the current reach a predetermined danger limit. The instruments are susceptible of a wide range of adjustment and are instantaneous in their action. They have frequently been called "electric safety valves," as they afford practically the same protection to an electric circuit that a safety valve does to an engine.

The Cutter Company have developed instruments suitable for either direct or alternating current, of any capacity required and for any voltage. The instruments are beautiful in themselves, being made from the most part of polished copper and iron and steel copper-plated, and are mounted on white marble or black enameled slate. Their accuracy in operation on the circuits for which they are intended is absolutely guaranteed, and the many large switchboards thoughout the United States, which are equipped entirely with this form of protection, give evidence of the favor with which these instruments have been received by leading engineers and electricians. A catalogue will be sent upon request.

a large amount of apparatus for the production of refined copper by electrolytic processes. One of the principal installations is at the refinery of the Anaconda Copper Company, Anaconda, Mont., where ten generators of 270 to 300 k.w. capacity have been installed. Another installation is that of the Boston & Montana Consolidated Copper and Silver Mining Company, Great Falls, Mont., where two 810-k.w. Westinghouse engine type generators are in service. The latest comer in this field is the Raritan Copper Works, of Perth Amboy, N. J., which are about to erect the largest copper refinery in the East. They have contracted with the Westinghouse Electric and Manufacturing Company for three 600-k.w. 150-volt engine type generators, 150 r.p.m., with a nine section switchboard for electrolytic service and the operation of two 75-k.w., 200-volt, engine type generators, which will be used for lighting and power service. The installation will be the most complete of its kind in the world. The Westinghouse Company has also sold recently to the Manufacturers' Building Company, Providence, R. I., 2 250-k.w., 500-volt, engine, type generator, 100 r.p.m., to be driven by an Armington & Sims Corliss engine. This generator will supply power for the operation of motors in the various departments of the Manufacturers' Building, which has accommodations for upward of sixty manufacturing concerns, being particularly equipped with conveniences for the production of jewelry, specialties, etc.

THE STANDARD OF CORRESPONDENCE SCHOOLS has been most decidedly raised by the conscientious efforts of the Electrical Engineer Institute of Correspondence Instruction in its attempts to furnish the profession of electrical engineering absolutely reliable and trustworthy instruction. Much of the success may doubtless be attributed to the eminent authorities who have certain departments of instruction in charge, among which we may name Prof. Francis B. Crocker, of Columbia University; Charles F. Scott, the well-known alternating expert; Elmer G. Willyoung; William Maver, Jr., the celebrated authority on telegraphy, and Thorburn Reed, a dynamo designer of acknowledged merit. The instruction which the student will receive from the papers prepared by these gentlemen will partake of a practical nature, which it is difficult if not even impossible to duplicate in some of the technical schools, and it might assuredly pay many who are supposed to have gotten beyond the grade where instruction is necessary, to procure these papers for their own information. Many a man whose attainments stand unquestioned in the profession might easily find it advantageous to enroll as a student and obtain these advantages, thereby refreshing his mind on subjects long forgotten and bringing himself fully up to date in the latest developments and practical applications of his profession. In connection with the work of the Institute mention should be made of the interesting book of information entitled, "Can I Become an Electrical Engineer?" which is sent free upon request and contains a complete portrait collection of the most prominent scientists and engineers who have succeeded in making the profession of electrical negineering what it is to-day. This book will be sent free on application to the home office of the Institute, at 120 Liberty Street, New York.

Why take any other Route?
WHEN IT IS
Only One Night to Utah,
Only Two Nights to California,
FROM THE
MISSOURI RIVER via UNION PACIFIC.
THE MOST DIRECT LINE.

New Wabash
Fast Train East.

"The Continental Limited," a new fast train on the Wabash, now leaves Chicago daily at 1:02 noon for Detroit, Niagara Falls, Buffalo, New York and Boston. This train arrives Buffalo next morning at 5 o'clock, New York at 3:30 and Boston at 5:50 P. M the next day—only one night on the road. The service, including a dining car, is first-class in all respects. Do not fail to ask for a ticket via the "Continental Limited" on your next trip East.

Other trains for the East via the Wabash leave at 8:50 A. M., 3:15 P. M., and 11:30 at night.

For maps, time tables, etc., write to F. A. Palmer, A. G. P. A, 97 Adams St., Chicago.

The Belknap Motor Co.

OF PORTLAND, ME.

is very busy at the present time. They are just installing one 40 k.w. direct connected generator and engine in the new building of the Y. M. C. A., Portland, Me. They are also putting in a direct connected electric passenger elevator at the Falmouth Hotel, Portland, Me., in place of an hydraulic formerly in use. They have just completed an electric direct connected freight elevator for the Portland Packing Co., taking out an hydraulic. A hand elevator at E. D. Pettingell's Pickle Works, Portland, has just been taken out and a new direct connected electric has been put in its place by this company. They are also completing a new electric freight elevator for L. B. Griffin, produce dealer, Portland, Me., and have just received order for a direct connected electric elevator for the Hotel Jocelyn, Prout's Neck, Me.

Their direct connected elevator business has become very large; they have installed more elevators in Portland and vicinity in the last two years than all other companies combined. An electric conveyor for discharging vessels has just been installed by them for the Maine S. S. Co., and they have a contract from the same company for a second one. They had previously installed one for the International S. S. Co. at Eastport, Me.

The Chapman Voltage Regulator, manufactured by the Belknap Motor Company, is getting to be one of the most important parts of their business. The Mt. Morris Elec. Co. of N. Y. City, ordered two several months ago, and so well satisfied were they with the results accomplished by their use that they placed their order for seven more, all of which have been shipped to them.

The People's Elec. Co. of Orange, N. J., put in one several months ago, and liked it so well that they have placed their order for a second, which is about ready for shipment.

Frank Jones Elec. Lt. Co. of Portsmouth, N. H., has placed order with them for three of the No. 1 type, which are to be finely finished and erected on pink Tennessee marble, which will be in keeping with the balance of the plant.

A TECHNICAL EDUCATION 50 CENTS A WEEK

THE new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary text-books.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 43 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

NOTICE.

Pursuant to resolution of the Mayor and Common Council of the city of Superior, passed and adopted July 19th, 1898, I, the undersigned, the City Clerk of said city, hereby solicit and advertise for bids for lighting the streets and public places of the city of Superior, as follows:

1st. For furnishing 50, 100, 150, 200 electric arc lights of 1200 or 2000 nominal candle power for the terms of 1, 2 and 3 years. Such lights to be disposed and placed about the various portions of the city as directed by the Common Council; stating the time when such lights can be furnished.

2d. For furnishing 50, 100, 150 and 200 Welsbach naphtha gas or gasoline lamps of from 80 to 100 candle power each for the terms of 1, 2 and 3 years, to be disposed and placed about the city as directed by the Common Council.

3d. For furnishing 200, 300, 400, 500, 600, 700, 800 and 1,000 common 16 candle-power naphtha, gasoline, or gas lamps for the terms of 1, 2 and 3 years, to be disposed and placed about the city as directed by the Common Council.

4th. For furnishing any combination of the above lights.

5th. For furnishing any other style or manner of light suitable for the streets and public places of the city of Superior for the terms of 1, 2 and 3 years.

All such propositions to be for lights burning all night, from dark until daylight; plat of the city furnished by the City Engineer on request; bids to be accompanied by certified check of $500 as evidence of good faith, drawn to the City Treasurer; and the city reserving the right to reject any and all bids; all bids to be in by the 16th day of August, 1898; all bids to be sealed and addressed to the undersigned.

Dated this 23d day of July, A. D. 1898.

F. J. SEGUIN,
City Clerk.

YOU WILL CONFER A FAVOR

both upon the advertiser and the publisher if you will mention the **American Electrician** when writing to companies whose announcements appear in this paper.

American Electrician.

Vol. X. New York, September, 1898. No. 9.

THE DEVELOPMENT OF THE HYDRAULIC POWER OF THE HUDSON RIVER AT MECHANICVILLE.

The development of the power of St. Anthony's Falls on the Mississippi at Minneapolis, Minn., is followed closely by the utilization of the power of the upper waters of the Hudson River at Mechanicville, N. Y., where an undertaking of no less magnitude has, within the past few days, been completed. Five to seven thousand h.p. is available at the power house and the use of high tension current permits of its distribution over a wide territory.

As in the Mississippi, the waters of the Hudson above the present point of development have been, to some extent, employed by factories using low head turbines directly driving their machinery, but not until the undertaking just concluded was decided upon had any very serious effort been made to take advantage of the great amount of power which has run to waste for ages down the stream of the main waterway of the Empire State.

Early in 1897 the attention of Mr. R. N. King, President of the Stilwell-Bierce & Smith-Vaile Company, of Dayton, Ohio, was drawn to this water power. His long experience with water powers and their development, led him speedily to recognize the possibilities which were presented. The site is but two miles from Mechanicville, eleven miles from Troy and eighteen miles from Albany, in each of which towns large quantities of power would doubtless find a market. But, most important of all, it lies only seventeen miles from Schenectady, where, covering not less than 130 acres of ground, the largest electrical works in the world are operated from an extensive steam plant, with which the electrical power from the Mechanicville cataract could readily compete.

After consultation with the chief engineers of the General Electric Company, in which the necessary assurances were given, Mr. King formed the Hudson River Power Transmission Company.

The hydraulic engineering features of the development were carried out in their entirety by Mr. A. C. Rice, Chief Engineer of the Stilwell-Bierce & Smith-Vaile Co., and it may be said that in the completed

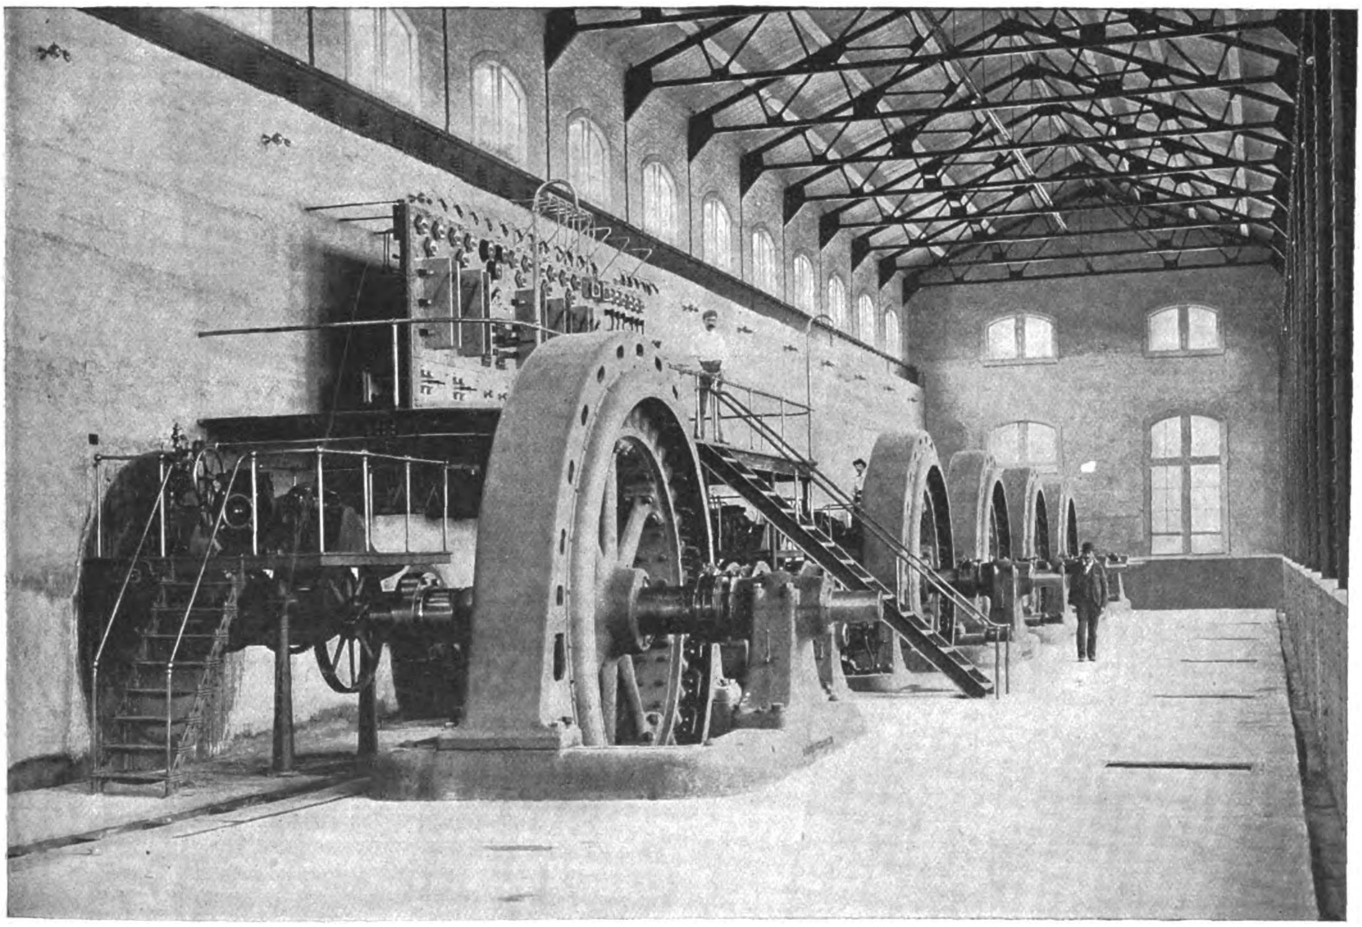

FIG. I.—GENERAL VIEW OF STATION INTERIOR.

work as it stands to-day little or no departure from the plans laid down by Mr. Rice has been made. As the General Electric Company was to purchase the largest amount of power, its advice as to the electrical equipment was naturally closely followed. The result brought about by the harmonious co-operation of both hydraulic and electrical engineers is a power transmission plant in every respect strictly representative of the most modern hydraulic and electrical practice.

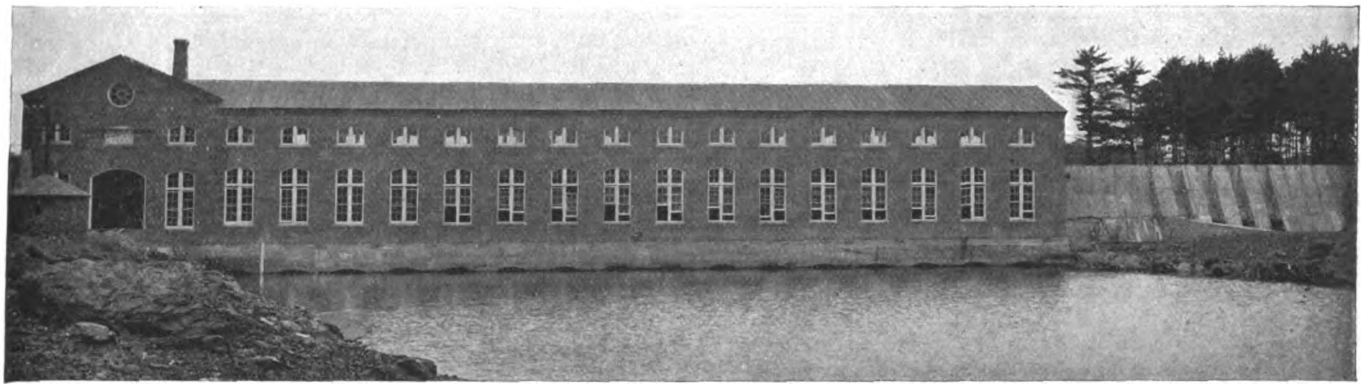

FIG. 2.—GENERAL VIEW OF POWER HOUSE.

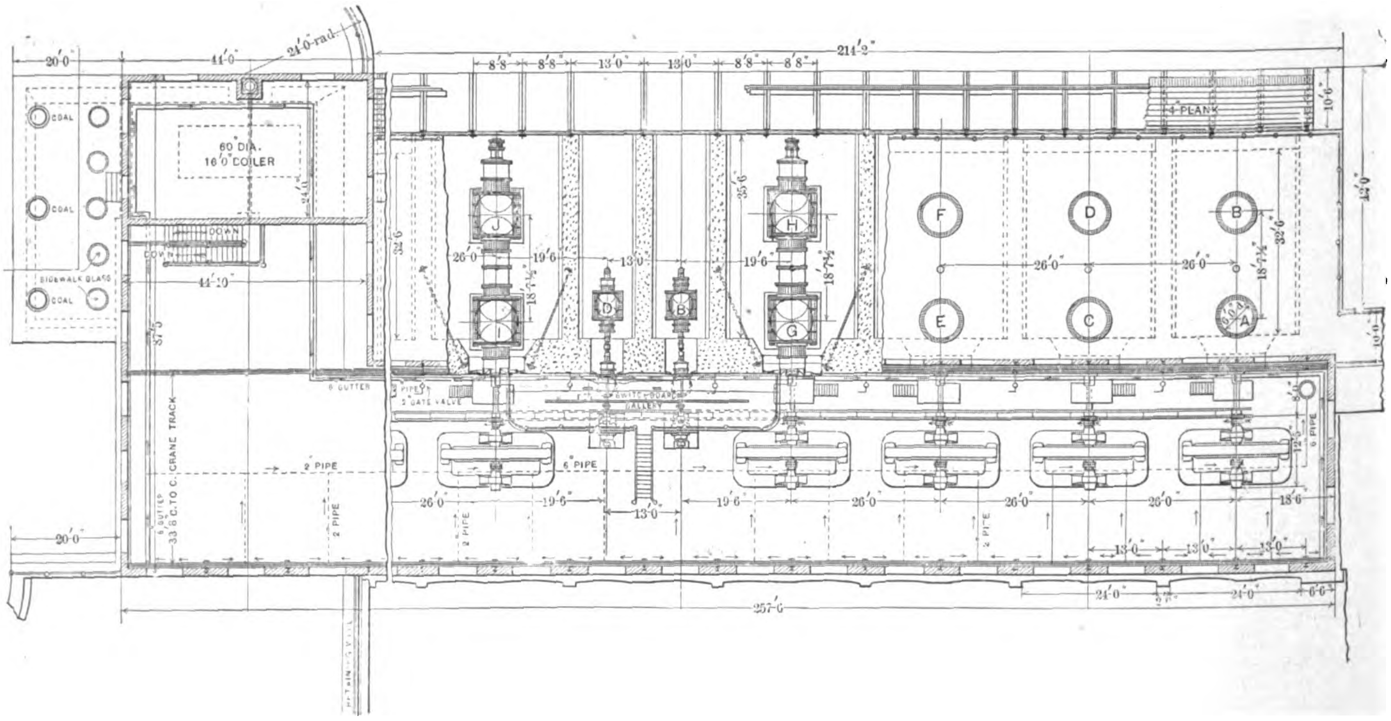

FIG. 3.—PLAN OF POWER HOUSE.

At the point chosen for the hydraulic development the physical conditions make the location an ideal place for a dam and power house. The banks and bottom of the river are of rock, as is Bluff Island, immediately adjacent, which divides the Hudson into two channels. During the greater part of the year there is water sufficient to produce from 7000 to 10,000 h.p.

The island is about one-third of the distance across the river from the western bank, the combined width of the two channels being about 1200 ft. The western channel is used for the head and tail races.

In order to make the excavations for the power house and the main dams, heavy cofferdams were built across both streams. The work would have been completed well within the time at first specified had not an extraordinary freshet swept away part of the cofferdam, necessitating long delay. The rock and shale resulting from the excavations proved unsuitable for incorporation into concrete, and the broken rock used was brought over a special track from the neighborhood of Schenectady.

The power house extends from the western bank about 215 ft. into the river and is connected with Bluff Island by a concrete dam, 26 ft. high above the bed of the river, 10 ft. wide on top and 18 ft. wide at the base. The upstream face is vertical and the downstream face is sloping. The top of this dam is at an elevation that the water will never reach; thus no provision is made to take care of falling water on the down stream side, but the dam is provided with four arch waste gates, 4 ft. wide and 6 ft. 9 ins. high, operated in the same manner as those in the main dam.

The main dam is on the eastern side of the island. It is built entirely of concrete, as, indeed, is the entire construction with the exception of the upper walls of the power house. The upstream face is vertical, the downstream face is curved and provided with a horizontal apron 14 ft. wide, which throws the falling water off horizontally, and thus effectually prevents wash or scour of the toe of the dam. The dam is 16 ft. high above the river bed, 8 ft. thick immediately below the crest, 16 ft. thick through the base and 30 ft. thick through base and apron. The dam is set between massive abutments anchored to the rock sides of the river bank and island. The eastern is 20 ft. long, 26 ft. high above river bottom, 16 ft. thick at the top and 34 ft. wide at the base. The western abutment is 100 ft. long, the other dimensions being similar to those of the eastern abutment. The length of the spillway between abutments is 800 ft. In the western abutment are twelve arched waste gates of ample proportions. Each waste gate is 4 ft. wide and 6 ft. high, and is opened and closed by a heavy iron hoist operated by rack and pinion. The eastern dam is practically a solid rock wall capable of

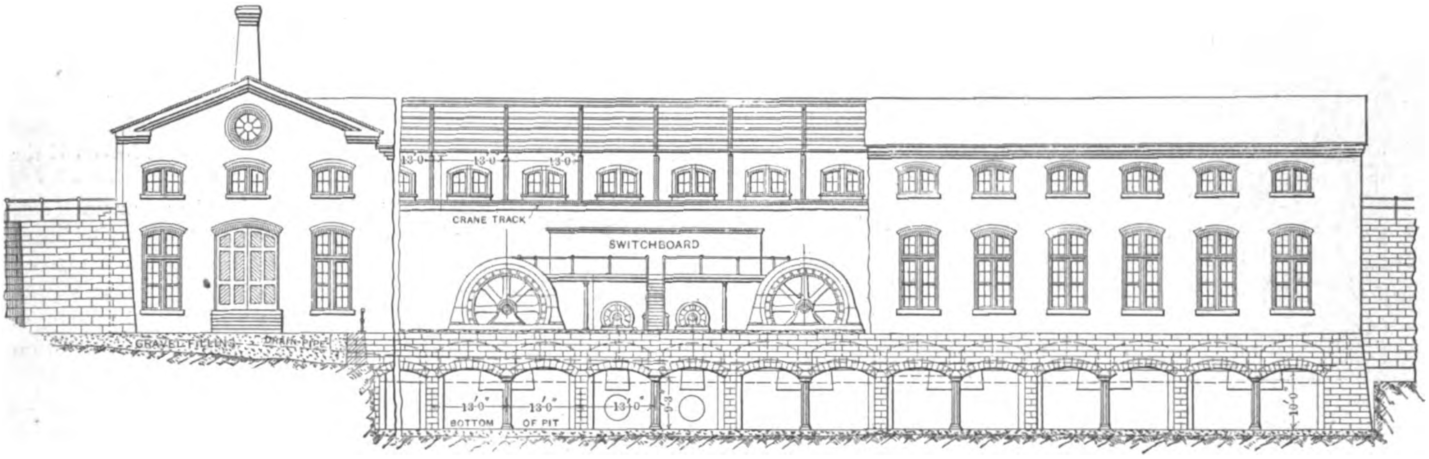

FIG. 4.—SIDE ELEVATION, LOOKING UP STREAM.

safely resisting any flood. It was severely tested in the spring of 1898, when a flood of extraordinary proportions came against it, yet, notwithstanding the fact that the dam was green, the flood in no manner injured it. To prevent any floating rubbish, ice, or logs reaching the rocks or choking the waste gates, a floating wooden boom stretches from the western end of the spillway diagonally for a distance of 400 ft. to the edge of the normal river bank, and then for a distance of 1000 ft. to the main embankment of the Mechanicville highway. It is anchored to a line of stone-filled cribs.

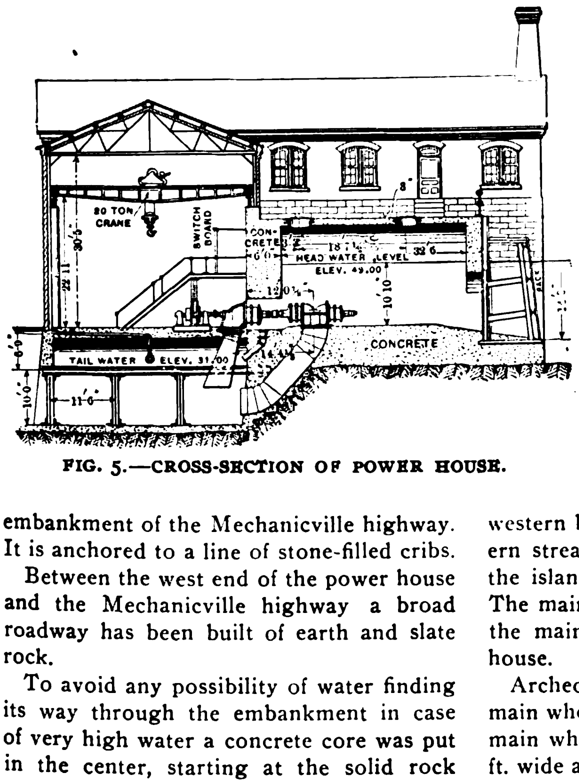

FIG. 5.—CROSS-SECTION OF POWER HOUSE.

Between the west end of the power house and the Mechanicville highway a broad roadway has been built of earth and slate rock.

To avoid any possibility of water finding its way through the embankment in case of very high water a concrete core was put in the center, starting at the solid rock and finishing 2 ft. below the surface of the road. The embankment forming the roadway is 40 ft. wide on the top, 124 ft. at the base and 18 ft. high at the deepest point.

The power house lies between the west bank and the short concrete dam, nearly filling the space between the island and the west bank of the river. It is practically a continuation of the dam, and, like the main dam, is of concrete with the exception of the upper walls. Its construction is of the most substantial character, the foundations are carried down to bedrock, and the house is carried on heavy steel box-web girders resting upon steel I-beam columns. The latter are imbedded in concrete walls carrying arches which form the floor of the generator room and the floor on which the wheel flumes rest. The walls form a separate and distinct tail race 22 ft. wide for each set of turbines, from which the water may be shut out at will.

The house is divided into two parts by a thick head wall. The upstream part contains wheel chambers for seven 1000 h.p. wheels, of which five only are at present occupied. The downstream portion contains the wheel governors and the electrical apparatus. The length of the power house proper is 257 ft. 6 in.; the width of the dynamo room between head wall and south wall 34 ft., and the width of the wheel chamber portion 32 ft. 6 in. The total width of the power house is 66 ft. 6 in. At the western end an L extension runs up stream 87 ft. 5 in. long and 44 ft. 10 in. wide. This portion of the power house is of brick. A retaining wall runs down stream from the power house along the western bank a distance of 50 ft. The western stream running between the bank and the island forms the forebay, 300 ft. long. The main tail race is 205 ft. wide and joins the main stream 750 ft. below the power house.

Arched chambers are provided for seven main wheels and two exciter wheels. Each main wheel chamber is 32 ft. 6 in. long, 22 ft. wide and 17 ft. 5 in. high and is provided with two 6-ft. manholes. Each exciter wheel chamber is 32 ft. 6 in. long, 17 ft. 5 in. high and 10 ft. wide. The head wall of the chambers is 6 ft. thick, the wall on the upstream and both sides 3 ft. thick. In the head wall of each main chamber is set a heavy cast iron cover through which the the turbine shaft passes in a watertight packing box, carrying the ring oil bearing for the shaft. The saving in space effected by the new arrangement of housing and coupling together of the turbines, patented by the Stilwell-Bierce & Smith-Vaile Co. has tended to diminish considerably the size of the power house.

A 20-ton crane from the works of Pawling & Harnishfeger, Milwaukee, runs the entire length of the dynamo room.

In front of the wheel chambers and running the entire length of the power house is a trash rack of steel bars supported on a framework of steel channel and I-beams. This rack effectually prevents the access to the wheels of any rubbish or floating material that may escape the boom.

The main wheel plant consists of ten pair of 42 in. horizontal Victor turbines of the latest type, built by the Stilwell-Bierce & Smith-Vaile Co., of Dayton, Ohio. Each main turbine consists of two pair of wheels which, at the normal speed of 114 revolutions is rated at 250 h. p. The wheel power of each set of turbines is therefore 1000 h. p. Five units are now in position; the two additional turbines will be installed shortly. The head under which the water wheels are operated is 18 ft.

The turbines for the exciters consist of three 18-in. Victor cylinder gate wheels, having, at 259 revolutions per minute, a total of 300 h.p. The quarter turns and packing boxes of these wheels are brought through the wall beneath the station switchboard.

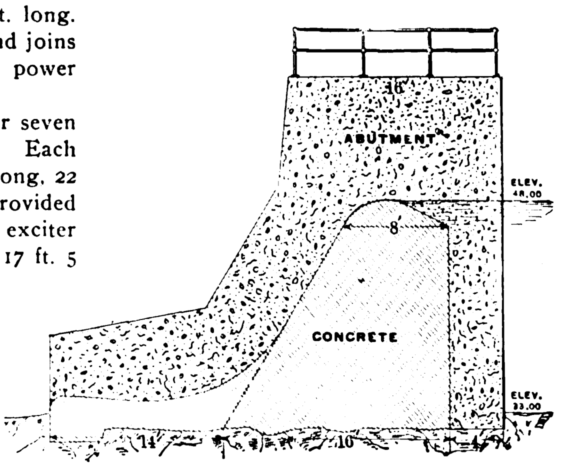

FIG. 6.—SECTION OF DAM.

Two draft tubes lead from each main turbine, the forward tube descending straight into the tail race beneath the power house, the rear or upstream tube curving and flaring downward and outward. Each tube is 9 ft. 6 in. in diameter at the bottom. Two draft tubes are also allotted to each set of exciter wheels, the setting following a similar arrangement. The rear tube is 4 ft. in diameter, the forward tube 3 ft.

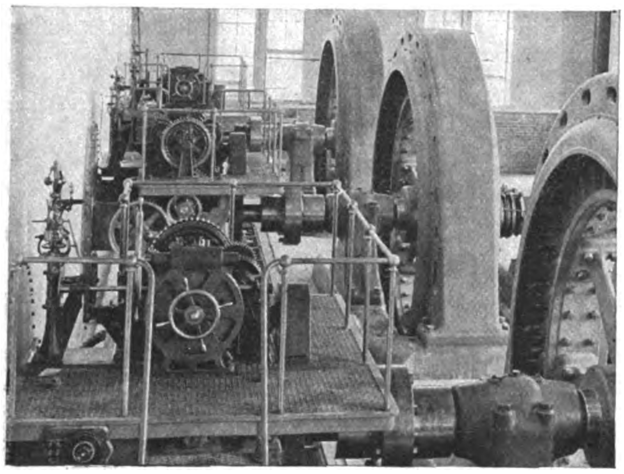

FIG. 7.=VIEW OF GENERATOR AND WATER WHEEL GOVERNOR.

The speed of each set of main wheels is regulated by a Geisler electro-mechanical governor, mounted on a platform directly over the turbine shaft, and between the head wall and the generator.

The use of electricity renders the mechanism of this governor extremely sensitive and effective, and the gates can be entirely opened or shut, should the full current be thrown on or off, in six seconds. The driving pulley is replaced by a rawhide pinion, giving a rigid connection between the governor and the wheel, and making 400 r.p.m. The speed may be increased to shut off or throw on in less than six seconds, if necessary. The Geisler governor is now in use in many of the most important electric power transmissions in this country, including those of Columbia, S. C.; Pelzer, N. C.; Lachine, Que.; West Kootenay, B. C.; Montmorency, Que.

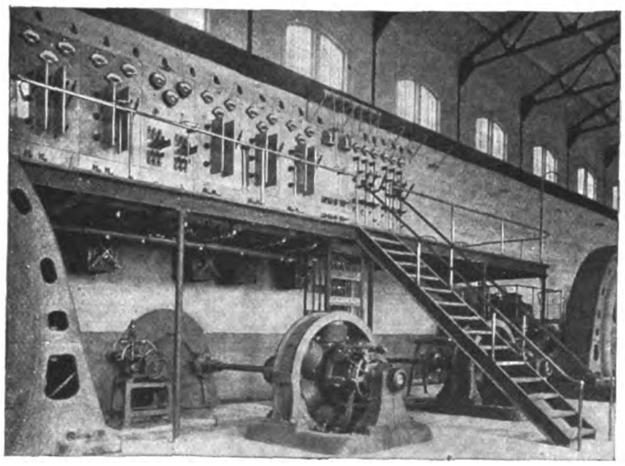

FIG. 8.—EXCITERS AND SWITCHBOARD.

The governors controlling the exciter wheel gates are improved "Snow" governors, which rapidly bring the speed to normal when changes are neither frequent nor heavy. They are especially adapted to the regulation of water wheels driving exciters and are provided with adjustable stops which limit the hoisting action on the gate as soon as the gate is fully open.

The dynamo room is a spacious chamber well lighted by windows on all sides. It is 255 ft. long and 34 ft. wide, 30 ft. 5 in. in the clear from floor to roof truss and 22 ft. from floor to crane. The ultimate generator capacity of the station is 7000 h.p. in seven generators each of 750 k.w. capacity. Five have been installed and are now running. They are unitooth, three phase, fortypole 750-k.w. 114-revolution, alternating current machines, having revolving fields and stationary armatures, and wound to deliver 36 amperes of current at a periodicity of 38 cycles and a pressure of 12,000 volts to the transmission lines. They are arranged for operation in parallel at constant voltage. By using the revolving-field type of generator and thus securing this pressure directly from the machine the use of step-up transformers to raise the voltage for transmission purposes is avoided. As the current is to operate synchronous and induction motors, to operate lights and to be converted into direct current through rotary converters, the frequency of 38 cycles was selected as most suitable for the different conditions required.

The alternators are similar in their main characteristics to those successfully used in the development of the power of the Lachine Rapids at Montreal. The armature frame or ring is of the box type, 15 ft. 4 in. in diameter and 36 in. wide. It is bolted to a base 18 ft. 2 in. long by 10 ft. wide, along which it may be moved parallel with the shaft, in order that the revolving field spider and poles may be uncovered should occasion require. The armature winding is protected on each side by iron shields. The pillow blocks are also bolted to the base and the bearings are of the spherical seated self-oiling type used in all General Electric generators.

The field ring is bolted to the spokes of the spider. It carries forty poles, each securely fastened by two bolts to the ring. The whole revolves on a shaft 15 in. in diameter provided with a rigid coupling on the turbine shaft. The dynamo shaft is extended for coupling to a vertical steam engine in case of necessity.

The following reasons for selecting this type of alternator have been given by Mr. C. P. Steinmetz, of the General Electric Company:

In addition to the advantage which the stationary armature type has over the stationary field type in allowing a high transmission voltage to be taken directly from the armatures, it allows of a fairly low saturation of the magnetic circuit, giving an almost straight saturation curve. This is preferable in power transmission, since a considerable increase in the voltage may be obtained if needed to cover excessive drop in the lines, due to heavy loads, etc., and the voltage may be maintained even if the speed remains low.

The exciters are placed one on each side of the stairway leading to the switchboard gallery. They are 6-pole 100-k.w. 125-volt standard General Electric machines with ribbed field frame and iron-clad armatures.

The switchboard, erected on a gallery on the north wall of the dynamo room, is built up of nine highly polished panels of blue Vermont marble, each panel 7 ft. 6 ins. high, 3 ft. wide, and 2 ins. thick. Of these nine panels five are used for the generators and two for the feeders; one is the total output panel and the last is for the control of the exciters. The generator panels occupy the left side of the board, and room on the gallery is left for two additional panels. The feeder panels are on the right hand side; the total output panel is between these and the generator panels and the exciter panel is the third panel from the left-hand end of the board.

Each generator panel is equipped with the following instruments: One inclined coil alternating ammeter reading to 75 amperes for the generator, and one direct current ammeter reading to 150 amperes for the field. Above each of these is a pilot lamp, and between each pilot lamp is a synchronizing lamp. Beneath the two ammeters is an inclined-coil voltmeter reading to 15,000 volts, and beneath this instrument are three single-blade double-throw, quick-break, high-tension switches, which, seen from the front of the board, are each mounted upon pyramids of corrugated hard rubber. Similar pyramids in-

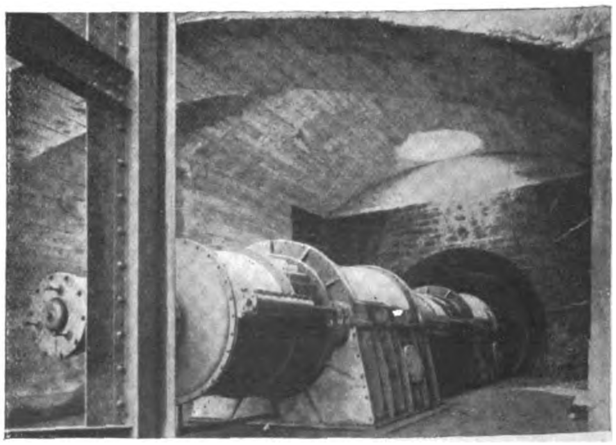

FIG. 9.--TURBINE CHAMBER.

tervene at the back of the board between the bus bars and the board. The corrugations give a total distance of about 8 ins. of surface between the metal clips and hinge, and the surface of the marble on each side. As these switches are to break a current of 12,000 volts, they are tested to break without difficulty currents of 21,000 volts. The switches are without handles. An eye is made in the end of each blade, into which a hook at the end of a stick may be inserted and the switch opened by the attendant from a safe distance. Further, to prevent any dangerous arcing from blade to blade, marble barriers 1¼ ins. thick, 3 ins. long and 12 ins. wide from the face of the board are erected between each blade.

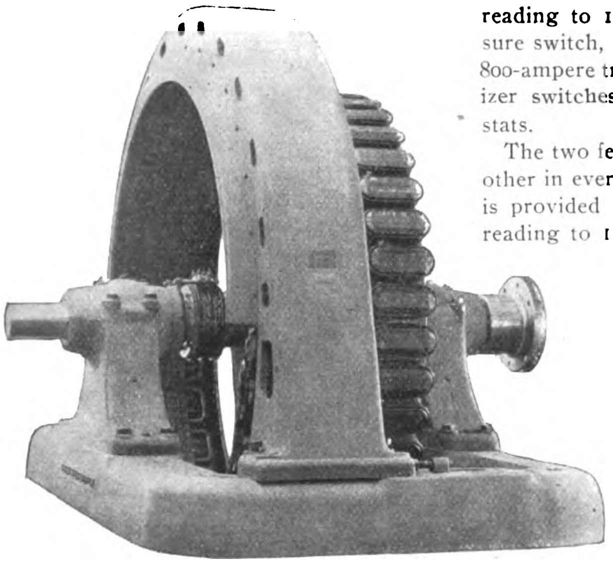

FIG. 10.—TYPE OF ALTERNATOR USED.

On the left-hand side of each generator panel sub-base are two 100-ampere double-pole double-throw carbon-break switches—one the field switch, the other the lighting switch. On the back of the panels are the high-tension fuse blocks.

These fuse blocks, designed for 20,000 volts, are of the snap-break expulsion type. They are mounted on pyramids of corrugated hard rubber, which carry copper spring contact clips between which two copper blades enter, connecting the fuse block to the line. The aluminum fuse is held tightly between two arms, which are movable around a pivot, and may be pulled apart by two strong spiral springs encircling this pivot. As soon as an increase of current in the line melts the fuse, its two halves are instantly pulled apart and thus the formation of an arc between the two halves is prevented. The melting of the fuse can only occur in a small chamber protected by wooden blocks. The whole device is covered by two vertical wooden boards. Sliding in between these wooden boards in vertical slots are fibre shields intended to prevent arcing over between the two arms after the separation of the two halves of the melted fuse. The two wooden blocks and fibre shields are held in position by four screws. The whole fuse block is inserted in the line simply by pushing the two blade-like copper contacts between the clip contacts, which are connected by solid copper rods to the bus bars. The wooden boards protecting the fuse are 10½ ins. long and 6⅜ ins. wide. The corrugated rubber pyramids on which the contacts are mounted are 3½ ins. high. The field rheostats are hung beneath the gallery, and are operated by hand wheels on the gallery and bevel gears below it.

The exciter panel controlling the two direct current exciters carries two pilot lamps, two circular dial ammeters, each reading to 1000 amperes, one voltmeter reading to 150 volts, one four-point pressure switch, one synchronizing switch, two 800-ampere triple-blade double-throw equalizer switches and two packed card rheostats.

The two feeder panels are similar to each other in every respect. Each outgoing line is provided with an independent ammeter reading to 150 amperes and a quick-break double-throw high-tension switch similar to those on the generator panels, and similiarly mounted on the board. Mounted also on corrugated hard rubber pyramids are the six circuit breakers or automatic plunger switches.

The high potential plunger switches consist simply of long copper rods sliding in hard rubber tubes. The upper ends of the rods reach into small rings, in contact with which they are held by a lever catching a small rubber head on the lower end of the copper rod. This lever is held in place by a spring, and is released by moving a rocker arm on the back of the switchboard. The moment it is released, a spiral spring pushes the copper rod downward, and by this movement, aided by the action of gravity, so suddenly is the contact broken that arcing between the rod and the ring is prevented. The rocker arm controls the three switches for each set of bus bars, so that they may all be released at once.

On the upper part of each feeder panel at the back is a current transformer for each outgoing line, two recording single-phase wattmeters, each reading to 25 amperes and 12,000 volts, and two potential transformers.

On the front of the out-put panel are two Thompson recording wattmeters for balanced three-phase circuits, each reading to 300 amperes and 12,000 volts, and twelve triple-pole single-throw 100-ampere switches with fuses for the lighting circuits. On the back are four potential and two current transformers.

The lightning arresters are of the G. E. short gap type. Arresters of this type have been installed on nearly all of the most important long-distance transmission lines in this country, and have proved a most satisfactory protection against damage by lightning.

The principle on which this arrester operates is very simple. It allows the passage of any high potential discharge, but effectually prevents the alternating current from following and maintaining an arc. The gap spaces in the lightning arresters at Mechanicville are very small—about 1-32 ins., each space lying between two solid metal cylinders 2 ins. in diameter and 2 ins. long. A low non-inductive graphite resistance is placed on the circuit, and the action of the arrester therefore is dependent upon the cooling effect of the large metal cylinders, aided by the reversal of the alternating current and the introduction of the non-inductive resistance. The line is protected by double-pole 2000-volt arresters, connected six in series to give the necessary number of spark gaps. There are three sets of these, one at Mechanicville, grouped around the first transmission pole in a small house 15 ft. square, one set on the Schenectady side of the Glenville bridge, where the overhead pole line connects with the underground cable, and the third at the works.

The lead covered leads from the generators are taken out at the base of the machine, and are laid in ducts in the floor. Rubber covered wire is used for the field connections. The cables rise on a frame from the duct to the floor of the gallery, through which they rise to the board. From the back of the board the line wires rise to supports bolted to the I-beam on the north wall, which supports one of the crane runways. The lines run along the north and west walls and pass out to the poles through a blind window over the door of the power house.

The line from Mechanicville to Schenectady is the only one at present laid down. It consists of three No. 000 B. & S. bare wires, this large gauge being employed in order to give the line as high a self-induction as possible. This insertion of self-induction in transmission lines is a departure from earlier practice. In cases where synchronizing apparatus is used self-induction is now considered necessary, and is artificially brought into the line in the shape of reactive coils in cases in which the natural self-induction is too small. The circuits are carried on poles of 30 to 60 ft. long and all 8 ins. in diameter at the top. Each pole carries one cross arm, on one side of which are two porcelain insulators of the petticoated type, a third being on the other side. For light-

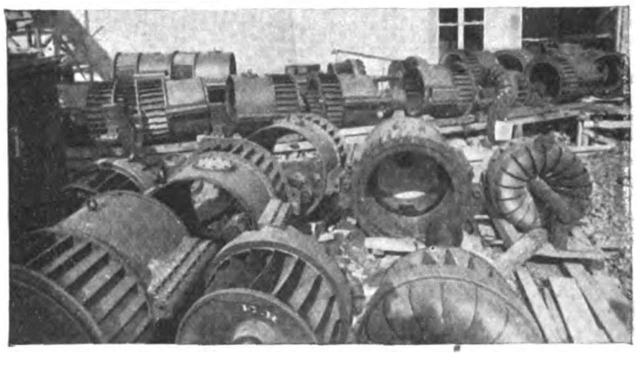

FIG. 11.—TURBINES BEFORE INSTALLATION.

ning protection a barbed wire frequently grounded runs along the top of the pole line.

The line takes a westerly direction to East Glenville and then due south to Schenectady. At the end of the Glenville bridge over the Mohawk—the town limits—it is carried down to the ground and connected to three cables of No. 1 gauge stranded copper, insulated by ¼ in. rubber and 3-32 in. sheet lead laid in terra cotta conduits. These cables run 1700 ft. along Washington Avenue, rise to poles again through Rotterdam Street to the Erie Canal, and along the canal to a point directly opposite the General Electric power station. They here cross the canal and enter the General Electric Company's works.

The introduction of this transmitted electrical power into the factory will work a considerable change. At present all the machinery is driven by electric motors, while the testing department demands an independent supply of current for the work it carries on. There are at present, therefore, two distinct generating plants. The 550-volt motors in the testing department are supplied from an engine driven multipolar generator of 500-k.w. capacity, while a smaller engine drives a number of exciters which allow of independent control of the excitation of all machines in this department. The factory is operated by a number of 250-volt motors, running on the same circuit as the factory lights. These motors will not be changed, and the steam plant which supplies them will be retained as a reserve in case the power from Mechanicville should fail. The electric power plant superseding the present steam plant at the works will, therefore, consist of two synchronous motors, one of 500 k.w., the other of 100 k.w., and three 400 k.w. rotary converters—the synchronous motors for the testing department, the converters to supply current to the factory motors.

The large engine driving the 500 k.w. multipolar generator is superseded by the 500-k.w. synchronous motors. This is a twelve-pole 400-revolution machine of the revolving field type, wound directly for 10.000 volts. The small engine driving the exciters is replaced by the 100-k.w. synchronous motor and eight-pole, 600-r.p.m. revolving-field machine similarly wound. This disposition renders this department independent of everything but the speed of the Mechanicville generators, which will be kept as nearly as possible constant.

The three rotaries supplying 250-volt current to the factory motors are ten-pole 400-k.w. 480-r.p.m. machines, having two commutators and two sets of collectors rings connecting to independent windings on the armatures. They receive the three-phase current from independent secondary coils of the same set of air blast transformers. When connected in multiple they furnish current at normal pressure of 250 volts, but as they may be called upon to furnish current to the testing department in case the demand exceeds the supply from the synchronous motor driven machine, they may be connected in series to give 500-volt current, operating in parallel with the 500-volt generator driven by the synchronous motor in the testing department.

The rotaries are operated in parallel and as well as all the factory lighting are operated from the same direct-current circuit, the latter on the Edison three-wire system, the neutral wire of the three-wire system being secured by connecting the transformers for the rotaries in Y with their secondaries and bringing to the neutral a lead from their common connection.

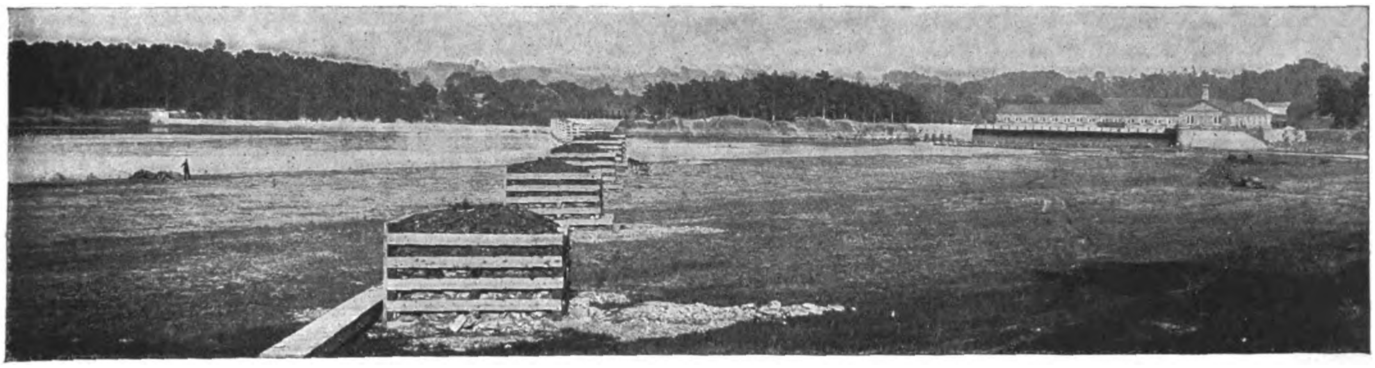

FIG. 12.—VIEW OF POWER HOUSE, SHOWING BOOM AND CRIB TO ARREST FLOATING REFUSE.

Synchronous motors were selected in preference to induction motors on account, first, of their more constant speed and greater efficiency; second, because they do not produce lagging currents, but the phase displacement and power factor may be controlled as desired by means of control of the field excitation.

Synchronous motors of the revolving field type and of good design are self-starting even under heavy load, and will easily carry two or three times full load without falling out of step for a time limited only by the heating of the motor.

To make the entire works system self-regulating in the direct current distribution and as far as possible independent of hand regulation, the rotary converters are given shunt field and powerful series field, so joined together that the machines operate as one unit. With constant voltage in the generating station at no load, the counter e.m.f. of the rotaries as given by their shunt field is below the impressed e.m.f. and a lagging current is produced. The self-induction of the lines is thus in opposition to the voltage, which is so reduced as to give 250 volts at the commutator brushes of the rotaries. As the load increases the counter e.m.f. of the rotaries rises, due to the series field, until at full and overload it is greater than the impressed e.m.f., and the current becomes leading. The e.m.f. of self-induction of the lines is then brought partly in phase with the voltage, which is increased so that in spite of the increased line current and consequently increased energy loss in the line, with constant generator voltage, the same voltage is produced at the commutator brushes of the rotaries at no load as at full and overload. This control is therefore automatic in every way, and did the synchronous motor not take current over the same line in varying quantities would suffice. To render this control perfectly automatic, therefore, small series transformers are inserted in the lines leading to the synchronous motor, feeding a small synchronous motor generator controlling the shunt field of the rotaries. By the combined action of their shunt and series fields, the voltage is automatically maintained constant at the commutator brushes of the rotaries and no hand regulation is required beyond that of readjustment in case the number of rotaries in operation is changed. The works of the General Electric Company were fortunately situated to make use of this natural power, and the results will certainly add to the argument that the choice of factory sites within transmission distances of large water powers is advisable.

The entire construction of the dams, power house and lines has been carried out with the highest engineering skill by the National Contracting Company, of which G. M. Furman is general manager, B. A. Mathews superintendent and J. A. Leonard constructing engineer. The electrical equipment is furnished by the General Electric Company, and the hydraulic equipment by the Stilwell-Bierce & Smith-Vaile Company, of Dayton, Ohio, to which company was confided the entire development contract. It took the Hudson River in its natural state and turned the complete plant over to the operating company.

The officers of the Hudson River Power Transmission Company are: General Edmund Fayes, of Buffalo, N. Y., president; R. N. King, president of Stilwell-Bierce & Smith-Vaile Company, of Dayton, Ohio, vice-president; G. M. Furman, Newark, N. J., treasurer; B. J. Richards, Boston, Mass., superintendent, and J. S. O'Shea, manager.

AMERICAN APPARATUS FOR THE METROPOLITAN ELECTRIC SUPPLY COMPANY OF LONDON.

Among the many contracts placed in America by British "consumers" during the last few years one of the most interesting and important is that recently given by the Metropolitan Electric Supply Company, of London, the largest municipal electric service company in Europe, to the Westinghouse Electric and Manufacturing Company and the Westinghouse Machine Company, of Pittsburg, Pa. The order calls for 7500 h.p. (in three units), of what are known abroad as "steam alternators." These units, though large for British practice, are but half the size of the Westinghouse generator units at Niagara Falls (5000 h.p.), but as they present a number of unique features of design and construction which have been developed by the Westinghouse Companies in their latest practice, a description of these alternators will be of special interest. The engines in particular are worthy of close study.

These three units are intended to supply primarily the arc and incandescent lighting service of London, but a portion of the power will be used for operating rotary transformers, which will, in secondary three-wire, direct-current distribution circuits, supply motors and storage batteries.

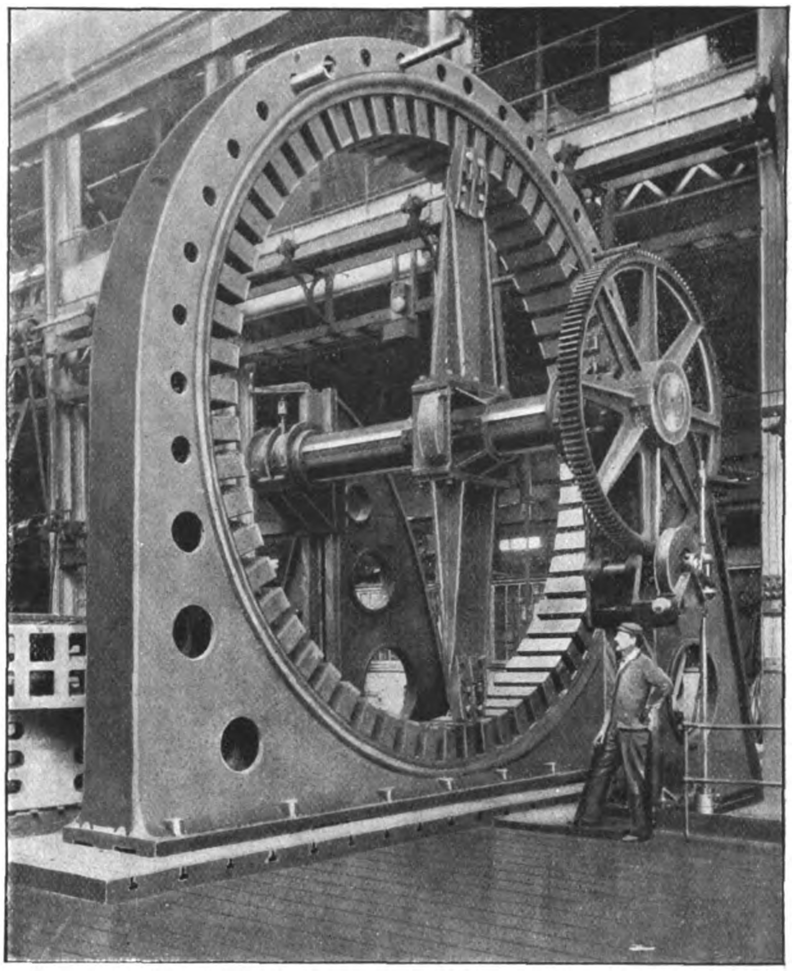

FIG. 1.—BORING LARGE ALTERNATOR FIELD.

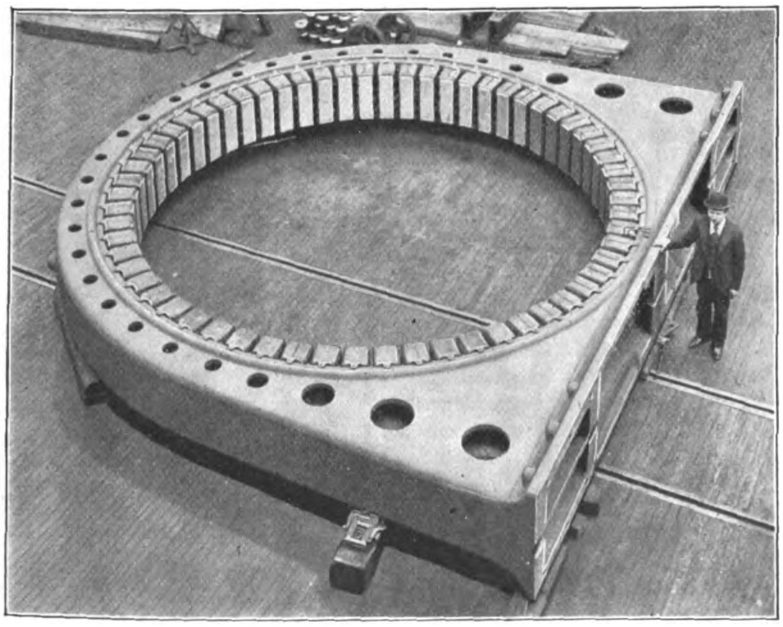

FIG. 2.—GENERAL VIEW OF COMPLETED FIELD FRAME.

The engines are the largest machines yet turned out at East Pittsburg, where the new shops of the Westinghouse Machine Company are located. The cut on the inset page shows a general view of the engine to excellent advantage, and by reference to the line drawing still further information can be had concerning this interesting prime mover. The engine when operating non-condensing is capable of developing the full rated power of the generator it is to drive, namely, 2500-h.p. at 133 r.p.m., the steam pressure being 100 lbs. If run at 120 r.p.m. with 140 lbs. steam pressure the engine can be loaded and will successfully carry 3500 h.p. All of the parts are strong enough to withstand a steam pressure of 200 lbs. to the square inch. The bed plates of these machines are of heavy box castings, intended to fit down over concrete foundations. The high and low pressure cylinders are 36 and 55 ins. in diameter respectively. The stroke is 36 ins. The cylinders are made of close grained cast iron, and, as the engine is of the vertical type, the danger of cutting the cylinder castings is practically negligible. The steam is distributed to the high pressure cylinder by a double ported piston valve, and two single ported piston valves perform the same office for the low pressure cylinder. The cylinders covers, pistons, etc., are provided with improved means to render their removal easy. Appropriate drains connected to the cylinders and steam chests and fitted with automatic water relief valves keep these important organs of the engines free from condensation. The drain valves are conveniently operated from the working platform by appropriate levers.

The crank shafts are of forged steel, 14 ins. in diameter at the bearings and 20 ins. at the armature hub. They are hollow throughout their entire length. The crank shaft extends, as will be noted in the pictures, so that the armature, which is the revolving element of the generator, may be mounted directly on the engine shaft and serve as a fly wheel.

The engines are fitted with permanent indicator rigs, which are accessible from the main platform, together with an elaborate system of lubrication, a system of cooling the bearings, and provision for varying the speed while running. All of these assist in enabling the engine to run for long periods without stopping. The main bearings of the engine are cooled by water, which is circulated about them. They are of the quarter-box type and can be moved in any direction by means of suitable wedges, which can be adjusted from without. The bearing shells are of cast steel or bronze, as the conditions may require, and are lined with the best babbitt metal. They are 14 ins. in diameter and 28 ins. long. Provision is made to allow the covers to be raised to facilitate inspection.

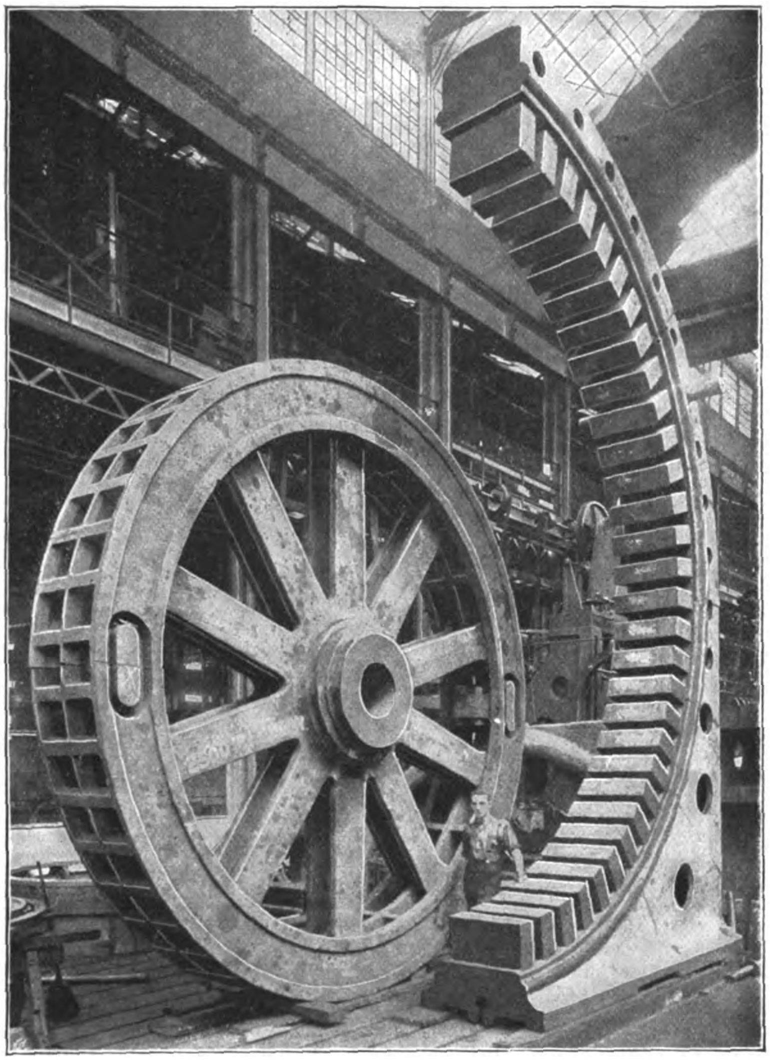

FIG. 3.—FIELD CASTING AND ARMATURE SPIDER.

The lubricators are sight feed. The oil is carried through brass tubes from the sight feed oilers and manifolds on the cylinders. These are connected to a reservoir on top of the cylinders, which is supplied by a force pump, which takes the oil from filters.

The engine is controlled by an open single weight inertia governor, which actuates the high pressure valve. The low pressure valves are operated by fixed eccentrics. The governor is keyed to the main shaft and is capable of 10 per cent adjustment while the engines are running. This is an important feature, for it enables the speeds of the machines to be varied to facilitate parallel operation. The maximum variation of governing at any speed within the rated limits is 1 per cent. The throttle is operated by a hand wheel, which is situated on the working platform.

The generators were built by the Westinghouse Electric & Manufacturing Company. They have a nominal output of 200 h.p. and are capable of delivering two-phase currents at a pressure of 500 volts. The field, or stationary element, is provided with 62 inwardly projecting pole pieces. These pole pieces are built up of laminated steel sheets and are cast into the frame. An excellent view of the field frame is shown in Fig. 1, in which it is in the process of being bored. This massive member, with its 62 pole pieces, cast, as they are, at accurately spaced intervals into such a heavy mass of metal, represents no mean specimen of the founder's art. The immense boring bar and the correspondingly large devices for centering the field frame about it are an illustration of the magnitude of the generators and the facilities which were necessary for performing and carrying out such a contract as this one. An interesting view of the completed field is shown in Fig. 2. In this picture, as will be noted, it is lying on its side and is complete with its field bobbins in place. The dividing line in this casting is vertical, and enables the two halves of the field frame to be withdrawn, thus exposing the armature for inspection or repair.

The field coils are wound with copper strips bent on edge and well insulated.

The armature spider is of cast iron, and built in two halves to facilitate shipping and assembling. A view of this casting is shown in Fig. 3, and this picture also affords an excellent view of one-half of the field frame. The arms of the spider are cast with splitting plates between them, so as to insure freedom from strains in cooling. They are secured in position on the crank shaft by two heavy mild steel rings, which are shrunk around the bosses at the base of the arms.

On the periphery of this casting are mounted steel punchings, which are suitably notched to receive the armature conductors. These are large copper bars of rectangular section, which are heavily insulated and embedded in the slots. The laminæ on the armature are assembled so as to allow for numerous ventilating ducts, thus enabling the ample passage of air through the core and keeping the temperature of the armature very low. The armature is wound with a distributed closed circuit winding, and the four collector leads draw their current from 124 equidistant points on the winding. The commercial efficiency of each generator is 95 per cent at full load and 91 per cent at half load.

The excitation of these gigantic machines is particularly interesting, as the exciters, which are, of course, machines of small capacity, are connected directly to the engine shaft, the speed of which, it will be remembered, is only 133 revolutions. The direct current dynamos which supply the exciting current at this extremely low speed are shown in Fig. 4. In the large illustration they will be seen connected to the extreme end of the engine shaft. An internal radial pole and drum armature are used. The brush ring is centered in a suitable groove turned in the yoke of the field frame and is operated by a hand wheel and worm, as shown in the picture.

The present contract has a further significance for American industry. The Metropolitan Electric Supply Company is planning new central stations and re-equipping old ones, and the assured success of the engines and generators which have just been described will undoubtedly cause the Westinghouse Company to be called upon to supply much additional engines and generators before the work of reconstruction is complete.

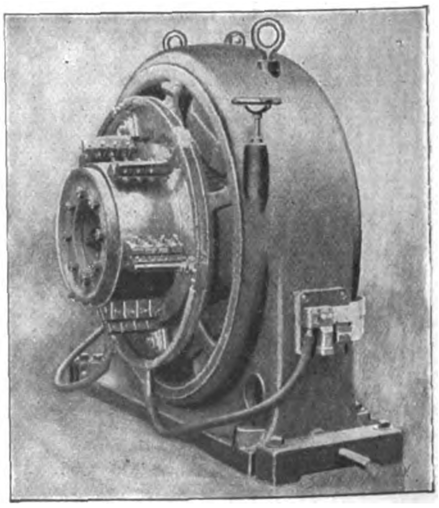

FIG. 4.—EXCITER.

NEW YORK'S ELECTRIC CAB SERVICE.

Motor driven common road vehicles antedate the steam railway. Their development and perfection has been slow and at times almost entirely obliterated by the more rapidly advancing steam traction. We have arrived at an age when mechanical motive powers and common roads and streets are nearing a high state of development and quite warrant the strenuous efforts which have been made within recent years to solve the motor carriage problem.

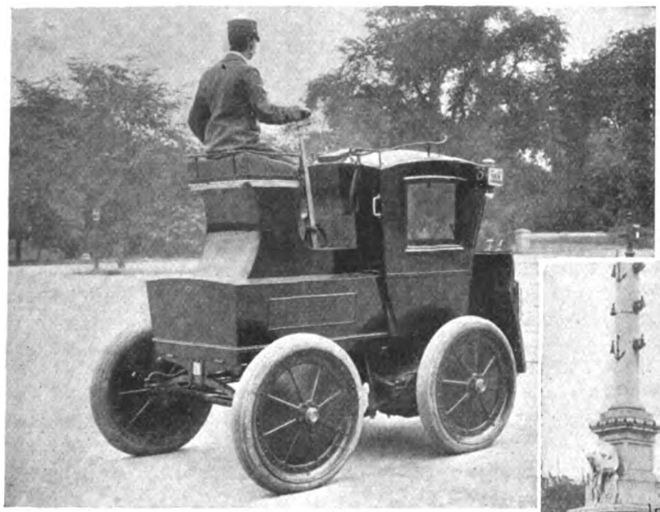

FIG. 1.—SIDE VIEW.

The propulsion of a wheeled vehicle over common roads by means of some self-contained mechanical energy is a very simple matter. Steam, gas and electricity are available as propelling agents, and their proper application to the wheels can be arranged in many ways. There are, however, so many features to be considered and conditions to be met, that as yet no single one of these propelling powers can be said to be universally successful, as the whole production of a satisfactory motor vehicle involves not only the application of a self-contained motive power to a wheeled conveyance, but many other considerations, dependent upon the particular service for which the vehicle is to be used.

Motor vehicles, propelled by steam, gas, electricity and even compressed air and other motive powers, have been produced in untold numbers within the last decade. Many excellent constructions have been evolved, but experience has already demonstrated that with the motors at present available the electric vehicle stands unexcelled, wherever it is possible to replenish the battery charge, and where a long running capacity is a secondary consideration. In such a case the many advantages of electric traction unquestionably overbalance its failings, even taking into consideration the heavy weight of battery equipment.

While electrically driven motor vehicles for private use have been entirely successful, yet it is quite obvious that this type in its present form is peculiarly adapted for public service from a centrally located charging station, the movements of the vehicle being confined to the districts about the station. This advantage of the electric vehicle seems to have been appreciated both here and in Europe, and electric motor cab and carriage services have been instituted in London and Paris. It will be remembered that about eighteen months ago an electric cab service was begun in New York City by the Electric Carriage & Wagon Company, the station being on West Thirty-ninth Street, near Broadway. The equipment consisted of twelve electric hansom cabs, built from the designs of Messrs. Morris & Salom, of Philadelphia. The outgrowth of this pioneer American electric cab service has been the organization of a larger corporation, known as the Electric Vehicle Company, whose recently completed electric cab and carriage plant in the center of Manhattan promises to eclipse the European installations in the completeness of its charging and handling plant and the detail with which the service is dealt. Regarding the old plant, it may be said that the twelve vehicles which it included were in continuous service about the streets of New York for almost fifteen months. They are in excellent condition even at the present day, and though superseded by the improved types, they could be called upon for good work at any time. The new cabs have been built upon the same general lines and are substantially of identical design, such changes as experience has shown to be essential having been made.

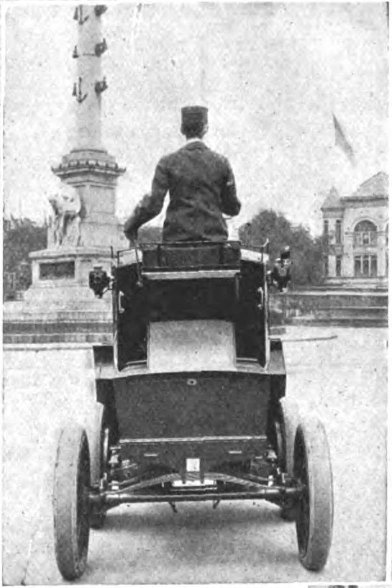

FIG. 2.—REAR VIEW.

The most notable part of the new plant is the facilities for handling these vehicles at the station, which is in striking contrast with the previous installations of a similar nature. Every possible provision has been made for economically and expeditiously charging, loading and unloading the batteries. The following description illustrates the several elements of the completed plant.

The service consists at present of an equipment of 100 cabs, and the aim has been to arrange the handling of the battery equipment so that the combined machinery for the purpose of manipulating it constitutes what may be said to be a single-man machine.

GENERAL ARRANGEMENT OF THE STATION.

The selection of a building suitably located on Manhattan Island was by no means a simple problem. Central location was essential in the district to be particularly covered by the service. This included the theatre, hotel and private residence sections. The very happy selection of the large rink structure of the former Michaux Club, located at 1684 Broadway, and extending through to Seventh Avenue, could scarcely be improved upon. The building occupies about 75 ft. on each of the main streets. Its length is about 200 ft.

The large unobstructed interior offered excellent opportunities for properly disposing the vehicles and their equipment. At the Broadway end a section of about 15 ft., extending the entire width of the building, is used for offices. On the ground floor are located the starter's and superintendent's offices and the waiting rooms, while the engineer's, manager's and auditor's office are on the floor above. A somewhat similar arrangement exists at the opposite end of the building, the ground floor at this end being used for the drivers' room and for storage battery repair, while the upper floor is used as a gener machine shop. The arrangement of the main space is otherwise shown by the illustrations. The battery room occupies almost half the entire floor space; it measures 37 x 100 ft. On each side of this space, running its entire length, is a heavy ste pillar construction which serves as the supporting structure for the battery crane and also for a substantial flooring covering the battery room. This upper floor serves as a carriage storage place. It is the intention to keep the entire unused vehicle equipment

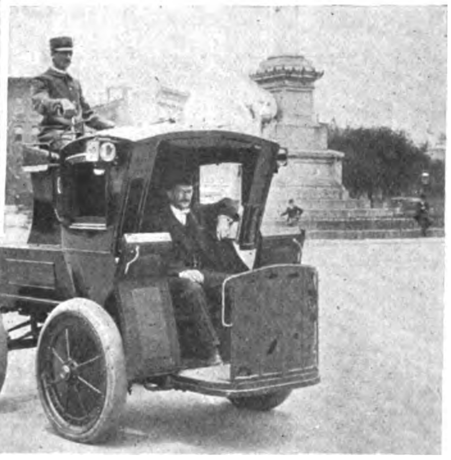

FIG. 3 —FRONT VIEW.

here, with the exception of such as may be on the main floor for the purpose of cleaning and other attention.

Two large vehicle elevators have been provided, one at each end of the battery room.

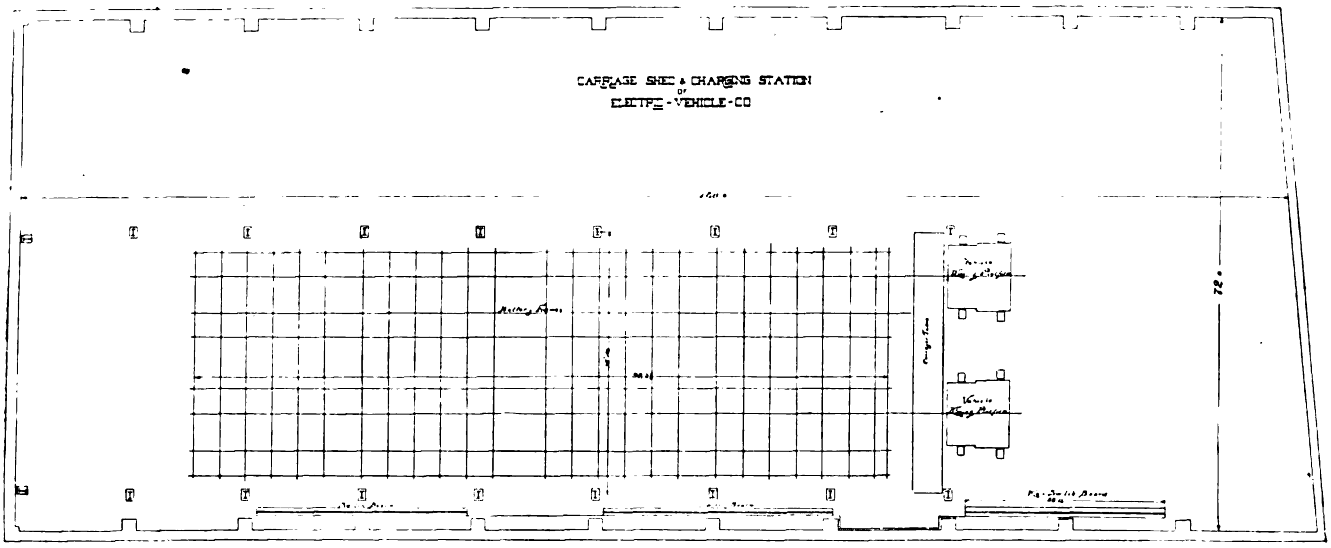

FIG. 4.—PLAN OF STATION.

In front of this room and facing the main entrance is the carriage loading machinery. When loaded, the vehicle leaves the station and accomplishes its mission, returns and is unloaded. Both the loading and unloading are accomplished almost entirely automatically. The carriage backs up against the charging table, its battery is removed and replaced, and the discharged cells are carried back into the battery room and deposited upon the proper racks and automatically connected with the charging circuits. If the vehicle requires attention or is not to be used for a time, it simply discharges its battery and is hauled to the space alongside of the battery room, where it is washed and cleaned and sent back to its resting place on the upper floor by the rear elevator till again wanted. If it is simply recharging, it, of course, receives a new battery. The time required for this operation is exceedingly brief, in fact, the writer witnessed the unloading and reloading of a vehicle which, even with the present somewhat incomplete state of machinery, took only three and one-half minutes. With everything in good working order it is reasonable to expect that the operation can be performed in less than two and one-half minutes.

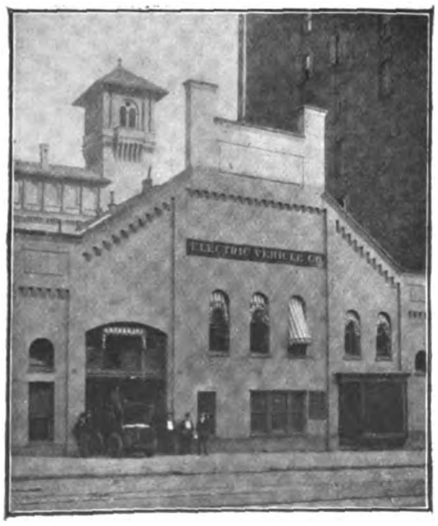

FIG. 5.—THE CHARGING STATION.

THE ELECTRIC HANSOM CAB.

While the 100 so-called electric hansoms are generally similar to their predecessors, a detailed description is perhaps warranted owing to their new features. The body of the cab may be described by simply saying that it resembles the ordinary hansom body with a rearwardly extending box. The latter serves as a battery compartment and also carries the seat for the driver. Aside from the similarity of the fore-body, the electric hansom cannot be said to bear any resemblance to the horse-hauled contrivance. Self-contained motive power essentially demands more than two wheels and more solid construction. The weight of the vehicle, including the battery, is about 2900 lbs. Its length from end to end is 9 ft.; at its widest portion the body measures 5 ft.; the wheel base is 4 ft. 7½ ins., and the gage of both front and rear wheels is 4 ft. 10 ins. In regard to the arrangement of the driving and steering gear the same disposition as in the old vehicles has been adopted; the two front wheels supporting the body proper are used for driving, and the two rear wheels under the battery box are arranged for steering. This arrangement presents a radical departure from common practice. Its designers, Messrs. Morris & Salom, claim that their present construction possesses many points of superiority.

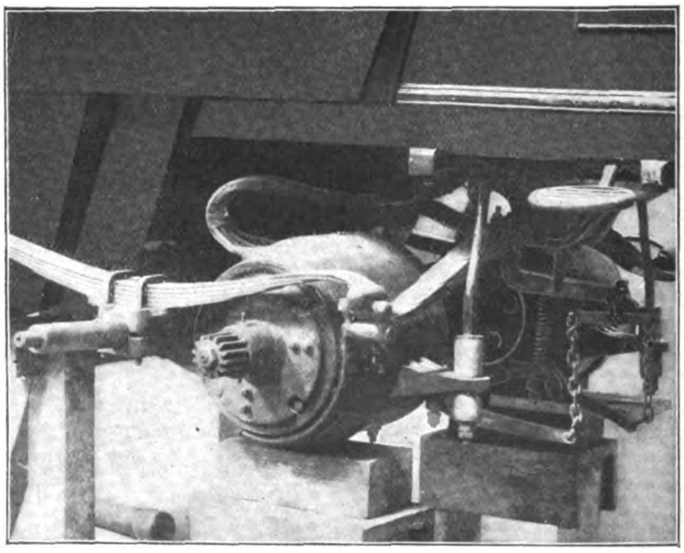

FIG 6.—MOTOR AND SUSPENSION.

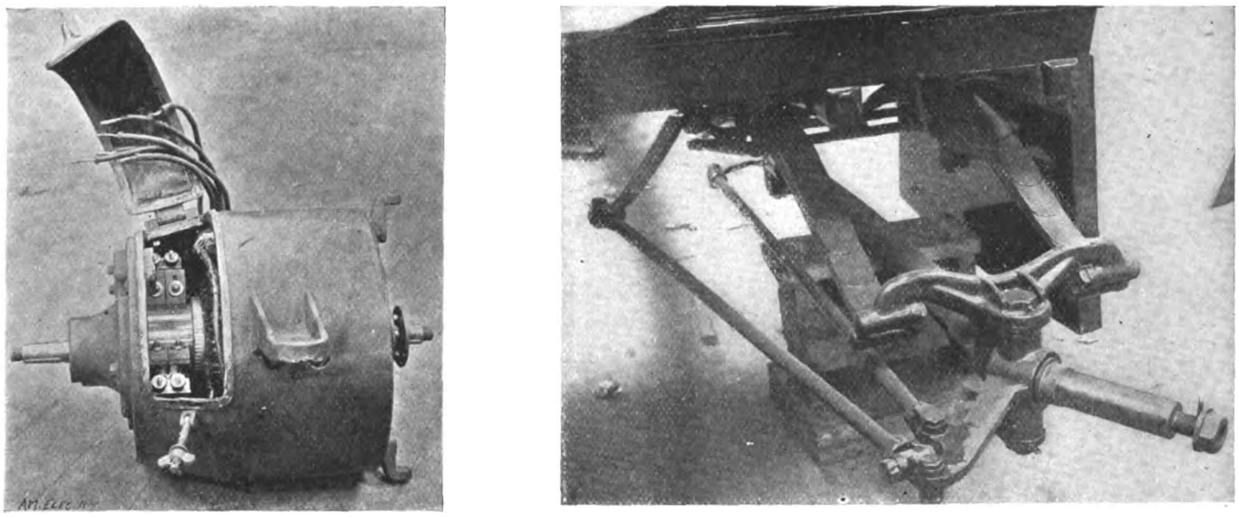
Probably one of the most striking features of the construction is to be found in the massive pneumatic tires and the small wheel diameters. Experience with the old vehicles demonstrated the failure of the smaller 3-in. pneumatic tire with which they were equipped, and for this reason the present 5-in. tire has been adopted. These tires are of the single tube type, built by the Hartford Rubber Works and the Newton Tire Company, and are made of ½-in.

rubber hose stock. Larger wheel diameters would have been used, had it been possible to obtain the necessary tires. The present 5-in. tires are pumped to the pressure of 60 lbs. The vehicle wheels are of a somewhat odd construction, being built of two circular plates, serving the place of spokes. These plates are of ⅛-in. stamped steel. They are fastened at their periphery to the convex edges of the metal rim and diverge to the hub, to which they are bolted, leaving a hollow space inside. The over-all diameter of both steering and driving wheels is 36 ins. These wheels weigh approximately 100 lbs. each. Several of the cabs have been equipped with a wooden spoked wheel and the results obtained have been found to be superior.

All four wheels revolve on roller bearings and are arranged with double ball thrusts. The width of the running bearing surface is about 5 9/16 ins. The driving wheels revolve about a fixed axle, measuring 1½ ins. at the bearing ends and centrally fastened at either end to a flat compound spring, upon which the forward end of the vehicle body is supported. Each wheel is separately driven by an independent motor and there is no interconnecting mechanical gearing between them.



FIGS. 7 AND 8.—MOTOR AND STEERING GEAR.

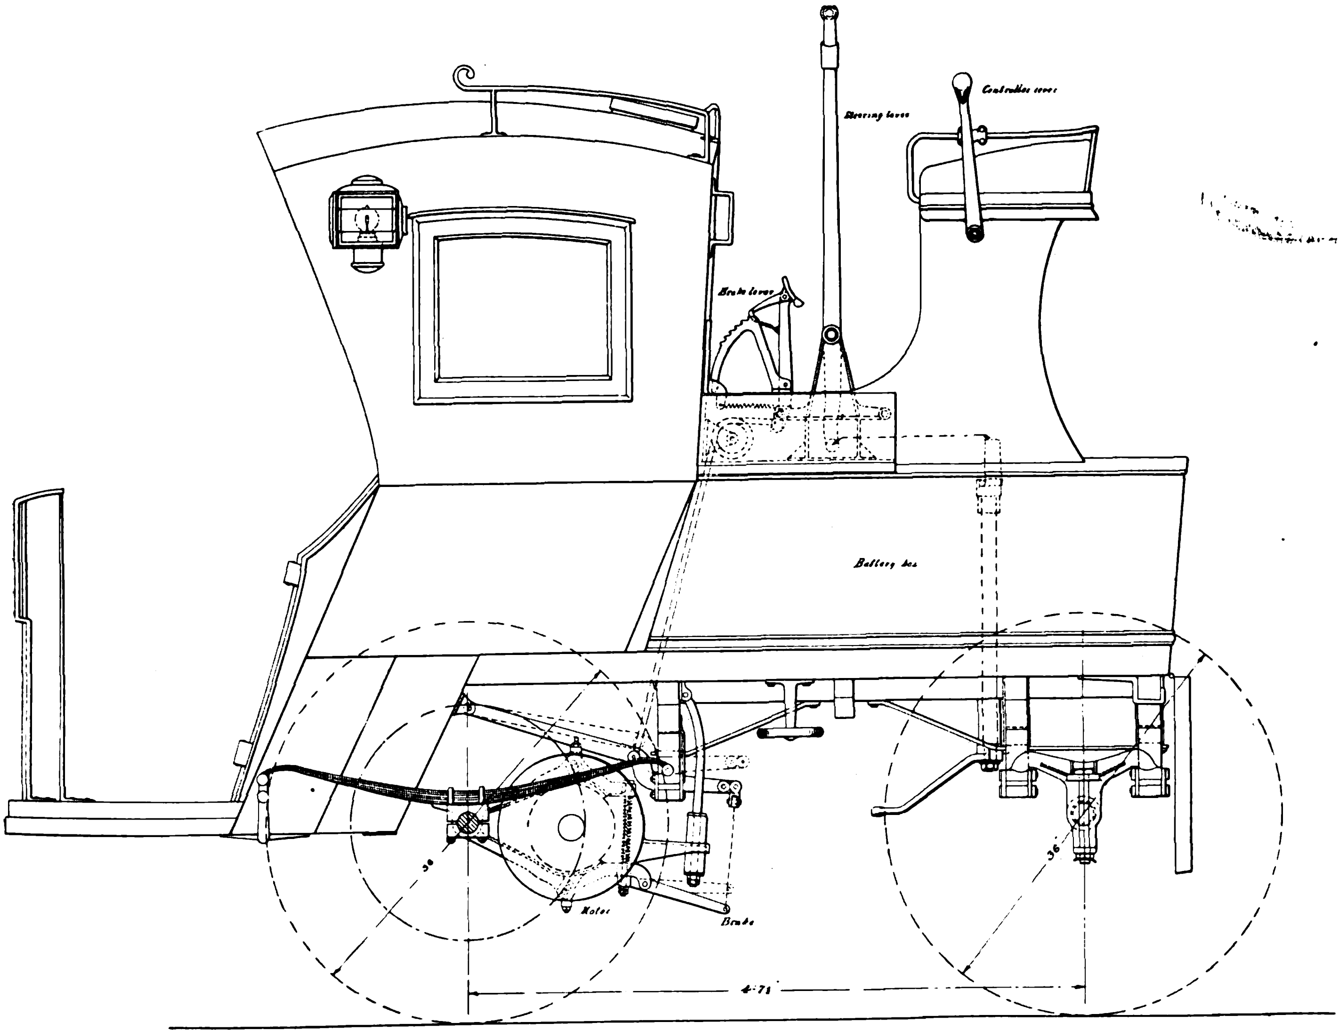


FIG. 9.—ELEVATION OF CARRIAGE.

The series-wound driving motors are of a new water-proof ironclad construction, and resemble in miniature the general type of street railway motor. They were built by the Westinghouse Electric and Manufacturing Company and have a capacity of 2 h.p. at 700 r.p.m. when working at 80 volts, the potential of the battery in each vehicle. With the exception of a small hinged door at the commutator end of the outer casing, the motors are practically sealed. They may be seen to good advantage in Figs. 6 and 7. In supporting these motors and gearing them to the drivers, electric railway practice has been followed. Each motor is pivoted by a projection to the fixed axle, adjacent to its respective driver. A small spur gear pinion meshes into an internal gear, 21 ins. in diameter, attached to the inside of each driving wheel. Thus fitted to the wheel, the gears almost directly transmit their strain to the rim, instead of passing it through the web or hub. At the opposite side of the motor a projecting arm is held between two rubber springs. This motor gearing possesses all the elements of the flexible pivotal suspension.

The steering gear is of the short hub pivoted axle type. Each of the steering wheels rotates on a short axle, which is pivoted close to the wheel hub on the fixed axletree. Arms project from each of the short axles and are connected together by suitable tie rods, which lead to the steering lever in front of the driver's seat. Fig. 8 will assist the explanation. The lever is about 26 ins. from pivot to handle and is moved longitudinally to the vehicle to accomplish the steering. The pivots to the steering axle have been arranged so that their center line almost strikes the wheel contact base. The advantage of this arrangement obtains in the fact that the steering can be rendered more stable by decreasing the leverage between the steering pivot of the axle and the vertical plane of contact on the wheel tire.

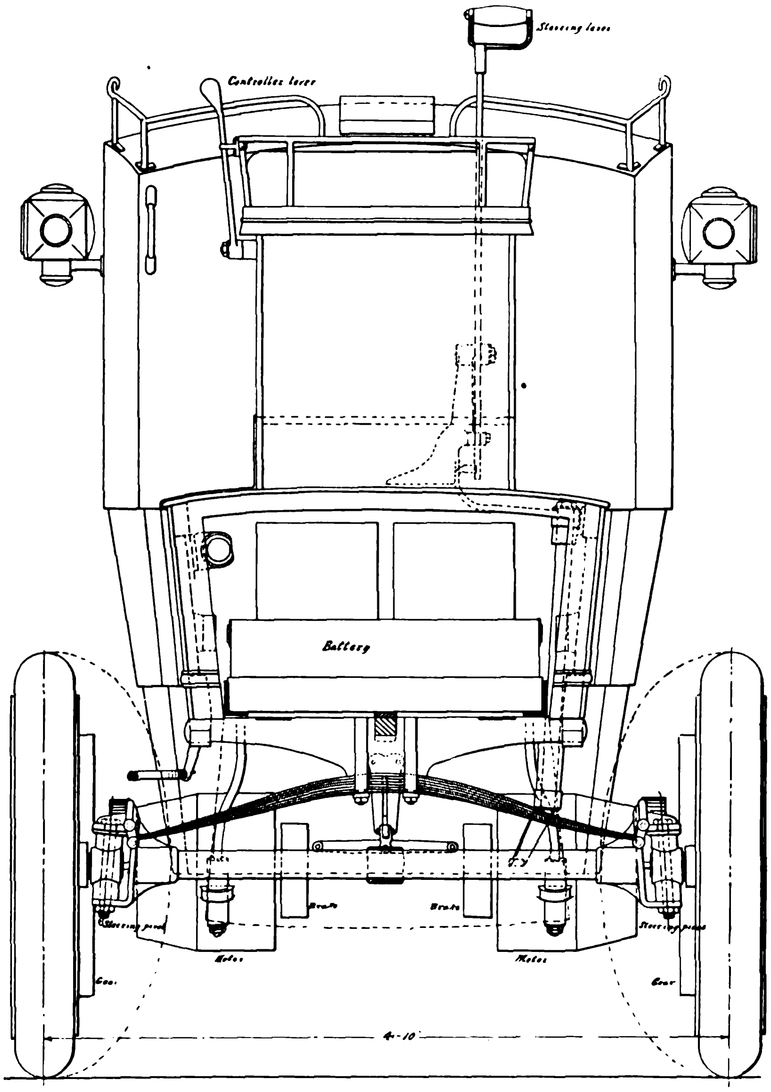

FIG. 10.—END ELEVATION OF CAB.

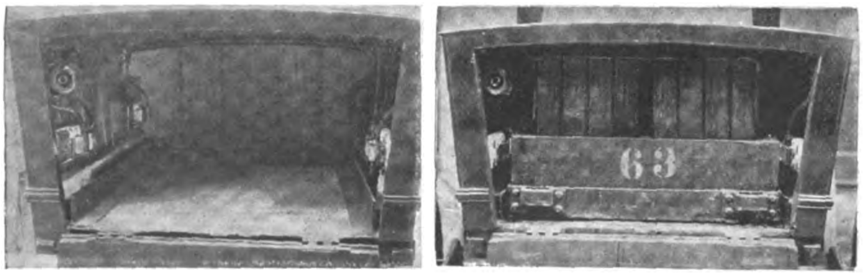

FIG. 11.—BATTERY BOX LOADED AND EMPTY.

A peculiar feature obtains in the arrangement of the under body of the vehicle. It will be noted from the illustrations that each set of wheels is independent. The driving and steering wheels are separately attached to the vehicle body, through the medium of the spring supports.

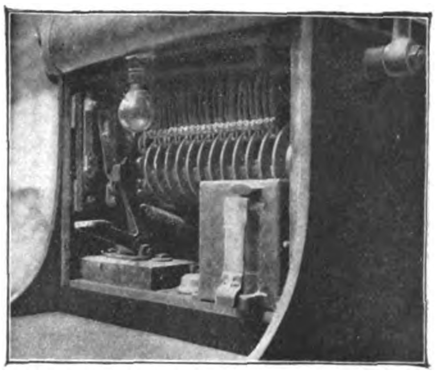

FIG. 12.—CONTROLLER.

Each cab is equipped with forty-eight cells of storage battery. They were made by the Electric Storage Battery Company, and use rubber jars, which contain two Manchester positive and three Chloride negative plates. The battery has a rated output of 100 ampere-hours at the normal discharge rate, but the irregular demands of this service change the rating. Each cell weighs 26 lbs., making the total weight of the battery carried by each vehicle 1248 lbs., exclusive of the holding tray.

An important improvement is to be found in the concentration of the entire battery equipment for each vehicle in a single box, thus making it possible to handle it as a unit. The tray is solidly constructed of wood, well painted and slightly tapered, so as to fit the vehicle box snugly and insure good contact. The battery in its tray measures 26 ins. in width by 3 ft. 3 ins. in length and 16 ins. in height. The connections between the cells are burned together and those between the battery and controller system are automatically made, when the former is placed in position. The automatic contacts engage with four contact strips on the side of the battery box. They have been specially devised and embody several features of merit. The bottom of the battery box is lead lined and provided with suitable drainage channels. The interior may be seen in Fig. 11.

FIG. 13.—CONTROLLER CYLINDER AND HANDLE.

The operation of the vehicle is centered in three controlling appliances, one of which, the steering lever, has already been described. All of those devices are located at the side or in front of the driver's seat. The speed of the motors is controlled by a switch cylinder, placed transversely under the driver's seat and operated by a rotary motion imparted by an upwardly projecting handle. This cylinder is used in combination with the reversing switch, which is provided with levers which can be conveniently operated by the driver's foot. The arrangement is interlocking and therefore it is impossible to reverse unless the controller is at "off." The reversing switch is normally set for the ahead position and so remains, unless pressure is kept upon the operating lever. Three speeds in either direction are provided, namely, 6, 9 and 12 to 15 miles per hour. The various combinations of the battery and motors are shown in the controller diagram, Fig. 15. It will be noted that the battery is divided into two electrical sections, and the series fields are also in sections. Various series and parallel arrangements of the field coils and battery produce the three speeds. With a single charge the vehicle can be operated from 25 to 35 miles, depending upon the character of the roads traversed.

FIG. 14.—CONTROLLER CONNECTIONS.

An emergency switch is provided, which has a removable key handle and is placed in an easily accessible position near the driver's foot, so that when occasion demands he can move the handle and thus cut off all current. This switch is also used when the driver leaves the vehicle. By removing the handle the switch is opened and cannot be closed until the handle is replaced; this prevents any tampering by unauthorized persons.

FIG. 15.—CONTROLLER CONNECTIONS ANALYZED.

The brake is operated by means of a foot lever and acts upon the armature shaft. It is of the double acting shoe type and is applied to the brake pulley. The brake shoes are in the form of curved levers, one end of which pivots on the axle.

The operator has one foot always on the brake lever and the other ready to operate either the reversing or emergency switch or the bell ringing push. His hands are occupied with the steering lever and the controlling handle. Practice has enabled the drivers to control the heavy vehicle so well that the uninitiated observer is at times amazed. Each cab is intended to carry two passengers and the driver, in addition to such small packages as can be carried on top of the fore-body.

An important feature embodied in the construction of the vehicle and also notable throughout the entire plant, is the duplicate construction of the various parts, including the controller, motors, switches and other parts that are likely to fail and cripple the working ability of the device of which they form a part. The speed controller contact fingers are duplexed so that each terminal from the battery or motor is connected to two stationary contact fingers. Each complete set is arranged in a separate row, engaging with the contacts on the cylinder. The contact plates on the battery tray are also in duplicate. The battery may be charged without removing it from the vehicle by connecting with the charging plug receptacle, fitted in one of the corners of the battery compartment and showing in Fig. 11. This receptacle is conveniently arranged and coacts with a suitable plug attached to the charging mains.

In addition to the hansom cab equipment, other similar vehicles are to be added to the plant. An elegant brougham is an addition. With the exception of the style of body, this carriage is similar in general mechanical and electrical detail to the hansom. In striking contrast with the new vehicles are two of the earlier Morris & Salom electric motor wagons, one being their first production. It is expected to add vehicles of larger capacity in the near future, and several of the omnibus type are being considered.

BATTERY ROOM AND CHARGING ARRANGEMENTS.

The battery equipment for the present service consists of 150 trays, each containing forty-eight cells. This allows 1½ trays per cab, which leaves ample reserve, even though nearly all the cabs should be in service. The disposition of the batteries when not in actual service on the vehicles or when charging is excellent. Owing to the large floor space available all of the battery holding racks have been placed on one level. The battery room is floored with cement, as is also the entire ground space outside. Each tray of battery cells has a separate rack, built of 3 x 4-in. yellow pine, mortised at the joints, held together by wooden dowels, and coated with a good water-proof paint. The height from the floor to the top on which the battery tray is placed is 33 ins.

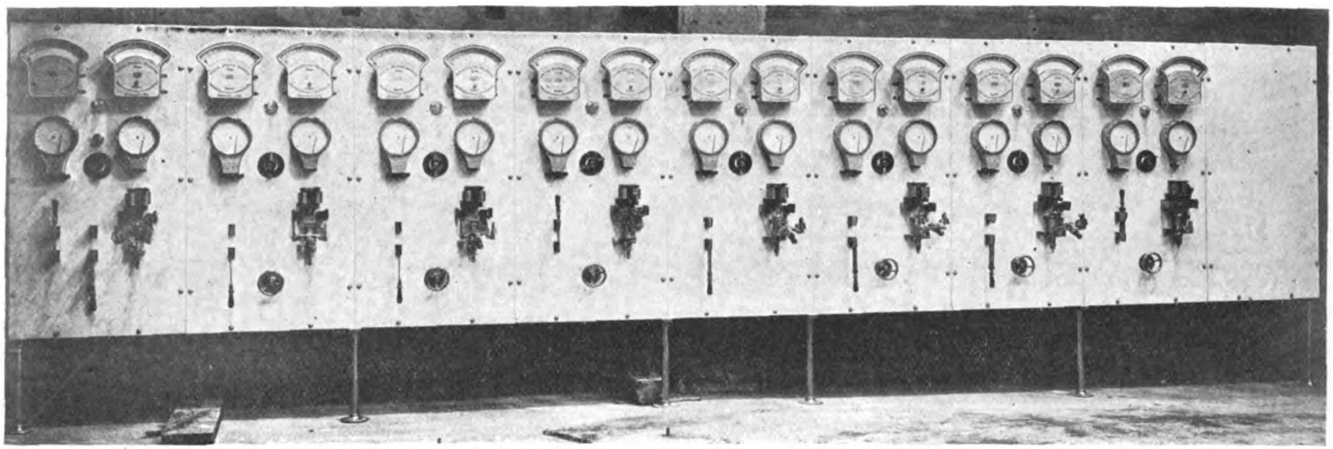

FIG. 16.—MAIN SWITCHBOARD.

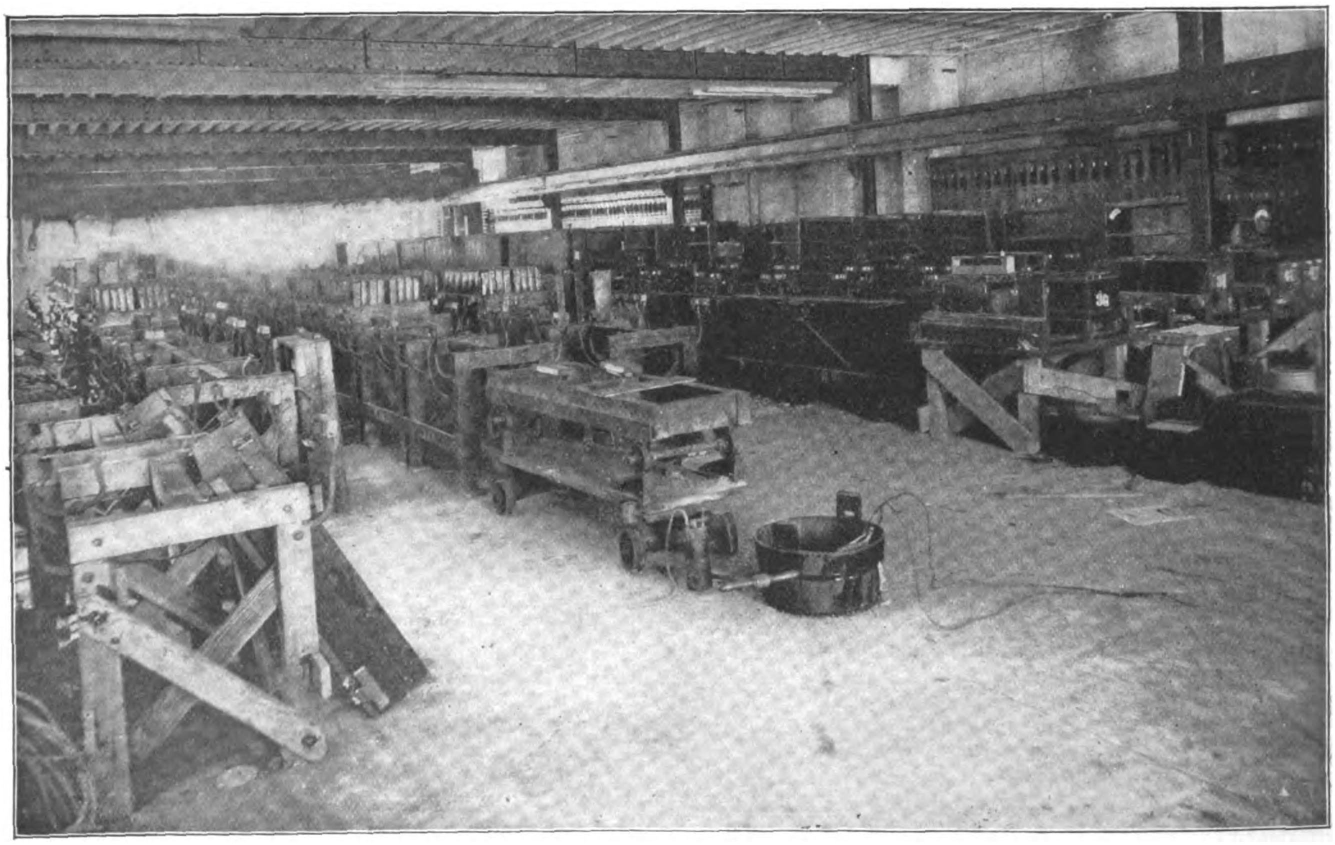

FIG. 17.—GENERAL VIEW OF BATTERY ROOM.

The arrangement of racks is shown in the general floor plan of the station. They range longitudinally from end to end of the battery room in eight rows, with a narrow passage between each row. The central passage is wider than the others, to accommodate the crane cab. There are also three wider passageways transversely across the battery room in addition to those at the ends. Thus, the eight rows are cut into four parts, each containing six racks, which are tied together by wooden planks and rigidly fastened to the floor. This divides them into eight sections, each accommodating forty-eight trays, with the exception of the end section nearest the loading machinery, which has eight additional racks, making an aggregate of 200. These sections are provided with suitable drainage channels, and a large wire channel runs transversely from the charging switchboard on the inner wall of the building along each of the passageways. The lowering of the battery into the rack automatically connects it with the charging wire. At each corner of the rack is a curved lever, pivoted on the side of the upper timbers. The upwardly projecting ends are fitted with insulated spring contact straps, and when the lever is moved these describe an arc, thus bringing them in contact with the connecting plates on the ends of the battery tray. The weight of this end of the curved lever causes it to swing free when the cells are raised. The other end of the lever is quite short and projects an inch or two above the top of the tray supporting timbers. When the battery is lowered its weight strikes upon these projecting ends, causing the other ends to spring up and make secure contact with the plates on each side of the tray.

FIG. 18.—CHARGING CONNECTIONS, MAINS TO BATTERY RACK.

As the cells in each tray are divided into two sections, it is necessary to provide each rack with four of these automatic contacts. This is clearly shown in the photograph, Fig. 19. The charging wires are connected to two diagonally opposite contacts, and the other two are cross-connected by a flexible rubber insulated cable. This connects the entire forty-eight cells in series across the line.

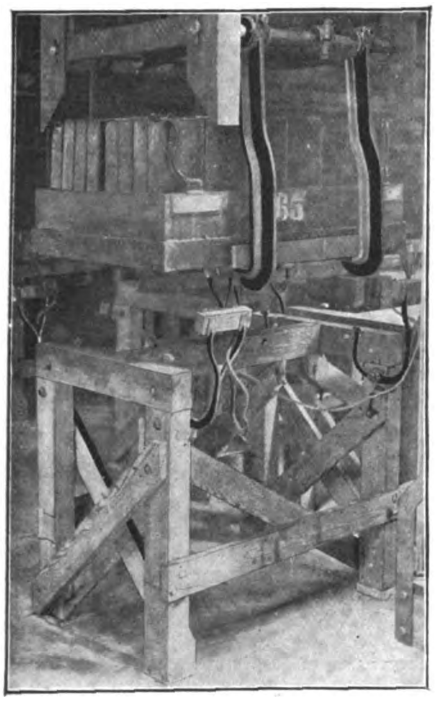

FIG. 19.—BATTERY RACK.

Instead of furnishing the charging current from an isolated generating plant in the building, it has been found preferable for the present to take the supply for charging the batteries and operating the various motors from the Edison street service. This choice might, at first sight, seem to be less economical, but it must be remembered that the cost of the current for charging the battery is but a small percentage of the entire cost of operating each vehicle and the rates for current for such service are comparatively low.

At the Broadway end of the building two three-wire 350,000-c.m. service connections are brought into the north wall, whence they connect through three pole switches to cables of 1,500,000 c.m. capacity leading to the main switchboard, which is located between the battery room and the offices. This main board is made up of nine white marble panels, each 3 ft. long, making the entire length of the board aggregate 27 ft., with a height including the supports of 8 ft. At this board the three-wire street service connects through the medium of the appliances on the panels to a series of buses of raised or lowered potentials. These buses of various voltages are carried to the battery charging panel further on in the battery room. The connections of the main board, as well as the charging board in the battery room, are shown in the combined diagram, Fig. 18. The neutral wire of the service simply passes through a single pole switch on the first panel to the left, and from thence directly to the charging racks, where it connects at each rack with one of the previously mentioned automatic contacts. The first four panels to the right of the main board control charging buses connected to the positive side of the service, while the succeeding four control negatively connected buses. The battery racks are connected to both the positive and negative charging buses through the switches on the charging board. The buses are thus connected at their respective panels through a single pole switch, an under-load or over-load, I. T. E. circuit breaker and a large rheostat, whereby the potential may be lowered to any desired extent. This arrangement is the same with all of the charging panels, except the first and fifth, which are arranged to boost the potential of the connecting charging buses, or keep them at the same point as the street service. In this case the rheostat is omitted and a double-throw pole switch is installed, which throws the buses in series with a boosting dynamo, or simply connects directly to the service buses. The capacity of the instruments on each of the charging panels and their respective buses, ranges in steps of 100, from 100 amperes for the high pressure panel to 400 for the low. The last panel on the right is to be used for light and power switches and instruments.

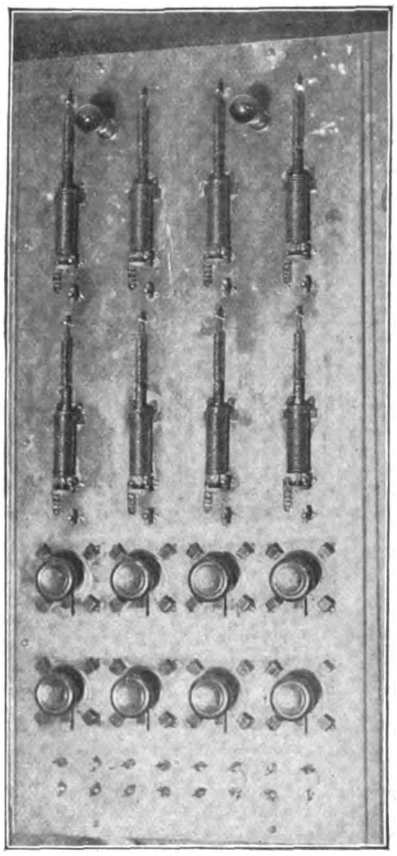

FIG. 20.—CHARGING PANEL.

The booster equipment consists of a 7½-h.p. 220-volt multipolar motor, centrally placed between two bipolar booster dynamos, as shown in Fig. 21. The armatures are directly coupled together. One booster raises the potential on the positive bus, and the other is used on the negative side and the capacity of each measures 200 amperes at from 5 to 15 volts. These machines were built by the Western Electric Company, and are placed on a heavy wooden platform above the switchboard.

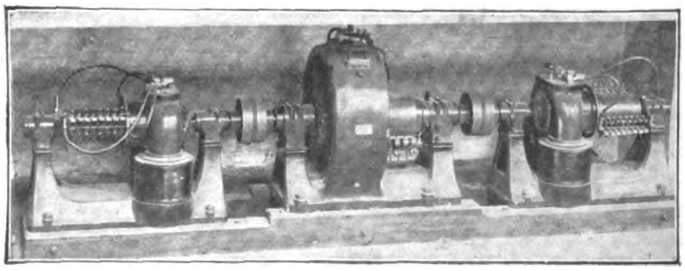

FIG. 21.—BOOSTER.

The object of the various charging buses will be apparent on examination of the charging panels. These are arranged in two groups in the battery room. They are built of heavy slate slabs, measuring 30 ins. x 60 ins. Each panel is equipped with the instruments for eight charging circuits leading to the racks. A separate wire from each battery rack extends in a lead armored cable laid in the previously mentioned trenches to its respective panel section. Each battery wire connects through a form of solenoid ammeter to a four-point switch arm, whereby it can be connected to any one of four charging buses. The upper row of ammeters and switches is connected to the positive buses and the lower row to the negative. In charging, a battery is connected, first with the lowest bus through the four-point switch and gradually worked up until the highest bus is reached. To govern the changing from one bus to another according to the current fed to the battery, the ammeters are provided with a tell-tale lamp indicator, which is set at charging current, 20 amperes low and 50 amperes high. Should the current fed to any battery reach these extremes a red or green incandescent lamp is lighted. Only one set of lamps is provided for each panel, and the lighting of the low range lamp shows that one of the batteries on that panel has fallen below the 20-ampere point and must be connected to the next bus. The only attention necessary is the shifting of the charging switches from time to time, and this is done by the man who operates the crane and loads and unloads the vehicles. In fact, he can control the entire equipment, almost without leaving his station on the crane cab.

To withdraw the fumes from the somewhat inclosed space which comprises the battery room, a 40-in. exhaust fan is placed on the upper floor and operated by a belted electric motor. The fan suction flue originates about the center of the partition wall, while the outlet is brought to the roof.

On the outside of the partition wall at the forward end of the battery room, charging receptacles are placed, so that any vehicle may be connected with the charging wires without unloading its battery. Batteries so connected are manipulated in the same manner as if they were on their racks in the battery room.

THE MECHANICAL MANIPULATION OF THE BATTERIES.

The most important element in this installation is the battery handling machinery. The various parts form practically one machine, which is manipulated by a minimum of manual labor, and is certainly worthy of much favorable comment. The work involved in handling a vehicle includes the carrying of the battery from the rack to the loading point, and here, after proper alignment, pushing the battery into its compartment. In unloading these operations are reversed. The battery is moved from the rack to the loading point by means of a novel electric crane, carrying eight electric battery hoists. This crane has a capacity of eight tons and runs the entire length of the battery room, which it spans from side to side. On each side of the operating cab, which is centrally suspended from the bridge and almost touches the floor, are the battery hoists. These are placed side by side, four on each side of the cab, and come directly over each row of battery racks. Fig. 25 will assist in comprehending the arrangement. Each hoist has a capacity of one ton and works in conjunction with a novel lifting and lowering grapple, which automatically engages with the battery tray. The grappling arrangement consists of two heavy iron jaws which are raised or lowered by two chains, one of which performs the hoisting and the other manipulates the grappling arms. The drums for each of these hoists are operated by a separate worm-geared motor. In raising a battery from the racks the grapple is lowered in its open condition until it reaches the limit of the chain, which is set so that the arms are then just below the bottom of the tray. The further rotation of the hoisting drum winds the chain up again, closes the grappling arms around the bottom of the tray and raises it to the desired height. The operator in the cab simply starts and stops the motor, which runs in one direction only and does the rest. The battery is now carried to the loading transfer table, which is also electrically operated. This mechanism is really a link belt conveying machine and extends across the entire front or loading end of the battery room. It consists of heavy iron crossbars with upward projections, forming the sections into which the tray fits. The battery is lowered and deposited in one of these carrying sections of the conveyor. The lowering and releasing is the reverse operation of the raising and is accomplished by an opposite rotation of the hoisting drum. The transfer of the battery tray from the conveyor table to the vehicle compartment is accomplished by hydraulic machinery. In front of the table are two vehicle loading and unloading platforms. Each of these platforms is composed of two wooden flat carlike structures placed side by side, so that their platform is on a level with the cement flooring of the station. The wheels upon which these platforms are placed run on parallel tracks in the platform pits, the motion being in line with the conveyor table. Each half of the loading platform has four wheels and the two parts are automatically aligned with each other and centered by means of suitable weights. The vehicle backs onto the platform, so that each pair of wheels has a movable car to itself; and the vehicle can then be shifted from side to side and suitably aligned with the conveyor rack. Another alignment is necessary to level the bottom of the battery compartment, due to the change in the level of the vehicle battery box, when loaded or empty. In fact, this part of the vehicle sinks several inches by reason of the compression of the springs and pneumatic tires.

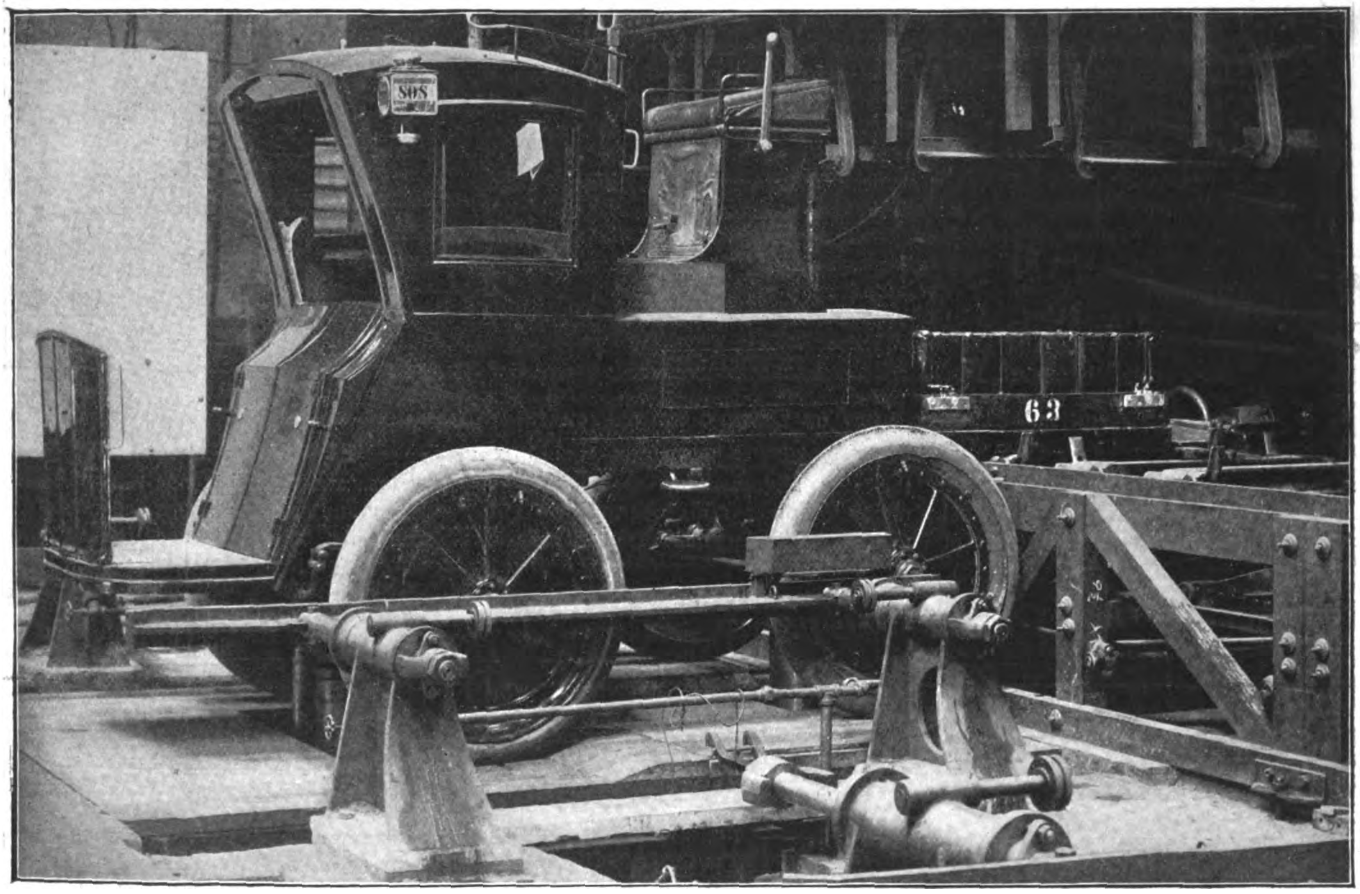

FIG. 22.—CAB IN LOADING POSITION HELD BY HYDRAULIC RAMS.

The vehicle is run into this position with the rear door open, and when thus aligned and leveled is ready to have its tray of batteries pushed from the table into the battery compartment or pulled out of the latter onto the table. These operations are performed by means of hydraulic rams from a point centrally located behind the table. This hydraulic machinery is shown very clearly in the illustrations, Figs. 24, 26 and 28.

Under each of the two parts of the moving vehicle platforms hydraulic cylinders are vertically placed. The plungers are attached to suitable raising bars, upon which the vehicle body rests while loading. These parts are normally below the surface of the platform, but when actuated are projected through an opening about in the center of each half, which is covered by a series of small hinged trap doors. These rams raise the vehicle, and when the elevating plunger parts are projected upward, the battery compartment is raised clear of the springs by the one and the hansom body by the other. After the vehicle body has been lifted, which constitutes the first operation, the side alignment is accomplished by means of other rams operated on either side of the loading platform. These bars act at about the hub centers of the wheels and extend horizontally so as to strike both steering and driving hubs close to each end. The bars are connected to the plungers of the horizontally placed ram cylinders. The two centering rams attached to each bar have different movements, the one opposite the front wheel having a travel of 11 ins., and the other one 7 ins. Both the lifting and centering rams act in one direction only, being returned to their normal position by heavy weights. The hydraulic rams and lifts are all mounted on solid masonry piers and their movement is a definite predetermined amount, and raises and

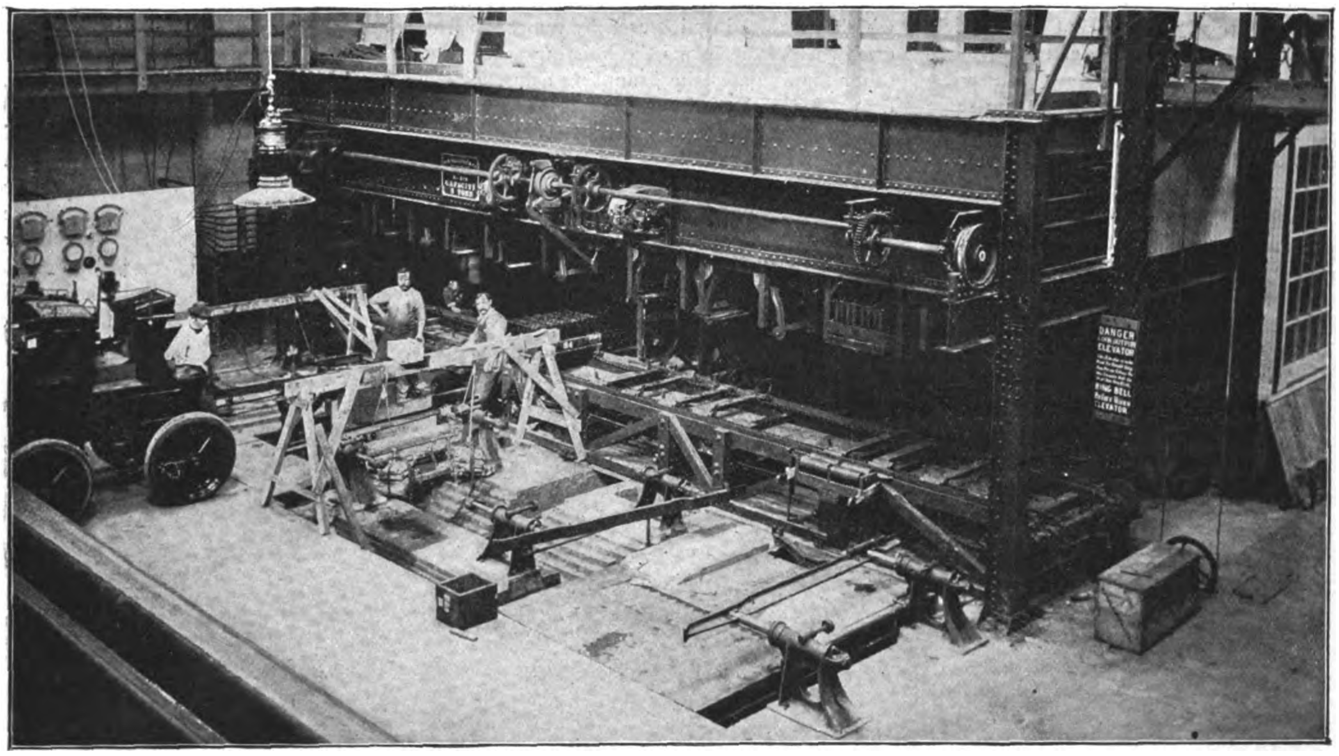

FIG. 23.—GENERAL VIEW OF LOADING STANDS, CRANE AND TRANSFER TABLE.

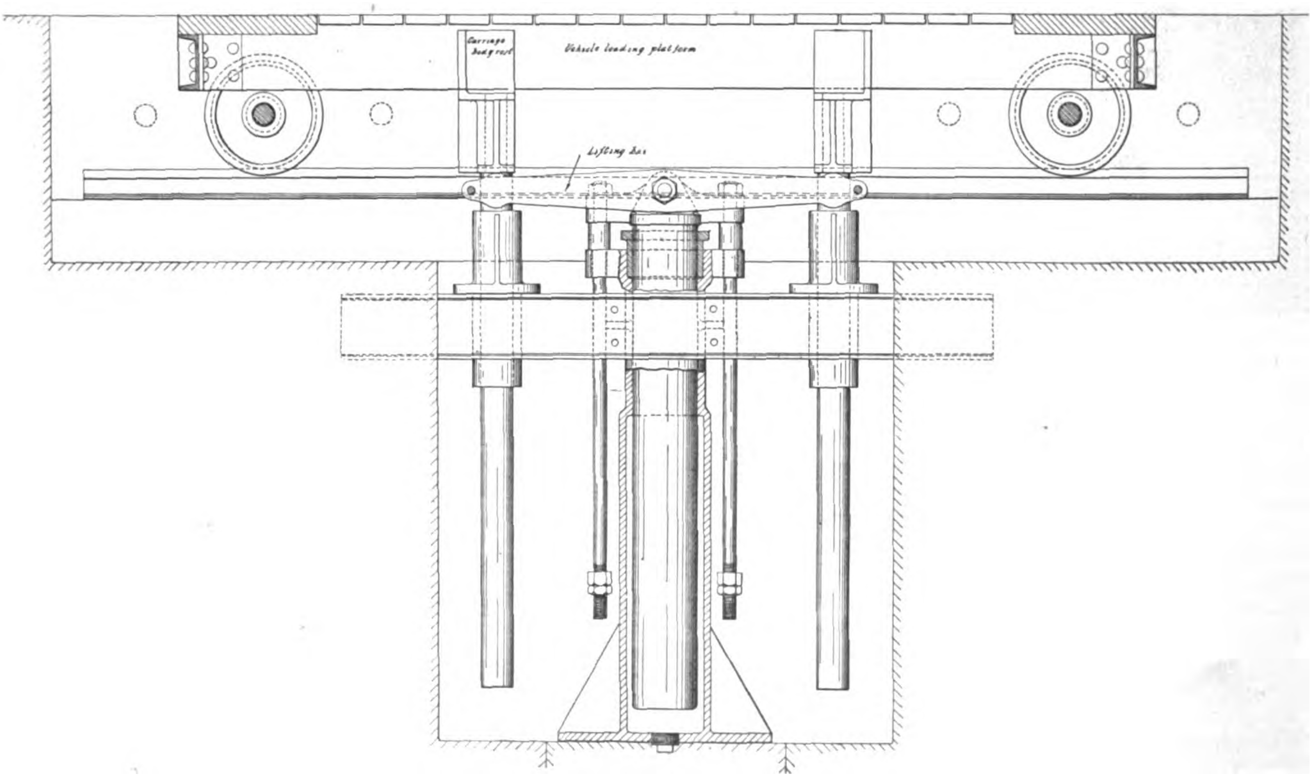

FIG. 24.—ELEVATION OF LIFTING RAM.

centers the vehicle to exactly the desired position.

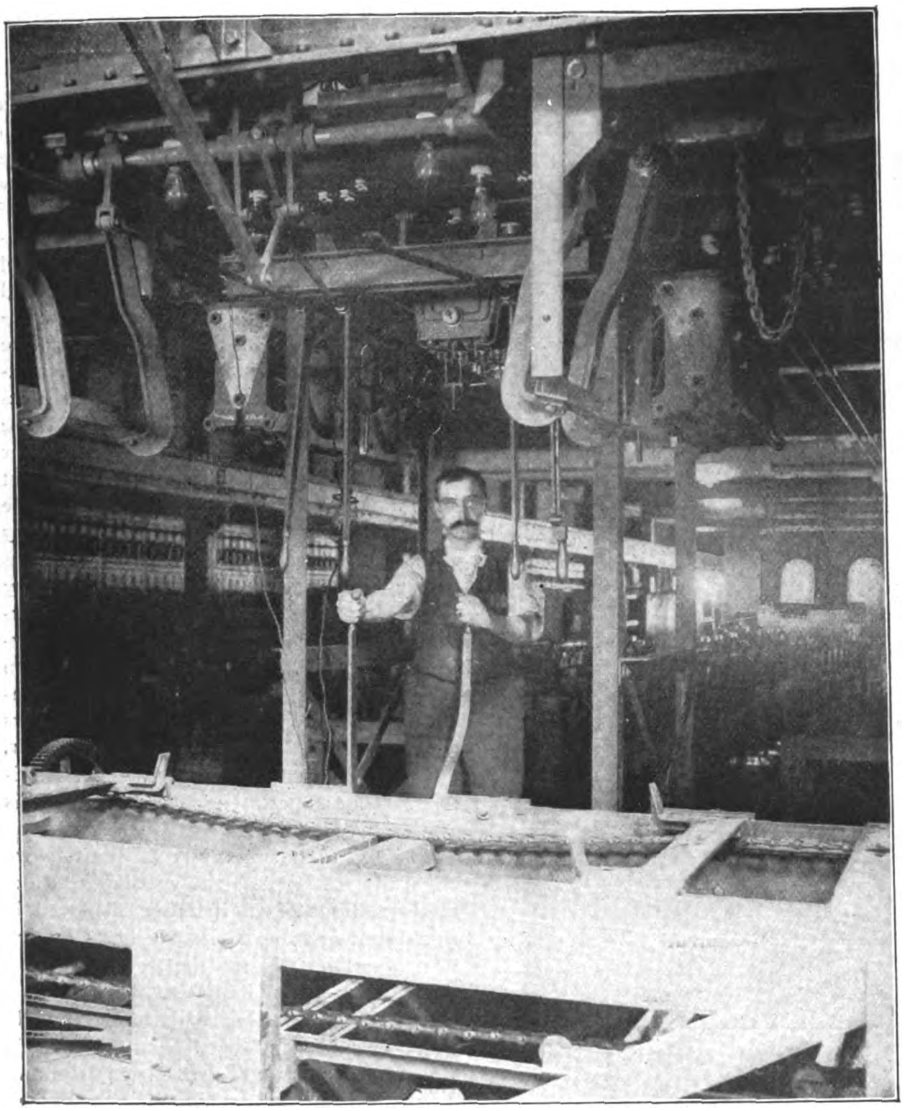

FIG. 25.—CRANE CAB, AND TABLE CONTROL.

In the rear of the conveyor table, placed horizontally in line with the center of the loading platform, is a long hydraulic pushing and pulling ram; its cylinder is on a level with the top of the conveyor table, across which the long plunger is projected, and in the loading operation simply pushes the tray into its compartment. If the battery is to be unloaded the plunger is extended so that a pair of hooks at its ends automatically engage with sockets on the end of the tray, and the return of the plunger pulls the tray onto the conveyor table. The hooks are released by means of a lever at the rear side of the table, which is accessible to the man in the crane cab. After loading or unloading, the hydraulic machinery is returned to its normal position and the vehicle leaves the platform.

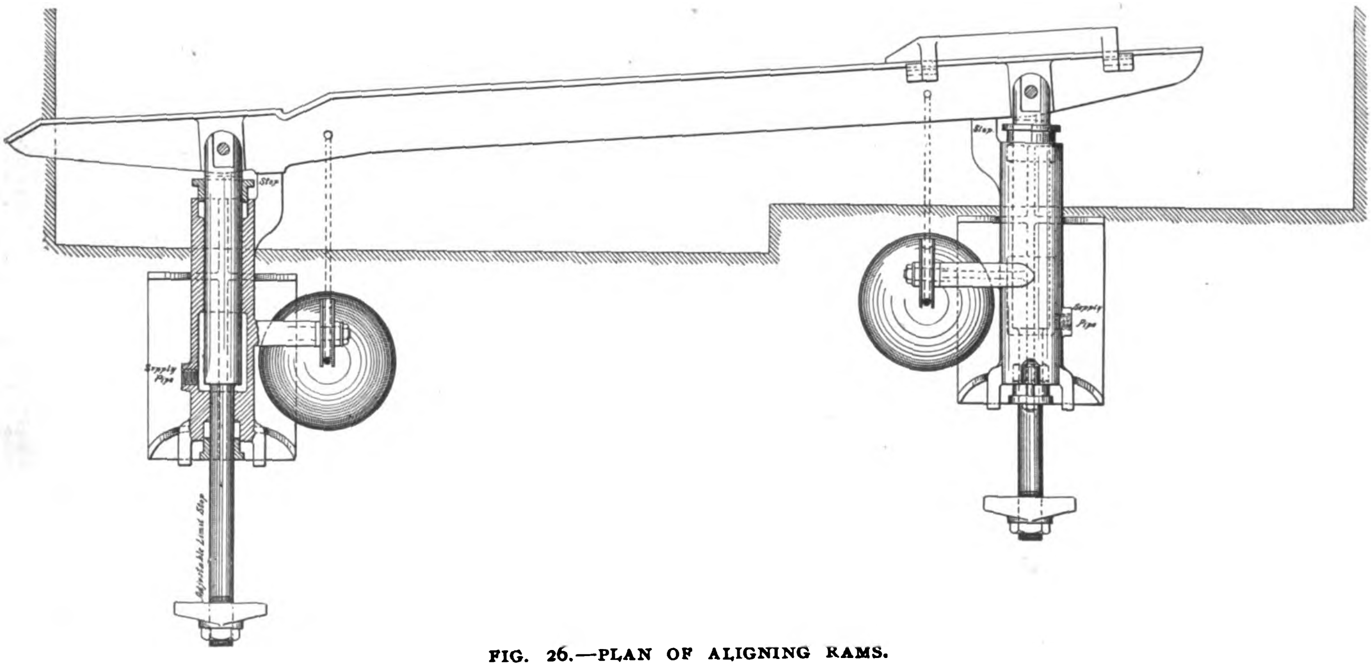

FIG. 26.—PLAN OF ALIGNING RAMS.

An excellent example of the possibilities of concentrated control is exhibited when this machinery is set in action by the crane operator from his position in the crane cab. At the top and sides of the cab are arranged the various switches and rheostats for the hoist and driving motors. Having carried the battery to the conveyor table the crane operator finds himself directly in the center of the latter, and at this point are the handles for its manipulation and the valves controlling the hydraulic cylinders, all of which can be operated without stepping from the crane cab. His position in the crane cab is shown in Fig. 25, and it will be seen that the operator can easily watch the telltale lamps on the charging panels. The batteries are transferred from one line to another by bringing them to the conveyor table and shifting them in line with any hoist. The crane, which, by the way, was made by William Sellers Company, of Philadelphia, as was also the conveyor table, is operated by Westinghouse four-pole motors, each of 5-h. p. capacity, and alike in all respects. This arrangement makes all the motors interchangeable. For the operation of the crane bridge and the conveyor table a double motor equipment is used, which further insures continuous operation. The current for the crane motors is taken from the trolley wires suspended above the crane bridge.

For the operation of the hydraulic machinery an electrically operated Gould triplex pump is used. This pump is placed at the wall end of the conveyor table and feeds a pressure tank, from which pipes are extended to the various controlling valves, located as has already been described. The water is taken from a tank 3 ft. in diameter and 5 ft. deep, sunk in the floor between the loading platforms, and is returned after being used. The working pressure is 150 lbs. to the square inch.

In addition to the loading stations just mentioned, an emergency loading station has been provided at the side of the battery room between the two vehicle elevators. No arrangement is made at this station for side centering, but the lifts and loading cylinders are arranged as in the others. At this station the battery tray is carried on a car to the rear of the vehicle, where it is handled by a loading and unloading ram, as previously described. The tray carrying car runs on a track extending from this loading station transversely across the battery room, and the handling of the battery by the crane from and to the car will be obvious from prior description. The car with one tray can be set in line with any of the eight rows of battery racks.

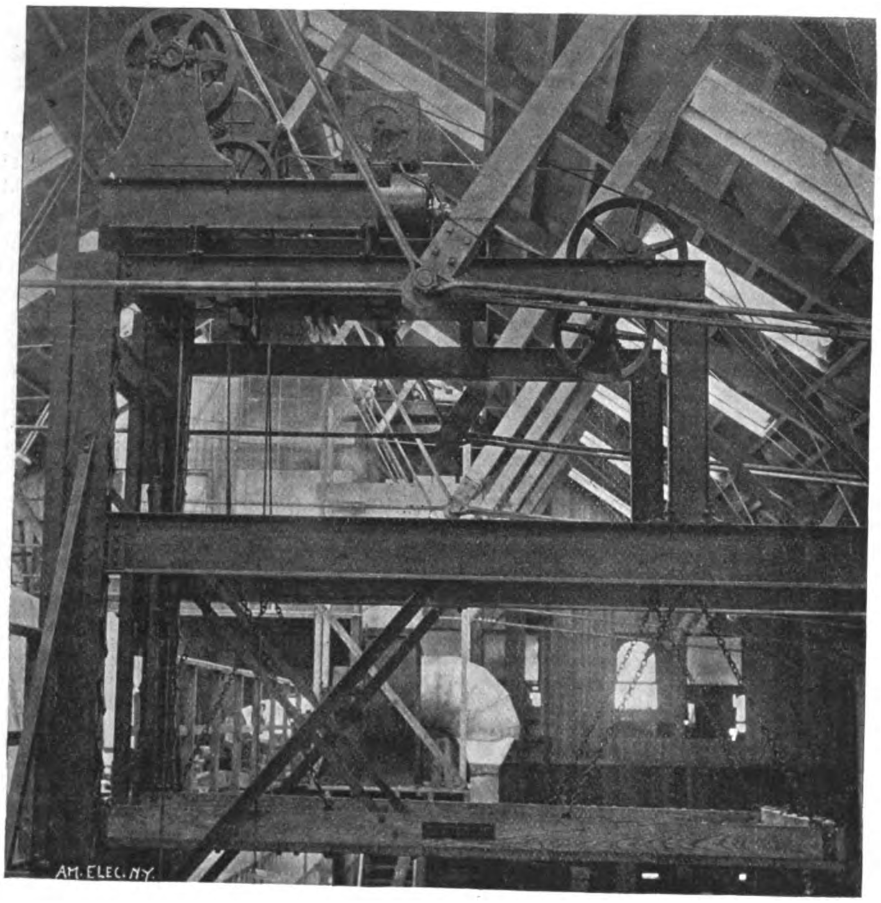

FIG. 27.—VEHICLE ELEVATOR.

The operation of the elements of this machinery is greatly aided by a number of interlocking safeties. On the crane an interlocking device co-acts with notches in the track girder and only permits of operating the hoists when they are properly centered over the battery racks or the conveyor table. The hoisting motors are also locked with the crane bridge motor, so that the latter can only be operated when all the hoists are up and clear from obstruction. The conveyor is provided with automatic motor stops at each end, so that the battery cannot be carried over the ends, and it is also interlocked with the loading machinery, so that the conveyor cannot be moved when the loading ram is in action, or vice versa. There are two vehicle elevators operated by worm gear electric motor drum hoisting machines. Each elevator has a capacity of 2½ tons and operates at the rate of 100 ft. per minute. They are controlled by rope operated starters. C & C motors are used.

SOME FEATURES OF THE PLANT AND ITS SERVICE.

As with other commercial enterprises, the question of revenue is the prime consideration. For this reason the aim has been to economize in the handling of the vehicle at the station, and that this has been well accomplished will be appreciated from the foregoing. The handling of the vehicle, aside from the loading and unloading, is simply a matter of unskilled labor and very little of that. If the vehicle is to be stored after unloading, it is washed as any other carriage would be and sent to the upper floor by the rear elevator. As the vehicles are wanted they are lowered by the forward elevator. Each cab is inspected by the starter before leaving the station and a record taken of its battery equipment. With the desire to increase the efficiency of the service a series of vehicle tests will shortly be inaugurated. This will include tests of current consumption under different conditions of running, speed on grade and level, and traction tests. Various special and standard testing instruments have already been arranged for this purpose. The bid for business seems to have been directed in the right direction. Rates for electric cab hire are almost one-half those asked for the horse-drawn service. For each single passenger, 30 cents for the first mile and 15 cents for each succeeding mile is charged, or the cabs may be hired by the hour at special rates.

The Electric Vehicle Company is worthy of the highest commendation for pioneering the electrical vehicle service on so magnificent a scale. The investment has been large, and it is to be hoped that the venture will prove remunerative. The officers are: Mr. Fred Vieweg, General Manager, and Mr. G. Herbert Condict, Chief Engineer. The superintendent of the plant is Mr. W. T. Headley.

In closing it is but just to say a word regarding the persons to whom the thorough methods of engineering displayed in this station are due. Mr. G. Herbert Condict, who is responsible for the general station design, was assisted by Mr. A. W. Gilbert, the constructing superintendent. It is to be sincerely hoped that the electric motor cab service will prove successful and further advance the emancipation of the horse.

AMMONIUM-CHLORIDE ACCUMULATOR WITH CARBON PLATES.

BY PROF. WILBUR M. STINE.

A reference is made on page 333 of the July issue of the "American Electrician" to a form of accumulator whose elements are simply carbon plates immersed in an electrolyte of ammonium chloride. Some rather remarkable statements are made by the inventor, Señor A. Sandaran, not only concerning the efficiency and ampere-hour

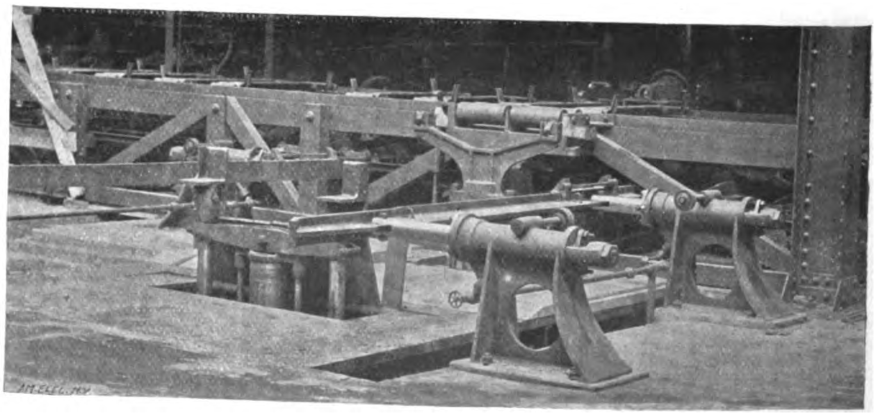

FIG. 28.—LOADING TABLE, SHOWING HOISTING AND ALIGNING RAMS.

capacity of the cell, but its permanence of charge as well. According to the stated data, a h.p.-hour seems to have been stored for each 7 lbs. gross weight of the cell (?), making this type probably the most remarkable one on record.

The article recalled to the writer some investigations made during the early part of 1891, and as the results were published at the time, Señor Sandaran's battery has been anticipated by at least seven years.

At this time the writer was engaged upon an extended investigation of the absorption of carbon elements for electrolytic gases and the utilization of this principle for the storage of electrical energy. Some of these results may be found in the "Voltaic Cell," by Park Benjamin, page 323, while others were embodied in a paper before the A. A. A. S., and printed in its Proceedings for 1891. On page 146 of this volume the following occurs: "A large cell on the same plan was prepared with carbon dust and saturated with a 20 per cent solution of NH_4Cl. As was expected, this cell proved capable of receiving a considerable charge without gassing. The potential immediately after charging was 1.7 volts, which invariably fell to less than 1 volt on standing twelve hours. The cell was varied and many tests applied; the results were encouraging and seemed to indicate that it might be a good type to develop for some purposes, as it is light and inexpensive."

Such cells were set up in the ordinary gravity battery jars of the size 6 ins. x 8 ins., and weighed in some cases about 15 lbs. Carbon plates 2½ ins. x 8 ins. x ¼ in. were used for the electrodes. One plate was placed in an ordinary porous cup and packed with some form of granular carbon. The cup was then placed in the jar, the other carbon plate added, and the remaining space was filled with similar granular carbon. The granular carbon was packed to secure electrical contact, but care was taken not to make it too solid and nonporous. This carbon was previously well washed, that the electrolyte should wet it thoroughly. One object in these tests was to ascertain the form of carbon most absorbent under such conditions; granular carbon such as is used for making arc-light carbons; animal charcoal, whose mineral constituents had been removed by acid treatment; and willow charcoal were successively employed. The treated animal charcoal gave excellent results, but the granular arc-light carbon was several times as efficient.

Though the polarity of the cell was varied, the greater capacity resulted when the electrode in the porous cup was the positive one on charging, due doubtless to the fact that the gaseous products of electrolysis about the negative electrode are less soluble and absorbent, and consequently more carbon surface is required. Various strengths of charging currents were tested, ranging from .02 to .5 amps. per square inch of active surface; decidedly superior results were obtained with low current density, since it requires considerable time for the gaseous products to be absorbed or pass into solution, otherwise the cells gassed violently, especially toward the end of the charge. Even with the lowest current densities the cells gassed considerably on charging, and the odor of the gases emitted was extremely offensive and the fumes were irritating. At the time it was concluded that these features were principally due to chlorine gas and its oxides. These fumes were so irritating and unhealthy that it would scarcely be possible to operate many such cells in a battery room.

When the cells were discharged immediately their action was energetic and the internal resistance reasonably low, but the e.m.f. was not well sustained. Upon standing they rapidly lost their charge, and in the course of twenty-four to thirty-six hours they became completely discharged. Their ampere-hour capacity was in all cases low, and in no instance is it recalled that it exceeded twenty units, while the watt efficiency due to secondary chemical reactions was very low.

The electrolysis of NH_4Cl produces complex and rather obscure chemical reactions. Apparently the radical NH_4, ammonium, comes off at the negative plate, splitting up into NH_3, ammonia, and free hydrogen, the ammonia dissolving into the water and the hydrogen being partially absorbed by the carbon present and partially escaping; the chlorine evolved at the positive plate passes into solution and is probably partially absorbed. On discharge these various products would recombine. But there immediately follows a complex set of secondary chemical reaction, whose exhaustive discussion is scarcely warranted in the present article. One point of considerable interest is that nascent oxygen results at the positive plate and attacks this so vigorously that the plate is rapidly disintegrated. This fact in itself would doubtless be fatal to the commercial success of such cells.

In any form of gas battery the gaseous chemical compounds or elements act only in solution. This accounts for the rapid decline of the e.m.f. on discharge; the electrolyte soon becomes impoverished, especially in hydrogen, which is only slightly soluble; in general, the gases occluded by the carbon pass into solution with considerable slowness.

The fall of e.m.f. then, is strictly not due to an increase of internal resistance. At present it seems impossible to construct such cells that they will not be very unstable, and rapidly lose their charge on standing out of action. Owing to osmosis and diffusion the dissolved products of electrolysis, such as ammonia and chlorine acids, will rapidly permeate the entire cell and recombine, and the charge thus be lost.

The results obtained do not indicate that such cells have a commercial value. They are inexpensive and no doubt can be made much lighter than the given capacity of ordinary lead storage battery. The rapid deterioration of the positive plate, the offensive and unhealthy fumes given off on charging, and the rapid dissipation of the charge on standing, are such serious faults that taken together with their low efficiency, the type is one of scientific interest rather than practical utility.

ARMATURE WINDINGS AND CONNECTIONS.

WENSTRÖM WINDINGS.

BY PROF. ARTHUR L. RICE.

If it becomes desirable to wind a four-layer armature into a two-circuit machine, the connections must, as in all other cases, be those for a wave winding and must fulfill the equation for wave windings:

Active conductors + No. circuits = No. poles x average pitch. If this equation be considered with reference to a four-pole machine with two-circuit winding, it becomes

Conductors + 2 = 4 x pitch,

which is impossible of fulfillment, if the number of conductors is to be divisible by 4, as would have to be the case in a four-layer machine; because, if to 4 x pitch—a number necessarily divisible by 4—2 be added, the sum cannot be divisible by 4. Some special device must be used when such a winding is wanted.

In a lap winding the only condition is that the number of conductors shall be divisible by twice the number of circuits. But a lap winding cannot be a two-circuit winding for any but a two-pole machine, therefore a combination of lap and wave windings must be used. This style has been called the Wenström winding; it follows no expressible law, but must be worked out for each case by study of the conditions, and the correctness proven by the winding table.

Take the case of the last article, four poles, 24 slots and commutator bars, 96 conductors; to be wound into a two-circuit armature. The winding is to be partly lap, partly wave; the wave part being in the connection to the commutator. The lap part amounts to the winding of several interposed conductors into a coil between those conductors which go to the commutator. Since the connection to commutator is in wave form, the number of conductors and bars used in making these connections must fulfill the wave winding equation. If there are twenty-four bars, there must be forty-eight conductors connecting to them, two conductors to a bar. Then 48 + 2 = 4 x pitch; 50 = 4 x pitch; or, 48 — 2 = 4 x pitch, 46 = 4 x pitch, and in neither case is the pitch a whole number. If one bar be unused, leaving 23 bars and 46 conductors, then 46 + 2 = 4 x pitch; 48 = 4 x pitch, pitch = 12; or 46 — 2 = 4 x pitch, 44 = 4 x pitch, pitch = 11. Therefore, twenty-three active bars and forty-six connecting conductors will be used. There will be 96 — 46 = 50 conductors left to be divided among the twenty-three active coils corresponding to the twenty-three active bars; 23 will go in 50 twice and 4 over, so that four conductors must be left dead and two intermediate conductors wound into each coil by the lap winding. The pitch to be used can only be determined by inspection, remembering that one conductor from each layer should be wound into a coil and that the lap connections should span about 90 degs. Four conductors which would wind into a coil must be left dead and one bar short-circuited to its neighbor.

Beginning at conductor 1, in the outermost layer, Fig. 1, the connection is taken to a conductor in the next layer at 90 degs. ahead, i. e., 22; from there to conductor 3, 90 degs. behind in the next layer, and thence to 24 in the innermost layer. Conductors 22 and 3 have been wound up by lap connection as the intermediate conductors of the coil; 24 must be joined by a wave-connected lead to the outermost conductor in a slot about 90 degs. ahead. If the slot exactly 90 degs. ahead is selected, the connection will be to 49, 70, 51, 72 in that coil, and then by a wave connection to 5, thus giving a progressive winding. If 45 is selected for the connection from 24 the course will be 45, 66, 47, 68 and then to 89, etc., giving a retrograde winding. The only advantage either way is that the retrograde has shorter leads. It has therefore been chosen.

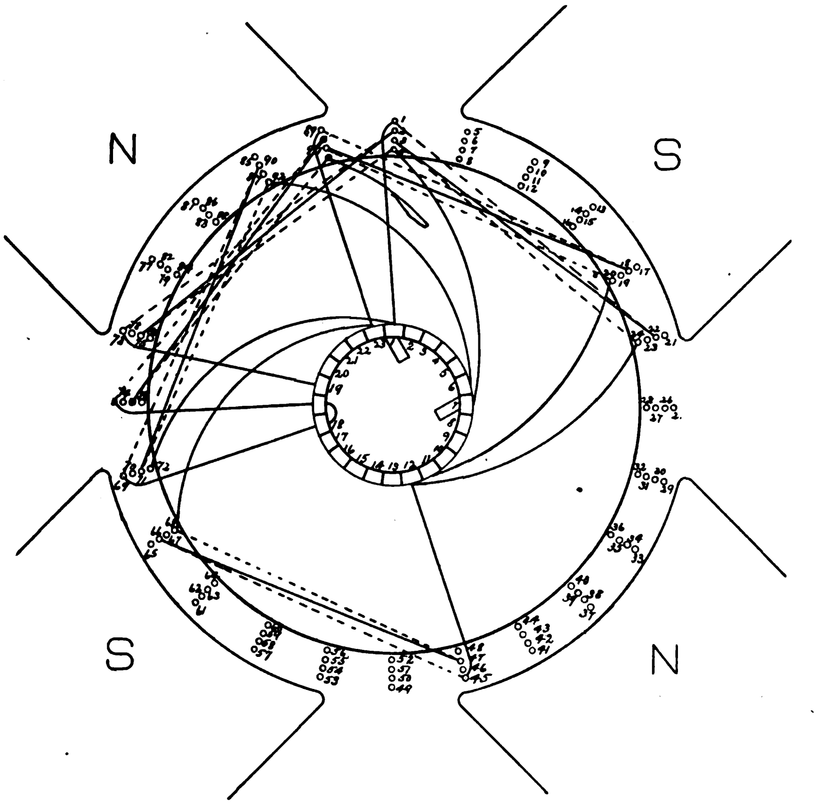

FIG. 1.—WENSTRÖM WINDING.

The connection gives eight conductors between a bar and the one adjacent; then between brushes, at 90 degs. apart, there will be 24 ÷ 4 = 6 bars, and 6 × 8 = 48 conductors, or about half those on the armature, so that it will be a two-circuit winding. The coil to be left dead has been taken as the one whose outer conductor would have been 73 if it had been used; the numbers are moved ahead in the same layer to the next slot, and all succeeding numbers in that layer must, of course be moved ahead one slot. For the second and fourth layers conductors 94 and 96 are the dead ones, so that their numbers simply disappear, as only 92 active conductors are to be used.

Only a part of the coils are shown to avoid confusion in the lines; the rest of the connection can better be followed from the winding table. The pitch from conductor 1 is 21 ahead to conductor 22; thence the pitch is 19 back to conductor 3; thence ahead 21 to conductor 24 and ahead to bar 12 which connects to conductor 45. The table will be:

	Bar	1	to	Conductor	1	to	Conductor	22
			“	“	3	“	“	24
to	“	12	“	“	45	“	“	66
			“	“	47	“	“	68
to	“	23	“	“	89	“	“	18
			“	“	91	“	“	20
to	“	11	“	“	41	“	“	62
			“	“	43	“	“	64 etc.

The table can easily be carried to completion by noting that, in the columns for bars, a number is always 11 ahead of the one just above (remember that the bar next after reaching 23 is No. 1); and, in the conductor columns, each number is 44 ahead of the one just above, remembering that after conductor 92 comes conductor 1.

MECHANICALLY STRONG INSULATORS.

The electrical artisan is woefully deficient in mechanically strong insulators. Porcelain and slate are brittle. Hard rubber deteriorates. Fibre absorbs moisture. Moulded insulators are not easily worked by machine tools, and mica is only valuable under compression strains. Inventors have been trying for several years, with the aid of ingenuity, hydraulic pressure and scrap material, to produce an insulator that will be generally adaptable. Such an insulator must be homogeneous and preserve its structure under high temperature or persistent moisture. It must possess a maximum of mechanical strength under all varieties of stress. If it is non-hygroscopic, its actual specific resistance need not be very high to make it a fortune to its compounder.

THE INDUCTION MOTOR.

IV. INDUCTION MOTOR ARMATURE WINDING.

BY ALFRED E. WIENER.

The winding of the induction motor armature, as stated before, consists in short-circuiting the rotor-conductors among themselves. In order to obtain the greatest possible effect in so doing, any armature-conductor must be connected to a conductor carrying a current of the same strength, but of opposite direction; that is to say, such conductors must be joined which include an angle equal to $\frac{180}{p}$ degs., if p is the number of pairs of magnet poles of the field.

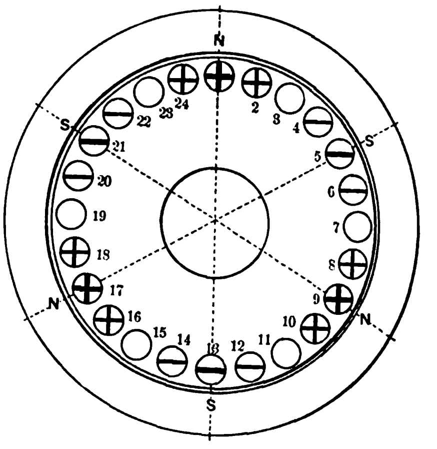

FIG. 1.—INDUCTION MOTOR WINDING, SHOWING STRENGTH AND POLARITY OF INDUCED CIRCUITS.

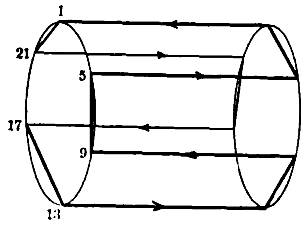

FIG. 2.—SERIES CONNECTION IN INDUCTION MOTOR ARMATURE.

In Fig. 1, an armature having 24 conductors is shown in a 6-pole field. The direction of the currents, which is the same for a 2- or a 3-phase motor provided that the field-polarity is the same in both cases, is distinguished by the + or — sign, respectively, and their relative strength is indicated by different thickness of the direction-signs. Accordingly, the conductors numbered 1, 5, 9, 13, 17, and 21, also conductors 2, 6, 10, 14, 18, and 22, etc., must be connected with each other. This can be effected in different ways.

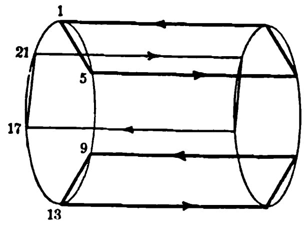

FIG. 3.—ADJACENT INDEPENDENT CIRCUIT CONNECTION.

(1). *Series-Connection.*—All the conductors of similar position with regard to the field-poles may be so connected with each other as to form one continuous closed circuit in which all the induced currents flow in the same direction, electrically, the conductors being placed in series to one another. Fig. 2 shows one group of equivalent conductors so connected in the form of a wave, 1—5—9—13—17—21, the complete winding for the case considered in Fig. 1 consisting of four separate circuits similar to the one illustrated.

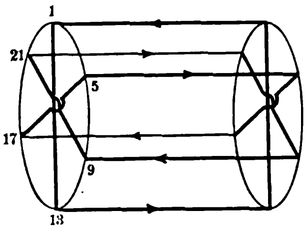

FIG. 4.—DIAMETRAL INDEPENDENT CONNECTION.

(2). *Independent Circuit Connection.*—A number of independent closed circuits may be formed, by joining each conductor with its similar in the adjacent space of opposite polarity, or else with the one diametrically opposite. Thus, in Fig. 3 three circuits, 1—5, 9—13, and 17—21, are formed when connecting each group of conductors in the manner first named. Connecting the conductors in the second fashion, the three independent circuits are 1—13, 5—17, and 9—21; see Fig. 4. In both cases the complete armature will have 4 × 3 = 12 separate circuits.

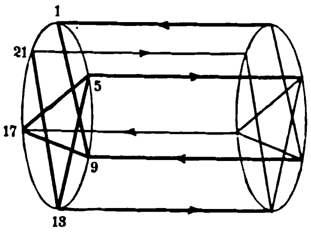

FIG. 5.—SERIES PARALLEL CONNECTION.

(3). *Series-Parallel Connection.*—All similar conductors of one polarity may be connected in parallel and joined in series with all similars of the opposite polarity, the latter being themselves grouped in parallel. In Fig. 5 the + conductors of the first group of similars, 1, 9, and 17, are accordingly put in multiple and placed in series with the parallel-connected — conductors, 5, 13 and 21, of the same group, the series-connection being effected by face-conductor 17—5. Four such circuits will complete the armature-winding in this case.

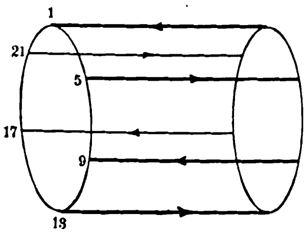

FIG. 6.—SQUIRREL CAGE CONNECTION.

(4). *Parallel Connection.*—All conductors on the armature may be joined in parallel, as shown in Fig. 6. For, when considering the independent circuit connection, Fig. 3, it is seen that it will be immaterial whether conductor 1 is paired with conductor 5 or with 21. Hence, in connecting conductor 1 both with 5 and with 21, conductor 9 with 5 and with 13, etc., the current from each conductor can be considered as flowing in divided circuit through two independent circuits, and thus a parallel grouping of all conductors is obtained which is electrically equivalent to the independent circuit winding. Similarly, the method of parallel connecting can be derived as a special case of the grouping depicted in Fig. 4. Here the e.m.fs. in the two halves of every closed circuit are equal, by virtue of the fact that only similar conductors are joined together; there is consequently not the slightest reason why the separate loops should not be connected at their crossing point, and again the short-circuited winding is arrived at. Finally, in Fig. 5 the series-connection, instead of being placed between conductors 17 and 5, may be divided among two pairs of conductors, or may even be distributed among all of them, thus— 1—5—9—13—17—21—1; but this is nothing else but the parallel connection illustrated in Fig. 6.

This parallel arrangement which, from its similarity in appearance with that familiar form, has received the name of the "squirrel-cage" winding, has the advantage over all the remaining methods of grouping that, since half the current from each conductor will flow into the next conductor on one side and half into the one on the other side, only one-half the cross-section is required for the connecting face-conductors. Besides this reduction in weight, the process of cross-connecting itself is by this method rendered extremely simple, mechanically, no complicated system of connecting and crossing of end-wires being required, but merely a pair of closed end-rings which are either inserted into slots provided in the ends of the conductors, or which are themselves supplied with sockets, or lugs, to receive the conductors.

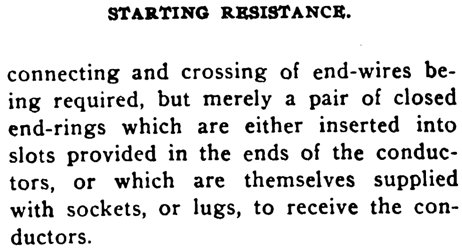

FIG. 7.—THREE-COIL WINDING OF INDUCTION MOTOR ARMATURE, SHOWING STARTING RESISTANCE.

Open Circuit Armature Winding.—In large induction-motors, for the double purpose of avoiding too great a current-rush when switching the motor into circuit and of obtaining a larger initial turning-force, or torque, it is necessary to insert starting-resistance into the armature-circuit. This is usually effected by connecting the armature conductors into three parallel circuits, one end of each of which is led to a common junction while each free end is connected to a collector-ring on the shaft. Each of these rings leads off, by means of a contact-brush, to an adjustable resistance, the three resistances being equal to each other and so connected to a starting switch that by its manipulation corresponding equal portions of the three resistances are in turn grouped in parallel, the switch-lever then forming a second common junction. Since for this arrangement it is necessary that the number of conductors per pole is a multiple of 3, in the adjoined diagram, Fig. 7, the connections are shown for a 12-conductor armature supposed to be acted upon by a 4-pole field.

If the number of conductors is simply a multiple of 3 without being divisible by the number of poles, a grouping into three circuits is possible, to be sure, but the currents in the three branches all flow either toward or from the common junction, so that a fourth collector-ring would be required to establish connection between the two common junctions. The same holds true in case of two parallel branches for any number of armature-conductors, hence the smallest number of collector-rings for any grouping into open parallel circuits is 3; and as the direction of the currents in the armature-conductors depends only upon the number of poles in the magnet-frame but not on the number of phases supplying the field-winding, it follows that the 3-coil winding shown diagrammatically in Fig. 7 will answer equally well for two-phase as for three-phase motors.

◆

A CONVENIENT RULE FOR THE CALCULATION OF THREE-PHASE CIRCUITS.

One of the most popular circuits in multiphase transmission is the three-phase, three-wire system. The calculation of the proper sizes of wire for a power transmission upon this system has frequently bothered devotees of direct current. In attempting its solution they very shortly are tangled up with the square root of three, which has unaccountably incorporated itself into their calculations, and they are also likely to calculate the three drops, one on each wire, and are then in a quandary as to whether these should be added, averaged, or the third neglected. A simple and satisfactory rule is the following:

The ratio of the amounts of copper used for equal power, drop and voltage is 100 for the single-phase and 75 for the three-phase system. The single-phase system, as is well known, is calculated by ordinary direct current rules and uses two wires. The three-phase system uses three wires. It then follows that, if we calculate the proper size of wire by ordinary direct current rules, and then divide the circular millage of that wire by 2, we shall have the proper size of wire for a three-phase circuit, because 75 per cent of the volume of two wires of a given size is equal to the volume of three wires of half that size, lengths being equal.

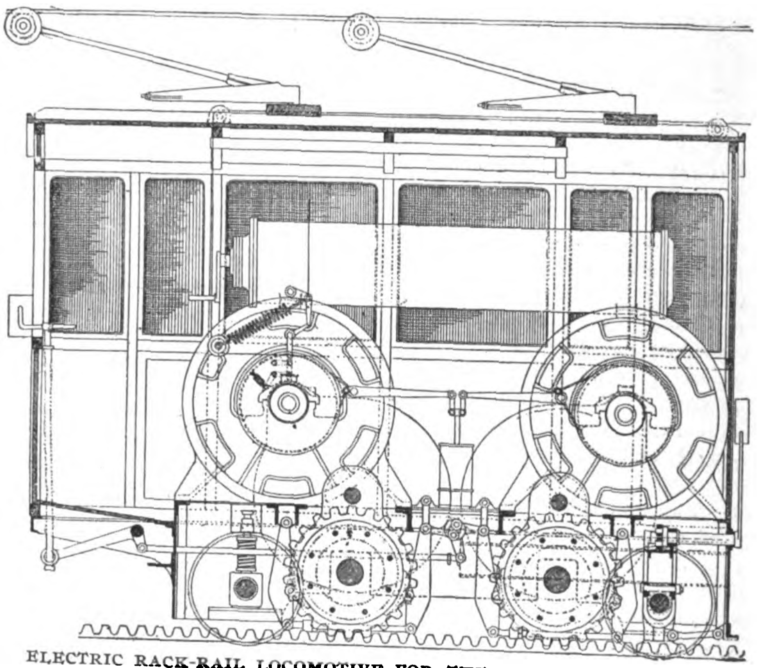
Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Electrolytic Manufacture of Hydrogen and Oxygen.—"L'Eclairage Electrique" describes an installation for the electrolytic manufacture of oxygen and hydrogen recently erected by the Société l'Oxyhydrique at Brussels. The electrolyzers consist of very narrow cells of steel plate, having perforated walls. These are put together with a copper solder. In each cell is an electrode of steel plate. Although not so stated, it is inferred that these are immersed in a tank of the electrolyte, which consists of a solution of soda kept at a temperature of 104 degs. F. The voltage at the terminals of a cell is 2.5 and the current density about 35 amps. per sq. ft. Under these conditions a k.w. hour produces 2.87 cu. ft. of oxygen and 5.75 cu. ft. of hydrogen. Of course, the commercial value of the process depends entirely upon the cost of electric power in the neighborhood of the plant. The gases obtained are very pure, the oxygen being 97 and the hydrogen 99 per per cent pure, the impurity in each case consisting of the other gas. By passing the gas through a red-hot tube these impurities unite with it to form water, which may be easily dried out, leaving the pure gas.

Electricity on the Jungfrau.—In the progress of the work on the electric railway to the summit of the Jungfrau electricity is playing a prominent part. According to an article in "Prometheus" (Berlin) the boring of the tunnel, of which the greater part of the line is composed, is proceeding by the use of electric drills of the revolving variety. There are five of these in use, each being mounted on a vertical beam wedged between the floor and roof of the gallery and operated by a 3-h.p. motor on the rear side of the beam. The boring points are made of crucible steel, toothed, but without diamond points, and each has a channel through which water is pumped (by an electrically driven pump) to wash out the boring dust. One of these outfits will bore a hole 1¾ ins. diameter and 40 ins. deep in the hard rock of the heading in 12 to 15 minutes, with a current consumption of 7 amps. at 220 volts. When each machine has bored four holes they are all taken down and the twenty holes are fired, explosive gelatine being used. This substance freezes at 4 deg. C., and then becomes very sensitive to shocks and exceedingly dangerous. Accordingly, an electric heater is provided for its storage at a proper temperature. Another use to which the electric heating apparatus has been put is melting the ice of the Eiger glacier to supply the boring machines with water for washing out the holes. This was during the past winter, when all the water in the neighborhood of the workings was frozen. It is stated that for each yard the tunnel progresses 1 cu. yd. of water has to be provided for this purpose.

Electric blowers are used to ventilate the tunnel, zinc tubes 1 ft. in diameter taking the fresh air close to the headings. At the workmen's headquarters near the month of the tunnel are buildings for offices, shops and dwellings, as well as a hospital, canteen, etc., and these are all electrically heated as well as lighted. The winter climate of the high Alps is very severe, the dwelling houses being lined with wood, then a layer of felt, a layer of air, and another ceiling of wood inside the stone walls. All lighting, heating and cooking in this village is by means of electricity.



ELECTRIC RACK-RAIL LOCOMOTIVE FOR THE JUNGFRAU RAILWAY.

The locomotives for this railway are of the rack pattern, as shown in the illustration. Each has two motors, of 150 h.p. each, running at 800 r.p.m., geared to the two sprocket wheels. The locomotive weighs thirteen tons and is intended to haul two cars, each seating forty passengers.

On the top of the Jungfrau it is proposed to place searchlights of great power to light up the neighboring peaks at night. There is also to be a hall hollowed out of the rock of the summit for the accommodation of visitors in stormy weather and this is to be, like the rest of the stations of this most remarkable railway, lighted and heated by electricity.

Improvements in Recording Pyrometers.—Mr. A. Stansfield describes in the "Philosophical Magazine" a new recording pyrometer, which promises to be useful in a number of investigations. He uses a thermo-electric couple of platinum and a platinum-rhodium alloy, fused together at the end and protected by a thin fire-clay tube. Insulation is effected by a slip of mica between the wires of the couple. If such an instrument is used at high temperatures the curve of records, if on a scale sufficient to show minor variations, must be at a considerable distance from the zero line. To obviate this difficulty Mr. Stansfield balances out the major part of the potential generated, leaving the minor fluctuations to affect a sensitive reflecting galvanometer. In front of this is mounted a photographic plate in a carrier, which is mounted on a float in a cylindrical vessel arranged to rise gradually as water is admitted to it. The light from a convenient source is allowed to fall upon the plate, and the combination of the motions of the plate and the spot of light give an autographic record of the temperature differences during the experiment.

Wireless Telegraphy.—The "Electrician" says: "One of the varied applications of wireless telegraphy received an interesting illustration at the Kingstown regatta, last week, when Mr. Marconi demonstrated the adaptability of his system to the transmission of press intelligence from a steam launch in motion. The yachting expert on deck dictated his account of the races while these were in progress, and a stream of dictated 'copy' descended below deck to Mr. Marconi, who sat in a cabin working his transmitter, whence the ether waves carried the news with a minimum loss of time to the receiving station on shore. Arrived at this point, the news was forwarded on to the press offices by telephone. It is stated that one edition of an evening paper contained two whole columns of news dispatched entirely by wireless telegraphy. This notable event is undoubtedly the germ of an important development of wireless telegraphy in the near future."

Searchlights on Captive Balloons.—The Russian War Department, says "Industries and Iron," is conducting a series of experiments on searchlights mounted in captive balloons, the current being supplied through the cable that secures the balloon. Searchlights up to 5000 c.p. have been used and these, when at an altitude of 1800 ft., illuminate a circular area of 1500 ft. diameter. It is not stated what this sort of light is to be used for, but recent experience with war balloons leads one to think that such an arrangement would be much more dangerous than useful in the presence of an enemy who has the use of his eyesight.

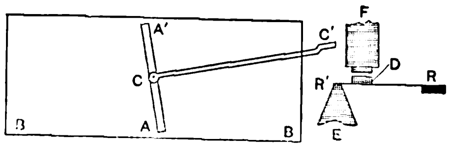
A New Electrical Thermometer.—An ingenious adaptation of the principle of the Bruger ohmmeter has been applied by a German firm to the construction of pyrometers or electrical thermometers, says "Industries and Iron." Two crossed coils are free to rotate in a strong non-homogeneous magnetic field. In circuit with one of them is a resistance of fixed value, and in circuit with the other is the resistance to be measured, in this case the temperature wire. The scale of the instrument is graduated to read directly in degrees. The apparatus can be made for any range of temperature, and by altering the shape of the pole pieces it is possible to produce an open scale in the neighborhood of any desired temperature. For high temperature work a platinum wire is used, a nickeline wire being utilized for moderate temperatures. Temperatures up to 1200 degs. C. (2200 degs. F.) can be measured with the instrument, and it is said to also work satisfactorily at very low temperatures. The current required is about 0.03 ampere at 5 volts, and the instrument may be left in circuit indefinitely without injury.

Electric Furnaces.—The (London) "Electrical Engineer" gives an abstract of the paper presented by MM. Gin and Leleux to the Académie des Sciences on electric furnaces. The fall of potential of an arc striking across a given medium they regard simply as due to the resistance of the mass of gas lying between the electrodes. If this mass of gas is regarded as a cylinder with a sectional area equal to that of the electrodes, and if this cylinder is assumed to be surrounded by a perfect thermal screen it can be shown that the temperature of the arc would increase as the square of the current and the ratio of the resistivity of the gas to its specific heat per unit volume, the latter factors being themselves variable with the temperature. When the arc is allowed to pass through a mixture such as that used in making calcium carbide the arc forms a sort of pocket around itself, at the upper pole of which is a crater through which various gases and vapors escape. The volume of this cavity increases up to the point at which the heat liberated by the arc is in equilibrium with the losses of heat to the surrounding medium. After cooling it is found that the interior of the pocket is lined with a brilliant layer of graphite, outside of which is a concentric layer of carbide in crystals, and behind this a layer of unaltered material. The result can be explained by assuming either that the carbide dissociates at the temperature of the arc or that the calcium oxide volatilizes so fast that part of it is lost and remains unreduced. Direct experiment shows that calcium carbide is dissociated at a temperature below that at which carbon volatilizes. The tension of the arc varies with the nature of the surrounding atmosphere. For example, with calcium carbide mixture, when the stationary temperature is reached the tension is from 18 to 20 volts, the electrodes being 4 ins. apart, while with a mixture of carbon and manganese oxide the tension is only 10 volts and the pocket formed considerably larger.

Expansible Enamels for Electric Heaters.—In most forms of electric heating apparatus or resistance coils, where the wire carrying the currrent is imbedded in a mass of enamel, difficulty is encountered by the different rates of expansion of the wire and the enamel, causing them to split apart, admitting air to the interior and oxidizing the metal and making the apparatus dangerous from the underwriters' point of view. "L'Elettricitá" contains a short note of the work of M. Damour recently presented to the Société d'Encouragement pour l'Industrie Nationale. His researches were undertaken to find a market for one of the by-products of the "Société du Biborax," natural borate of calcium, or pandermite. The method of finding the enamel with the highest coefficient of dilation was as follows: A number of mixtures of pandermite and one other substance were made and tested for dilation. Of these the best were selected and each in turn mixed with a third substance. This process of trial and exclusion was followed through many steps and excellent results obtained. Among the best mixtures are the following: Mixture A: 50 parts Fontainbleau sand, 18 parts pandermite, 23 parts carbonate of lime, 35 parts carbonate of soda. Coefficient of dilation: 0.00001012. A mixture of 9 parts of mixture A and 1 part of rutile (titanium oxide) has a coefficient of 0.00001016. Ninety parts of A, 5 of magnesia and 5 of cryolite give a coefficient of 0.00001019. A mixture of 9 parts of A and one part of bicalcic phosphate increases the coefficient to 0.00001058. A still simpler mixture, consisting of 30 parts of pandermite, 20 of cryolite and 50 of feldspar has a coefficient of 0.00001055. As the coefficients of expansion of platinum, iron and nickel fall within the limits of the figures above, these metals may be used in connection with the new enamels with great satisfaction.

A Direct Acting Quantity Meter.—M. R. Blondlot recently presented to the Académie des Sciences a description of a very ingenious quantity meter which is based on a principle that seems to lend itself readily to practical application. A long hollow coil is set up so that its axis is horizontal. In the center of this coil a second coil in the shape of a ring is suspended so that it is free to oscillate around a vertical axis, its plane being vertical. The current to be measured is led through the two coils in series, mercury cups being used to connect the stationary and movable parts. Now if terrestrial magnetism is compensated the movable coil takes a position of equilibrium under the action of the current, with its spires parallel to those of the stationary coil. If the movable coil is displaced it will make a number of isochronous oscillations around this position of equilibrium. The period of swing, T, is inversely proportional to the square root of the moment of the couple exerted by the two coils. This moment is proportional to the square of the current intensity, i, so that the product, iT, is evidently a constant. Hence the proposition that the same quantity of electricity always passes during the period of one free oscillation.

The apparatus for practical use is arranged as shown in plan by the illustration. A A′ is the movable coil, carrying the index C C′. The oscillations are confined to one side of the position of equilibrium. R R′ is a light spring, fixed at one extremity. When the index swings to its middle position it establishes a contact with the end of the spring R, closing the circuit of the electromagnet e, and thus giving the movable part of the apparatus a "kick" which keeps it swinging. Of course, if there is no current the apparatus will stop. All that is necessary to use this apparatus for current measurement is to find its constant, or the amount of electricity passed at each oscillation, and count the impulses given by the magnet e. This is done in practice by a counter moved by the magnet itself, so that there is no mechanical connection between the oscillating coil and the counting apparatus. The instrument is said to be sensitive and satisfactory and it certainly seems to be capable of development.



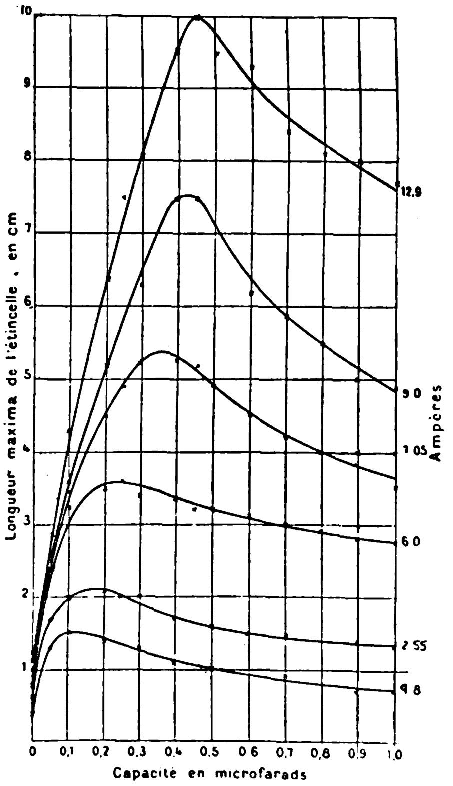
PLAN OF OSCILLATING QUANTITY METER.

Electricity in the Philippines.—According to a note in "Industries and Iron" there are about 720 miles of telegraphs in the Philippine Islands and about seventy miles of steam railway. There is no electric railway. The city of Manila has a telephone exchange, overhead lines with porcelain insulators being used. The electric light station at Manila supplies current to about 12,000 incandescent lamps and 260 arc lamps. The installation was made by an English firm having headquarters at Yokohama.

Electro-Deposition of Platinum.—In the "Electrical Review" (London), Mr. Sherard Cowper-Coles gives a number of formulæ for solutions to be used in electro-plating platinum. Among the most modern that he mentions are Boettger's solution, which consists of the double chloride of platinum and ammonia dissolved in water to which a few drops of liquid ammonia has been added. The solution is worked warm. Another solution due to Boettger consists of the double chloride of ammonia dissolved in 8 parts of sal ammoniac mixed with another of the double chloride of platinum and ammonia, freshly precipitated at a boiling temperature, dissolved in a concentrated solution of neutral citrate of sodium. The resulting liquid is a deep orange color with a feeble acid reaction. It should be worked cold with a current density of about 3 amps. per sq. ft., and an e.m.f. at the terminals of 7.5 volts. If the solution contains about 1½ ounces of platinum to the gallon excellent bright deposits are obtained. Gore gives a solution of chloride of platinum dissolved in a solution of potassium cyanide, the proportions of metal being about 1 oz. to the gallon and the bath being used warm. Jewreinoff states that the platinum anode is freely dissolved in a solution made by dissolving 10 parts of metallic platinum which has been converted into the chloride in 10 parts of caustic potash in water, the yellow precipitate being dissolved by the addition of 20 parts of oxalic acid in solution and the application of heat. To this solution is added 30 parts of caustic potash solution. The bath is, of course, strongly alkaline. Another bath recommended by the same author, in which he also uses platinum electrodes, consists of 3 parts of platinum converted into chloride and dissolved in 300 parts of water, to which is added 25 per cent. of sulphuric acid.

Wind as Motive Power.—An interesting paper by Prof. La Cour, a well known Danish scientist, on the above subject is abstracted in "Engineering." The history of the utilization of natural powers is of great antiquity. The first technical paper on the subject emanated from Hero of Alexandria about 2000 years ago, but though the subject was widely discussed and commented upon it seems to have lain in abeyance for about 1500 years, when a new move was made by various Mahometan scientists and the movement culminating in the invention of the steam engine was inaugurated. To this day the problems connected with wind-mills have not all been solved. While it is recognized that the shape of the vanes should be portions of curved surfaces, the best and most efficient curves have not yet been calculated. Much of the earlier mathematical work on this subject was fallacious because founded on incorrect physical assumptions as to the action of the wind on the vanes. The "suction" on the lee side of the vane is now known to be an important factor in the action. At present the most important practical point in connection with such machinery is how best to neutralize the inconvenience caused by the irregularity of the wind and thus adapt wind-mills to dynamo driving.

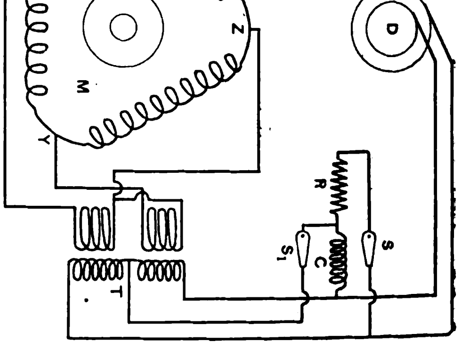
Condensers for Induction Coils.—The length of the secondary spark of an induction coil is considerably increased by the use of a condenser in the primary circuit, but the exact part played by this condenser is not definitely understood. The most general opinion is that the extra current of the primary circuit charges the condenser, instead of expending itself in sparking at the interrupter, and by more quickly causing the dying out of the primary current increases the e.m.f. in the secondary. This explanation seems insufficient, and a Japanese scientist, Mr. Tulbizuno, has made some researches upon the effect produced by the variation of the capacity of the condenser shunted around the interrupter, of which an account is given in "L'Industrie Electrique." He used a coil 4½ ins. in diameter and 8 ins. long, fed by a battery of nine secondary cells, and a condenser having a capacity varying from 0.05 to 1 microfarad. The sparks were discharged between a point and a plate, both carefully cleaned after every spark. The results obtained are plotted in the accompanying curve, where the current intensities in the primary are given in amps., and the spark lengths plotted as ordinates and the capacities as abscissæ. The curves distinctly show that for a given current intensity there is a definite value for the capacity giving the longest spark.



CURVES OF SPARK LENGTH, CAPACITY AND PRIMARY CURRENT.

Electric Light in Cotton Mills.—The "Mechanical World," in a leading article, says that the inclosed arc lamp nearly approaches the ideal of perfection for the lighting of cotton mills. In these mills and in many other establishments where textile industries are carried on it is necessary that the light shall not falsify colors, and at the same time that it shall be evenly distributed, and not especially dangerous from the fire underwriters' point of view. The inclosed arc possesses all these advantages, and, in addition, is cleanly, and not apt to give off any smoke or dust injurious to the fabrics, while with long-burning lamps it is not necessary to trim oftener than two or three times a year when ordinary working hours are observed.

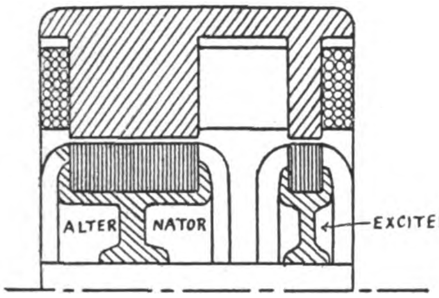
Phase Transformers.—The usefulness of some simple form of phase transformer enabling single-phase currents to be split up into polyphase currents and thus permitting the use of a simple conducting system of one wire would be especially appreciated in the field of railway work, where any attempt to use polyphase currents for power purposes is met at the outset with the difficulty of a double trolley system. In a very valuable paper, in "Zeitschrift für Elektrotechnik," Herr Gustav W. Meyer discusses all the forms of phase transformers with special reference to this application. An ingenious device for operating a three-phase motor on a single-phase current supply is illustrated. The motor, M, has the usual field winding and a three-phase winding on its rotor. The stator is connected as shown to the two ends and the middle point of the secondary of an ordinary split transformer, and in the primary circuit with this is connected a non-inductive resistance, R, and a self-induction coil, C, as shown. By the switches S and S_1, these can be cut in or out of the circuit. At starting they are cut in, as shown, and produce a sufficient displacement of phase to start the motor. After the motor attains speed the switches are opened and the reaction of the three-phase winding on the rotor induces a current in the part XY of the stator winding, the machine continuing to run as a three-phase motor, though supplied with single-phase current. It is claimed that this method surpasses the rotary phase transformer of Arnó and Ferraris on account of its simplicity and cheapness and absence of moving parts.



STATIONARY PHASE TRANSFORMER.

Self-Regulating Alternator.—An extremely ingenious method for the compounding of an alternator without the necessity of rectifying the current for this purpose is described by E. Danielson in

"Elektrotechnische Rundschau," an abstract appearing in "Science Abstracts." The exciter armature is mounted on the main shaft and the same field winding serves for both alternator and exciter, the latter being series-wound. On the armature of the exciter is wound the compounding coil, which is supplied with an alternating current, either the main current of the machine or a transformed current being used. This winding is so arranged with respect to the generating winding of the exciter armature that the currents in the two oppose each other, and is so proportioned that when the main alternating current is in phase with the e.m.f. the exciter armature reaction strengthens the field sufficiently to make up for the drop due to resistance and inductance in the alternator armature. If the main alternating current lags behind the e.m.f. the armature reaction of the exciter will be increased so as to strengthen the field, and so the exciting current and field of the alternator, so that the effective voltage across the terminals of the latter is maintained constant. The method compensates automatically, not only for the ordinary drop due to self-induction and resistance, but for armature reaction due to phase displacement as well. It is equally adapted to polyphase and single-phase machines.



SELF-REGULATING ALTERNATOR.

A machine of this type will doubtless regulate very well if the speed is maintained absolutely constant, but it is evident that it is doubly sensitive to irregularities in speed of driving.

Broken Trolley Wire Cut-Out.—In a letter to "Elektrotechnische Zeitschrift" G. B. Folco describes a system for cutting out broken trolley wires which have fallen and not made a good enough earth contact to work the magnetic cut-outs at the central station. He replaces the usual section switches with his apparatus, which are a variety of magnetic cut-outs, having their coils in a special circuit, as shown in the diagram. If now a break occurs, say, in the section m_1m_2, the current passing through the switch apparatus a_1 to the further sections of the line would be diverted through the coil of the magnetic cut-out and open the line at m_1. This system requires that there should be cars in operation beyond the point of the break, so that it is inoperative for the terminal section; but the author points out that the terminal section may be made as short as desired, so that the system seems a very simple and satisfactory one.

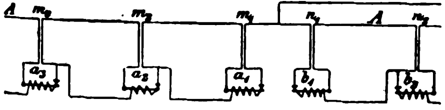


DIAGRAM OF TROLLEY WIRE CUT-OUT.

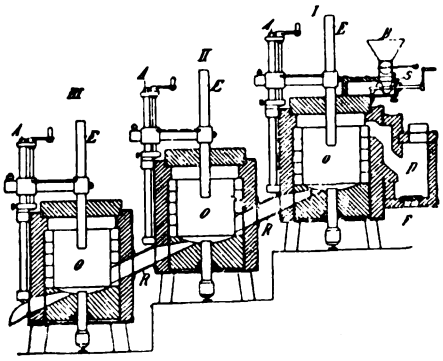
Regenerative Electric Furnaces.—A system of regenerative electric furnaces is described in "Zeitschrift für Elektrochemie," from which the accompanying illustration is taken. Three or more furnaces are arranged as shown, the material to be operated upon being first introduced into the upper furnace through the hopper H. Gaseous products escape by the flue at the right, depositing dust in suspension in the dust-chamber D, from which it may be removed through the hand-hole F. The melted products flow down through the tube R into the second furnace, parting there with some of their heat. When the second oven is thus sufficiently warmed, it is put in operation, and similarly the melted products from each furnace flowing through those below heat them and thus utilize an otherwise wasted amount of energy. It is claimed that a furnace system of this type has shown an economy of over 20 per cent greater than that exhibited by the ordinary detached furnace. It is not stated in the article to what variety of electric furnace work this system is especially adapted, but its use is evidently restrained to those processes in which there is a liquid product.



REGENERATIVE ELECTRIC FURNACES.

Ozone.—Mr. John B. C. Kershaw writes in the (London) "Electrical Review" a résumé of the methods for the commercial production of ozone, and compares the cost of this oxidizing agent with that of others. The methods of producing ozone are as follows:

Andreoli's Method.—This uses plain aluminum electrodes, made by covering wooden boards of the size required with aluminum foil, while the "grid" electrodes are made by stretching serrated aluminum wires across an appropriate wooden frame. The two electrodes and a sheet of glass acting as a dielectric are clamped together in a wooden frame, and any number of these units can be built up to form an ozonizer of the desired capacity. Alternating currents of high voltage are used for working these instruments, the ½-k.w. unit taking 0.13 amps. at 2800 volts. This form of ozonizer is said to yield 125 grams (4.37 ozs.) of ozone per k.w.-hour. Otto's ozonizer is made of a thin sheet of metal laid upon a sheet of glass or fixed between two glass plates. The air enters at one end and passes in a zigzag manner between the several elements forming the ozonizer. Otto's chief discovery is that the "output of ozone is proportional to the periodicity of the alternating current used." He states that the output is a maximum when a periodicity of eighty per second is used, and claims a yield of 155 grams of ozone per electrical h.p.-hour. The Yarnold ozonizer consists of a flat-shaped box containing a number of glass plates coated on one side with gold leaf. These metallic films are connected alternately in parallel with the two sides of the supply circuit. The air is passed into the spaces between neighboring plates, and does not come into contact with the metallic films. A yield of 175 grams per electrical h.p.-hour is claimed. The Siemens & Halske ozonizer consists of an arrangement of tubes, each unit consisting of an inner metal tube and an outer glass tube covered with tin-foil on its external surface. Water flows through the inner tubes to keep down the temperature, while air is circulated through the annular spaces between the tubes. Its output is stated to be 20 grams per electrical h.p. hour, and the machine has been in use in Germany for about fourteen years.

Among the numerous uses that have been suggested for ozone or ozonized air produced by these apparatus may be mentioned: Aging wood for musical instruments, maturing wines and spirits, sweetening foul beer casks, drying and thickening oils, bleaching waxes and fats, seasoning linoleum, bleaching fabrics and yarns, sterilizing drinking water and producing vanillin and similar organic bodies. While a number of these processes are dependent upon ozone there are many cases where other oxidizing agents can be used, and it is necessary to compare the cost of the various processes of oxidation. The author gives the following table of the comparative costs of producing 1 kilogram (2.2 lbs.) of active oxygen, electrical energy being assumed to cost 3 cents per electrical h.p. hour, which is the least that can be expected considering the small quantities used:

Source.	Cost in cents.
Bleaching powder	36.6
Sodium bichromate	96.0
Ozone (Yarnold's ozonizer)	123.0
" (Otto's ozonizer)	132.0
" (Andreoli's ozonizer)	167.4
Sodium manganate, acid solution	172.0
" " alkaline solution	306.0
Ozone (Siemens and Halske ozonizer)	522.0

These figures show bleaching powder to be the cheapest oxidizing agent, where the use of this form of chlorine gives satisfactory results. There are many applications, however, in which ozone finds ready and legitimate use, and it is to be expected that its use in the manufacture of oils, fats and organic chemicals will rapidly extend.

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED

Electrical Industries.

Mr. W. D. Weaver, editor of the "American Electrician," who has been temporarily absent, is expected home during the next few weeks. At the opening of hostilities with Spain Mr. Weaver was commissioned chief engineer of the U. S. S. "Glacier," which is now in West Indian waters. Mr. Weaver is a graduate of the Naval Academy of Annapolis, and after having made a most honorable record in the Navy, resigned some years ago to enter the field of electrical journalism.

Electrolytic Action on the Brooklyn Bridge.

A recent accident on the bridge, which resulted in the buckling of several of the girders, has been the subject of numerous scare heads in the daily papers and mysterious illusions to the deadly current that is supposed to be continually gnawing at the foundations of the bridge.

There is, without question, a considerable current flow in the cables of the bridge. This is evidenced in numerous ways. A compass needle placed over the cable will deflect at right angles thereto, and frequently flashing arcs are noticed between the traction cables and the pulleys on the the traction cables and the pulleys at the termini.

The current has been thought to have its origin at the foot of Fulton Street, where there is heavy traffic and frequently congestion of traffic. From this point the current that is fed into the ground must reach the Kent Avenue power house by a somewhat circuitous route around Wallabout Bay. A portion is supposed to enter the bridge at the Brooklyn anchorage and traverses the cables, for the most part, across the river to the New York end. It thence proceeds up the East River shore and across the river above Wallabout Bay to the station. Experiments with the compass needle, however, show that the current is frequently travelling toward Brooklyn, and therefore that the traffic at the New York end has raised that locality above the Fulton Street potential. Particularly is this the case when the bridge trains are operated entirely by electricity. Wherever the current leaves the bridge structure is the point to be watched.

The cable anchorages, set, as they are, in masonry and concrete, seem to afford a rather poor exit for the current, for it is inclined to follow the traction cables into the termini. Important matters like this, however, should not be decided on speculation; it should be definitely determined just how much current enters the cables and where it is leaving them.

It ought not to be a difficult matter to provide some immense copper clamps to grasp the cables just before they enter the anchorages and securely ground them, in this way deflecting the current from the anchorage proper, and, comparatively speaking, it should be an inexpensive undertaking.

The Future Street Railway Motor.

Each succeeding year there is developed a new street railway motor, lighter, more convenient, cleanly and powerful, and easier to maintain and repair. It is generally admitted that we have by no means seen the end of these improvements. The steam locomotive of to-day has become very nearly a standard product; the improvements made upon it are of a minor character; and we must expect within a few years to see the railway motor in such a condition. Apropos of this convention season it is, perhaps, in order to speculate as to what form this finished railway motor will take.

The 500-volt devotees have much to apprehend from the alternate current system. The three-phase systems at Lugano, the Gorner-Grat and the Jungfrau have met with success in sufficient measure to warrant further experiment and installation. The long distance suburban railway traffic is increasing, and with it comes a great demand for an economic distribution of electric power, and the engineer naturally turns to alternate currents. The induction motor has been practically perfected for stationary work. It is commutatorless and some types dispense with brushes. Its moving wire circulates currents of low voltage only. It is capable of being built and is, in fact, inherently built on ironclad lines. It is light in proportion to its output and is otherwise a thoroughly desirable railway motor. In fact there is only one objection that is offered by electric railway engineers, namely, the uneconomical control at variable speeds. In this it must be admitted that the direct-current motor has the advantage.

We must remember, however, that there is something besides motor efficiency to be considered in an electric railway system. The cable system has only one economical speed, and it has for many years been a commercial success and only very recently is it being displaced. The induction motor, on the other hand, can easily have two economical speeds, by means of subdividing the pole pieces and controlling on the intermediate notches by means of resistances, and modern engineering is rapidly bringing the control of the induction motor on these lines to an economy approaching that of the direct-current motor. Inasmuch as in other respects the induction motor is immeasurably superior to the direct-current motor, it is evident that the former must soon receive a trial. It may further be noticed that on interurban service the speed of the motor is not continually changing; top speed or half speed are usually employed; in fact, the motorman is directed not to run his car on any but the series or parallel positions, except on starting and stopping. In such service as this the control of the direct-current motor is no better than that of the induction motor.

The conclusion seems to be that the introduction of the induction motor is delayed, not by want of electric improvement, but by prejudice. Soon some daring investor or engineer will install an interurban induction motor system in this country, and that day will mark a revolution in American electric railway practice, if the reports we hear from both at home and abroad are to be believed.

The conduit systems now in use with two underground conductors are easily adaptable to the use of multiphase circuits by using the ground as an additional return. Of course, in overhead work the system will be considerably hampered on account of the double trolley. The double trolley, however, is a practical device, as direct current work has demonstrated in many instances, and engineers will not hesitate at its adoption, if greater advantages can thereby be obtained.

Straight Teeth Versus T Teeth.

Within the last year or two there has been considerable discussion as to the relative merits of straight and T-shaped teeth in armature construction. Both unquestionably have their advantages. The T-shaped tooth claims among other features the great advantage of securing the coils singly and securely without the aid of band wires by means of a wooden filler in the top of the slot. Further than that, the heating of the pole piece due to eddy currents is very much less marked with T-shaped teeth than with straight teeth. In a toothed armature the flux of force goes almost entirely through the teeth and during the revolutions of the armature the teeth carry each a tuft of lines of force after the manner of a paint brush, subjecting the surfaces of the pole piece to rapidly varying densities of magnetization, thereby producing intense eddy currents. It is evident at once that with the T-shaped tooth the slot is narrower and the rate of change of magnetization due to this cause is very much less. However, modern dynamo design is using laminated pole pieces, both to eliminate these eddy currents and to reduce the section of field magnet waist, by the use of soft wrought iron plates, and in such a construction the advantage of T-shaped tooth disappears. Moreover, a bobbin or coil wound in a slot with overlapping teeth is more highly self-inductive and therefore will not commutate as well in regions in advance of or preceding the true neutral line. Further than this, an armature with T-shaped teeth is harder to wind; the slots are more inaccessible; and, if the overlapping of the teeth is very great, the conductors will have to be forced in from the ends of the slots, after the fashion of tunnel winding.

Considering straight teeth, it seems that the only objections that can be urged against them is the heating which they cause in the pole pieces and the necessity of band wires. A laminated pole has practically eliminated the first of these difficulties, and as it is being adopted for various reasons it cannot be said to be forced upon the designer on account of the use of straight teeth. The band wires are certainly a disadvantage, although it is urged by their users that they contribute greatly to the ease of the repair of the armature, and that the removal of a few bands frees all of the coils. Unfortunately, however, it is almost always necessary to place these bands in the clearance, where they will be subject to the action of eddy currents; and any attempt to secure them by means of transversely soldered joints creates a spot for eddy currents, which may be generated in sufficient magnitude to melt the joint apart. The frequent failure of band wires due to these and other causes and the disastrous results attending their failure have certainly created a prejudice against them among designers and engineers in general. With certain types known as "straight out" or parallel winding it is possible to strongly secure the ends of the coils in regions outside of the clearance, and this, of course, is a great advantage. The chief advantage of the straight tooth, however, seems to be the fact that it permits the use of a machine-formed coil and very much cheapens the cost of winding the armature and generally simplifies its construction and makes more thorough insulation possible. Certain it is that the formed coil permits a very rapid winding of armatures. By means of these devices it is possible to insulate and wind a 100-k.w. armature core complete in less than twenty-four hours. With any other form this work would take several days at best, and if the old wire-wound types were used several weeks would be required. It is probable, therefore, that the straight tooth will become the preferred American practice, and it remains for some inventor to provide a means for securing the coils which is more satisfactory than band wires, which, it may truthfully be said, are a relic of the old days of dynamo building.

Electric Cab Service.

We describe in another column the complete electric cab service which is now operated in the streets of New York City. We find here a vehicle weighing 2800 lbs., and carrying a paying weight not exceeding 400 lbs. With the present storage battery we have of necessity a very heavy vehicle. The battery itself weighs over 1200 lbs., very nearly half the weight of the entire equipment. If we remove the battery and motors we shall have a carriage body weighing in the neighborhood of 1300 lbs., which, though, of course, heavier than the horse-hauled cab, cannot be said to be enormously heavier. It seems that the heavy wheels and solid construction of this vehicle are the outcome not of theoretical judgment and design, but of practical experience. The promotors of the electric automobile have witnessed the failure of a 3-inch pneumatic tire and of various parts in the construction of previous vehicles, which they had thought to be amply strong. In the present construction weight and strength has been very grudgingly added by the designers as it was needed, and until the weight of the electric equipment can be lightened it is perhaps the best that designers can do. We must look for improvement in the reduction of the weight of the storage battery. This once effected, other improvements will follow immediately and naturally. Concerning the handling machinery it will be noted that a carriage body weighing 1600 lbs. seized in viselike jaws by hydraulic rams and lined up with a battery which is apparently much more compact and portable, for the purpose of loading the latter into the former. The suggestion at once is, why not align the battery with the vehicle?

It appears that the handling devices were built to fit the vehicle and, taking this into consideration, the arrangement becomes one of ingenuity and reflects great credit on its designer. The vehicle loads from the end and the moment the batteries are loaded the entire body sinks several inches on its springs. However perfectly we may align the batteries to the vehicle for the purpose of loading, this alignment will be instantly destroyed as soon as the operation of loading is begun. It is obvious, therefore, that the vehicle must be held steady as well as the batteries, and this was done. It may be possible in subsequent designs to load from the top, in which case an ordinary crane will answer, and the present ingenious, but expensive device will be superseded. A movable driver's seat does not seem an insurmountable problem, and would permit the simplification indicated.

Much of the accurate control of this vehicle is due to its admirable brake. This acts upon the armature shaft, which exerts a very small torque as compared with that of the wheels. It can be easily stopped, and if it is stopped, the vehicle is brought to a standstill. Electric railway traction will certainly find in this device a hint in the solution of its own braking problem.

SHUNTS FOR ELECTRICAL INSTRUMENTS.

It is very frequently desirable to construct a low resistance which is a certain ratio to that of an indicating instrument, It may be a galvanometer, a voltmeter or some similar measuring instrument. In the following paragraphs is described a simple, convenient and accurate method for making such shunts as these.

The construction of a shunt can be best understood by reference to the drawing in Figs. 1 and 3, each of which displays a convenient method.

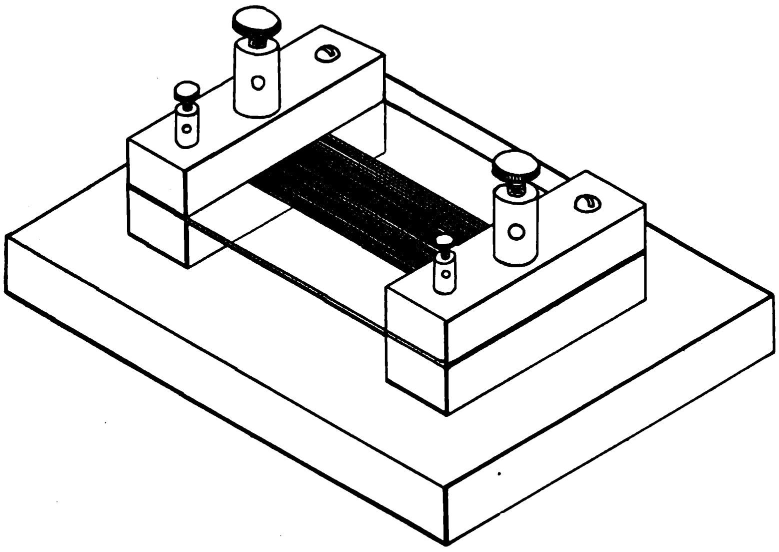

FIG. 1.—CONSTRUCTION OF SIMPLE SHUNT.

Taking first the description of Fig. 1: A board is provided which is reasonably secure from shrinking or warping troubles, and on it are mounted two copper clamps, sufficiently heavy for the purpose. The ends of these copper clamps are tapped and drilled so as to receive a wire, as shown in the figure. A large grip is provided at the one end for the main current wires; and a smaller connection is provided at the other end of the block to receive the wire from the instrument to be shunted. The clamps secure between them a piece of mica, upon which is wound a certain number of turns of high-resistance wire of low temperature coefficient. It will be seen on inspection that the clamps grip the coils of the wire at their ends, and put all of the wires spanning the gap between in multiple. If the blocks are accurately machined so as to make the lengths of all the component shunts equal, the resistance can be calculated beforehand, and the construction should be easily made without involving an error greater than 1 per cent.

In the second form but one clamp is used, the halves of which are secured together by insulated bolts. The mica is wound in the same way as before and a carefully predetermined amount is allowed to project from the jaws of the clamp, but the surplus on the other side of the jaws is carefully trimmed off. In this way a number of loops of wire are connected between the jaws and substantially supported so that they will not interfere with each other. Such shunts as these will pass very large amounts of current in proportion to the metal they contain without heating, as they expose very large surfaces for radiation. This is a valuable feature, because it is highly important that the resistance of the shunt shall not change during its operation, and even though its temperature coefficients may be very low it should not be heated any more than is absolutely necessary.

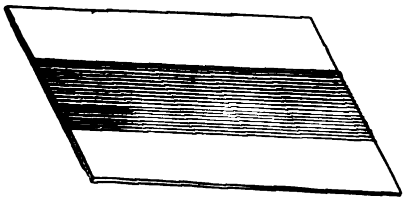

FIG. 2.—SHOWING WIRE WOUND ON MICA.

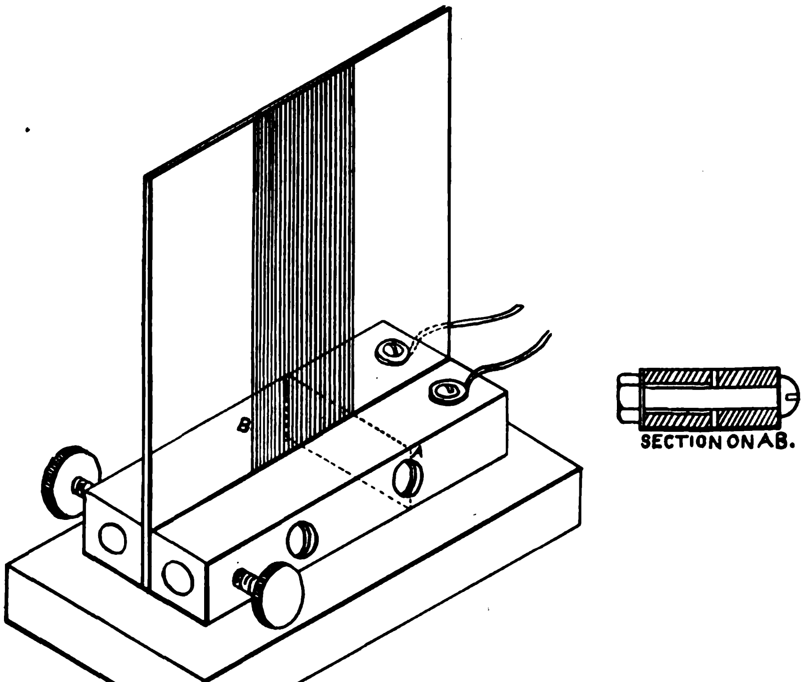

FIGS. 3 AND 4.—CONSTRUCTION OF SHUNT.

The calculation of such a shunt is very simple, and can best be illustrated by a practical example. Let us suppose, for instance, that we have a voltmeter which deflects completely across the scale when a potential of 1 volt exists between its terminals. Assume also that the scale divisions read to hundredths of a volt. We wish to put this instrument in multiple with a shunt and pass current through the combination, and have the shunt of such resistance that the indications of the voltmeter may be read as amperes, 1-10 of a volt answering as 1 amp. It is evident, then, that if we take a shunt whose resistance is 1-10 of an ohm and apply this voltmeter to its terminals, that it will practically register amperes as just described, for the amount of current the voltmeter takes is a negligible addition to the current in the shunt, being frequently less than 1-50 of 1 per cent.

The problem therefore becomes that of constructing a shunt, the resistance of which shall be exactly 1-10 of an ohm. For this purpose select a high-resistance wire, say of 4 ohms to the foot. Measure a length of some 6 or 8 feet with a Wheatstone bridge, and divide its length in feet by its resistance in ohms in order to determine the feet per ohm accurately. Do not rely on trade tables. They are seldom if ever accurate, especially in the case of special alloys.

Assuming 4 ohms per foot for sake of a figure, it is easy to see that to get a resistance of 1 ohm we should use a piece of wire 3 ins. long, and if we set the blocks of our shunt 3 ins. apart and wind five complete turns upon the mica slip which is bound between them, we shall have ten wires in multiple, each of which measures 1 ohm. Their joint resistance is of course 1-10 of an ohm, which is what we desire. If we were using a shunt of the type shown in Fig. 2, it would be necessary to wind ten turns on the mica and allow the latter to project 1½ ins. from the jaws. The same results would then be obtained.

It is frequently the case that the possessor of a low reading voltmeter desires to make up several shunts for his instrument whereby he can vary the range of its capacity in indicating amperes. For instance, with the 1-volt instrument already described it is easy to see that by using one wire, a 1-ampere instrument will result, with ten wires a 10-ampere instrument; with 100 wires, a 100-ampere instrument, and so on.

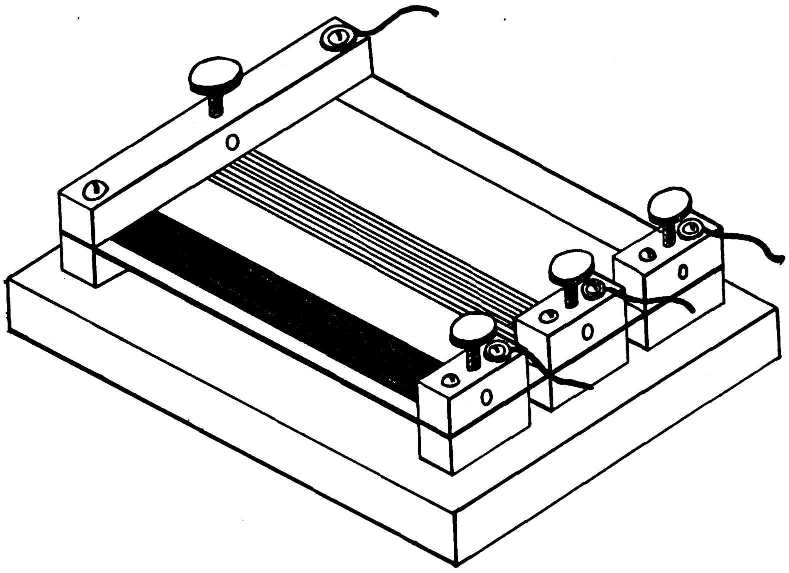

FIG. 5.—CONSTRUCTION OF TRIPLE SHUNT.

Fig. 4 shows a combination shunt board in which this feature is realized in a compact and convenient way. Three shunts are provided, each of which is connected to a common terminal, and the other ends each have individual terminals. The application may be seen at a glance. A very effective way to make heavy shunts is to shape a rod of high-resistance metal in the form shown in Fig. 6. Such a rod is preferably square. Four binding posts are provided—two in the ends to receive the main current, and two at an intermediate distance, which receive the voltage leads passing to the indicating instrument. These leads should be provided with terminals, as shown in the figure, and should be made of a permanent character, as the variation of their length varies, and sometimes to a very great extent the indications of the instrument, if the resistance of the latter is low. It can be easily seen that a shunt prepared in this way is very durable, simple and portable. The method of adjusting the shunt is very simple. The shunt is prepared in the proper way, connected in series with an ammeter whose indications are known to be correct. The instrument for which the shunt is to be calibrated is connected and the distance between the terminals is so adjusted at the start that the indications of the instrument will be slightly low. This may be done by calculation, and an accuracy of 1 per cent should be reached if the resistance of the metal is accurately known. The effective area of the shunt should then be reduced by saw-cuts symmetrically spaced, as shown in Fig. 6. These cuts should be made while the instruments are connected in circuit, and it will be found that the resistance can be very readily increased to cause the readings of the instruments to correspond accurately with each other. The source of current should be a storage battery upon which no other demands are being made. In this way the current will be a practically constant quantity. With a few shunts of this character, which can be built at a trifling expense, the electrical engineer can very largely increase the utility of his measuring instruments.

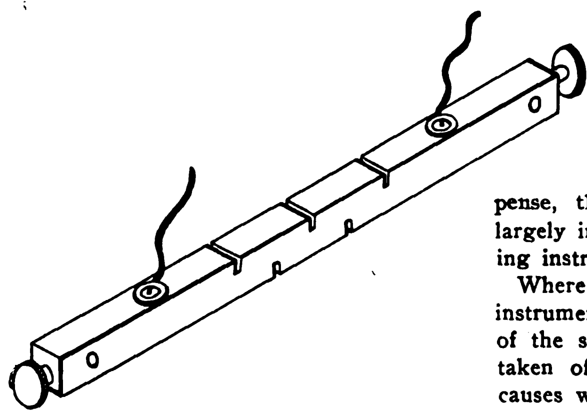

FIG. 6.—BAR SHUNT ADJUSTED BY SAW CUTS.

Where the resistance of the indicating instrument is high, as compared with that of the shunt, there need be no account taken of the reduction of potential it causes when attached to the terminals of the shunt, but where the error cannot be thus neglected the resistance of the shunt is obtained from the following formula:

$$S = \frac{R}{CR-1}$$

where S= the resistance of the shunt, R= the resistance of the voltmeter and C the current in amperes flowing through the circuit when the voltmeter indicates 1 volt. In instruments that are originally built to be used as shunt ammeters it is usually necessary to employ this formula, for their resistance is frequently so low that even an alteration in the length of their leads affects their accuracy.

REPLACEMENT OF DERAILED CARS.

BY WILLIAM HERBERT BONNER.

A derailed street car has often been, within the writer's experience, the cause of great loss of time and money to a railroad company, solely from the fact that no proper means were at hand to quickly restore the car to the rails. Every minute's delay caused by the car being held up costs money, even though it be only because the motorman must make up the time lost. On a road having a close schedule this means that all starts must be made in less time than usual, the result being that the motorman moves his switch over quickly to the parallel connection, thereby using an excess of current, which must be paid for eventually. When the blockade extends to several cars this effect is multiplied. Some damage generally results to the paving alongside the rails, where the flanges of the wheels grind and cut into the material of the roadbed, so that the longer ineffectual attempts are made to guide the car on to the rails by means of stones and fishplates and other odds and ends, the worse it will be for the roadbed. I have watched the crew of a wrecking car struggling for more than half an hour in praiseworthy but misdirected efforts to get a car back on the track. They would jack the car up at each side near the front wheels until the flanges cleared the rails, then let down at one side and push the car over in the hope of it falling down into its proper place. That operation was a long one each time, and the car always settled down in the stones alongside the track.

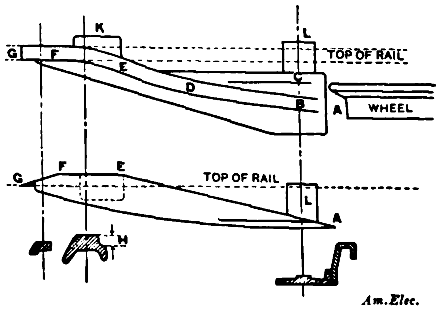

FIG. 1.—WINDING RAIL FOR DERAILING ACCIDENTS.

In the case of steam railroads it would obviously be out of the question to proceed by any makeshift methods to replace derailed cars, and a rational means is adopted which may well be applied to street cars. This consists in providing a winding rail, to be placed under the wheel outside the track, one end of the rail being laid upon the track and the other end on the ground, and the car is then drawn up on the main rails with very little loss of time. The winding rail employed is illustrated in Fig. 1, which shows a plan and side elevation. The rail as here described is not applicable to street railroad purposes, except when the lines run through country roads, where T rails may be used. A modified form will be considered presently, suited to city streets. The lower end A, Fig. 1, terminates in a flat edge perhaps ¼ in. thick, and from this end start two raised sides or flanges

B C, which act as a guide to the entering flange of the car wheel. The flange B is, in fact, the lower end of the winding rail, or guide rail, itself. As these two flanges approach each other B continually rises, so that when the wheel has reached a point (D) where there is no longer any possibility of its slipping down sideways, the flange C will be passed over. At the highest part of the guide, between E and F, the surface is flat, to allow the wheel flange to pass over. The thickness at this point (H) in the sectional view, should therefore take this into account. From F to G is a sharp incline to allow the car to run down to the main rail.

In order to hold the guide rail in position a flange should be provided at K, and at L a strip of wrought iron may be bolted to the frame and carried over the main rail to secure the lower end. The construction of both these pieces will be clear from an inspection of the sectional views given.

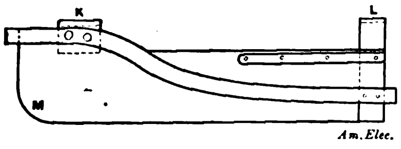

FIG. 2.—LIGHTER FORM OF WINDING RAIL.

This guide rail may be an iron or steel casting, and the illustrations are prepared with that idea in view; but it would be just as well, in the case of a street railroad, to have an oak block made the full length of the rail, from near the point G to A, and a winding strip of wrought iron 2½ or 3 ins. wide and ½ in. thick, screwed down to form the wearing surface. The advantage of such a construction is its lightness, for it would be no easy matter to handle a casting of such a size, and there would be some liability of breakage. The flange K should then be made of a strip of wrought iron also, the general construction being shown in Fig. 2.

In order to provide some means of electrical connection between the car wheels and the rails, the iron flange L should be riveted to the guide rail at B.

No mention has as yet been made of the guide to be used for the wheel on the other side. This need not be of the same shape at all, for the wheel does not require to be lifted over the rail. A plain wooden block, of the form shown in Fig. 3, will therefore suffice, and the wheel will run up on its flange. This will, of course, produce slipping, because the wheel on the other side is running on the tread, but if the block is faced with wrought iron there will be no trouble on this score. A block could be made of such a shape as to allow the wheel to run on the tread, but this would necessitate making a curve of the same shape as that on the other block, and it would also be necessary to set the two blocks more accurately with regard to each other, in order that the two curves might correspond.

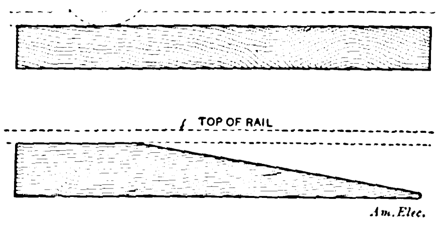

FIG. 3.—WOODEN BLOCK TO ASSIST IN REPLACING CARS.

Either the front or the rear wheels of a car are pretty sure to be close to the rail, so that usually no other operations are necessary than the one indicated; but, if this is not the case, it is an easy matter to move the car along by means of a crowbar until sufficiently near to the rails. The guide rail described may of course be used on either side of the track, as it is only necessary to run the car backward on to the track if it has left the rails on the right-hand side.

The length of the guide rails is determined principally by the distance from the top of the track rail to the ground. This may be only 1 in. or it may be the full height of the rail from the ties. In the first case the guide rail may be very light and short, while in the second case it may be 2 ft. 6 ins. or 3 ft. long. When the road level comes nearly to the top of the rail, only a slight modification of the above design is required. The total length becomes less, for the wheel has to be raised a smaller distance, and the thickness of the underlying block is also reduced, being merely that required to make up the difference between the two levels. In fact, a light guide rail of such a pattern may be used in many cases by supporting the raised corner M, Fig. 2, by means of a block of wood. The strip L may also be omitted, and contact with the rail may be secured by a through connection from the strip K.

ELECTRIC RAILWAY PRACTICE.

CAR WIRING.

BY WALTER MUNROE.

During the past few years the equipments of electric cars have undergone a marked change, and this change has been reflected in the varied methods of car control and consequently in the car wiring.

At the present time, however, the various types present considerable similarity, present practice having settled upon the method of using two controllers, one for each end of the car. These controllers are connected to each other by a number of flexible insulated wires inclosed in cotton hose. The ends protrude some distance beyond the end of this hose and the wires are tapped at convenient points with leads for the motors, resistance coils and similar devices. It is the object of this article to give some ideas on car wiring, and also to show their application.

Starting with the trolley wire, we follow the current down to the trolley base. Here the roof wire is tapped on. This wire runs along the roof through two overhead switches and then down near one end of the car to the floor. It then goes through some circuit-breaking device, a lightning arrester and a choking coil to the cable.

In the roof wiring there is opportunity to use various methods. Starting from the trolley base, we may use a well insulated wire and carry it toward the side of the car on the upper deck, until we reach a point just outside the ventilating windows. Then pass it through a hole down parallel to the windows to the lower deck. Continue it along, cleating it well up under the overhanging roof to the hood, then round the corner and in this direction until in line with a hole bored just outside the base of overhead switch fastened underneath. The wire enters this switch through a hole in the hood and leaves through another directly under the overhanging upper deck, and along on the other side of the car to the overhead switch at the other end. Leaving this it comes back along the hood parallel to the entering wire, up to the windows, and from thence down to the car floor and into the cable.

Another method is to start from the trolley base, carry the wire directly along the upper deck to the window at the end, thence through a hole in the roof to the hood and through an overhead switch. From the switch it passes back parallel to the first wire to the upper deck, across and by a similar hole through the second switch. From this point the wire is run just as in the previous case.

Where the wire traverses a length of roof exposed to the weather, it may be well to cover it with a heavy canvas strip lashed to the roof. This should be well painted, especially along the edges, in order to insure a waterproof joint. This second method necessitates boring more holes through the roof, with consequent chance of leakage through the ventilating windows. If a well insulated wire is used, it may be safely left uncovered. The only exposed portions are the short stretches on each hood.

The holes where the wires go through the roof should be lined with canvas, well painted or white leaded, and this canvas should be tacked down around the wire and hole. This point should be made water tight. When running the wire near the ventilating windows iron rods should be avoided by giving the wire a wide sweep and securely cleating in that position. In all car wiring, either on the roof or under the floor, all iron work, whether in direct connection to ground or not, should be given as wide a berth as possible.

On open cars the trolley wire is oftentimes brought from the roof down a groove cut in a corner post. It should be effectually covered up and protected by a piece of molding. Great care should be exercised in protecting from abrasion from any of the metal fixtures that may be fastened to this post.

In the closed cars, the wire can very conveniently be run down through the door casing.

No attempt will be made in this article to give the details of the diagram of any of the prominent manufacturers; but a method of wiring applicable to all will be described. The fuse box should be so placed as to be easily accessible. It should in no case be placed where the flash or noise will endanger or frighten passengers. There have been many cases of injury to passengers, panic-stricken at the pyrotechnic display of a violently blown fuse. The practice of placing fuse boxes under the seats in closed cars, in plain view of the passengers, is not to be commended. The lightning arrester should be tapped in next to the fuse box, and its ground connection should be of ample size and as short as possible. The place occupied by the lightning arrester should be chosen with some care, in order that it may be protected from injury and from mud and water from below.

There is an old type of lightning arrester which is still used in many cases, where it is necessary to place it in an exposed position. The air gap in the ground circuit is in a slit between heavy slate plates. The gap points are of metal. When correctly installed, it is so fastened that the plane of the slit is vertical and the longest dimension of the arrester horizontal. Then this prevents any foreign matter from staying in the slit or air gap, and also the retention of any melted matter from the gap points in case of a heavy discharge. A better way is to place the arrester in a wooden box, somewhat greater than its dimensions, and lined with heavy asbestos paper. The box should have ample ventilating holes in the vicinity of the slot. This box can be hinged to a baseboard and fastened down with a hook and eye. so as to facilitate inspection and cleaning. The baseboard can then be fastened to a floor timber, hinged at the top, so that the box can be readily opened. The location of the resistances is important. They should be placed so as to be out of the way of wheel-throw and the splashing of mud and water. At the same time, they should be close to the cable at the point where the resistance leads come out. This will save wire, labor in cleating, lessen confusion and minimize losses.

If there are a number of cars of the same type, it would be well to look over the floor timbers carefully and determine the best place for the resistances, choking coil, lightning arrester, etc. This being determined, the plan should be used as a sort of standard for similar cars.

The lead wires into the resistance boxes should enter in such a way that there is little chance of grounding on the frame due to abrasion. Loop the wires, if necessary, but cleat up so that there is as little motion as possible. There is always a chance of the resistance boxes becoming hot enough to scorch the floor of a car. To provide for this the "bays" in which they are installed may be lined with heavy asbestos sheet.

The method of connecting the motor leads to the cable taps is important. There should be sufficient slack to allow for all motion of motor relatively to the car floor, but no more. They should be covered with an extra heavy braided insulation. It is a good plan to slip over them a length of flexible conduit used in interior wiring, Rubber tubing is not to be commended, as it soon deteriorates.

The prepared cables, containing the wires for the controlling apparatus of electric cars, are frequently assembled at the car barns. A stranded, well insulated wire, having a double braid covering, is often used in this work. A flexible wire is much better, as it is much easier to handle and there is less danger of weakening the wire due to frequent bending. Wires equivalent to about No. 6 B. & S. are suitable for a double 25-h.p. equipment. Six or seven such wires may be drawn into 1½-in. cotton hose, this serving the purpose of assembling the wires into a compact form, and also protecting them from moisture, dust and dirt. After the wires are in the hose, it is a good plan to give the cable a good coating with insullac or some similar compound, as an additional protection.

Before starting work on the cables it is necessary to know the total length of the cable measured from just inside each controller base, and also the distance (measured along the cable) from one end of the car to the beginning of each set of taps for motors, resistance boxes, etc. To do this a flexible cord may be used, placing it along the line that the completed cable is to occupy. The positions where the taps are to emerge can then be determined.

It should be remembered that the canvas covering should extend through the end frame timber just into the controller base, hence all distances along the cord should be measured from this latter point. The wires themselves, of course, extend beyond the hose sufficiently to connect with the connection board of the controllers. If the hose and wires are made too long, the taps may be placed in their proper positions and the cable anchored at these points. Then any slack may be taken up by looping the cable out of its direct path. By this method you are sure of having enough wire and one measurement may be made to serve for different types of cars. It is, however, a rather slipshod method of working and requires extra wire.

The taps should be placed about 3 ins. apart and should have a double or preferably a triple-braided covering. They should project at least 3 or 4 ins. beyond the side frame timbers. After the distances have been determined on the flexible cord before mentioned, it will be found convenient to lay them off on a floor or long bench, as the wires can then be fixed by direct comparison.

Having determined the proper length, those points are to be bared of insulation 1½ to 2 ins.) on each side of the place of attachment of the tap. They should then be bent into a "U" shape at this point, for this will be found very convenient for treating them with soldering compound and then dipping them into a ladle of melted solder. They should be given a good smooth, solid coating. The bared ends of the stranded taps should be separated into two equal groups of wires, and these groups wound in opposite directions around the tinned wire. A careful joint should then be made by pouring or dipping. It is of considerable importance that joints be very well made, for there is always a chance for heating and burning of insulation, with consequent opportunity for a short circuit. The joints should then be covered with good insulating tape and treated with "insullac" on every layer until the last is of same diameter as original wire. If much difficulty is experienced in getting the last wires with their attached taps into the hose, the following method may be used:

The last one or two wires may be pulled in without their taps attached. They can then be pulled out sufficiently far (through the slit in the hose made for the group of taps) to permit the last taps to be put in place. A pull from both ends of the wire will then snap them back into place. The slits are then sewed up (overlapped) closely around each tap and treated with "insullac."

The following is a convenient method of placing the cables in position: Put the ends of the cables through the holes in the platform and wedge them firmly in place with wooden wedges. Then bring the groups of taps to their proper places and fasten the cable securely at these points. After that, any slack may be taken up as conveniently as possible.

There are various methods used to fasten the cables to the floor and timbers. One method is to use a cast iron strap of a U shape, with projecting ends for fastening to the wood work. When using these, the tendency is either to leave the cable loosely chafing about or else to have it so tight as to crush the insulation or covering. In either case there is chance abrasion.

A very good method is to use strips of waterproofed canvas, rather heavy, and 1½ ins. wide. These are cut in length sufficient to surround the cable easily and leave enough for a screw fastening through both ends. These are strong enough, for they can be used double if necessary. With these, each point fastened may be made to grip the cable and prevent vibration.

The actual connection of the motors, controllers and accessories to the cables is very easily completed by referring to the diagrams furnished with the apparatus.

CONNECTING ROTARY TRANSFORMERS.

Unlike the direct current dynamo it is not always safe to connect rotary transformers for series operation. They may be connected and will operate well in parallel. A moment's thought will show why series operation is impossible if the rotaries are fed from the same static transformer. The D. C. brushes of the rotary are in direct metallic connection with the transformer terminals and to provide another rotary taking current from the same transformer would be analagous to providing four terminals to a battery and connecting the + and — terminals together with the expectation of obtaining double voltage from the other two. Where the rotaries are fed by separate static transformers series connection is permissible, and this is also the case where the rotaries have independent windings. In the latter case there is also the advantage of adjustable direct current voltage by varying the field strength. With the combined winding rotary varying the field simply alters the power factor without changing the D. C. voltage.

EXPANSION OF STEAM PIPES.

BY WILLIAM BAXTER, JR.

That metals are expanded by heat is as well known as that a hot fire will boil water; nevertheless, many men who set up boilers and engines appear to totally ignore the laws of expansion and make the pipe connections wholly with a view to reducing the cost to the lowest point, or else produce the most pleasing effect upon the eye. Most of those who follow this course are men who have never had occasion to install a plant of any magnitude, and consequently never having had any trouble from the effects of expansion, take it for granted that in some way not known to them the elasticity or some other property of the iron counteracts the thermic action. There are many who actually believe that although a steam pipe will elongate when heated by the steam, if free to move, that if constrained the elasticity of the metal will enable it to compress to the same extent as it is expanded, so that upon the whole its length remains unchanged. This notion, it is hardly necessary to say, is entirely incorrect, and those who believe it fail to notice that every case that apparently substantiates it proves just the contrary, and if properly investigated it would be found that the pipes run in such a direction that they can spring sufficiently to compensate for the expansion. When the pipes cannot spring as much as is necessary they soon begin to leak, and from that time onward continue to be a source of annoyance until their location is changed. A pipe connnection in a straight line from the boiler to the engine is hardly possible, owing to the fact that the outlet from the former is several feet higher than the inlet in the latter, therefore there will be at least one bend, and if there is not too much difference between the parts of the pipe on each side of the bend there will generally be little or no trouble experienced from the effects of expansion.

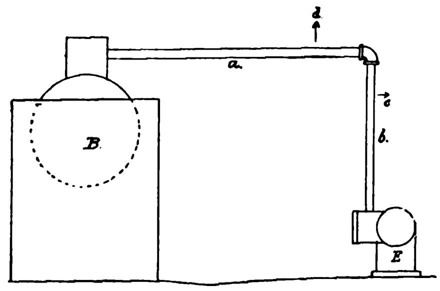

FIG. 1.—SIMPLE STEAM PIPE CONNECTION.

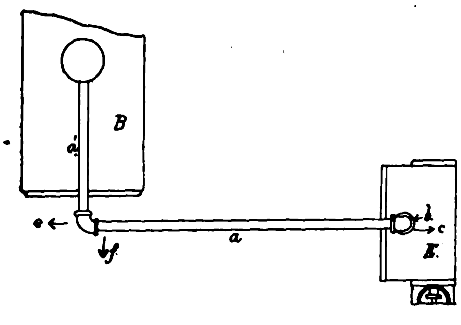

FIG. 2.—MODIFICATION OF FIG. 1.

About the simplest manner in which an engine can be piped is as shown in Fig. 1, in which B represents the boiler and E the engine; a and b being the pipe. If the section b is very short, the displacement of a in the direction of the arrow d, caused by expansion, will be small and will not produce a serious strain upon the joints at the ends of a; but the movement of b, in the direction of the arrow c, will be sufficient to strain the joints at the bend and at the top of the steam chest enough to cause them to leak, and if b is short enough and a sufficiently stiff, may actually result in breaking the pipe b. If a and b are of equal length, the strain upon the joints will be reduced to the lowest point. The longer a and b are the less the strain will be, although, within very wide limits, the length makes very little difference, owing to the fact that as the length increases the side displacement due to expansion increases.

When the pipe has two bends, as in Fig. 2, the strain impressed upon it by expansion is greatly reduced, for then the section a′ can move in the direction of arrow e, thus reducing the displacement of b in the direction of c. In addition to this, the elongation of b can be compensated for in part by the movement of a and a′ in the direction of arrow d, in Fig. 1, and in part by the twisting of a′. In the same way the elongation of a′ can result in moving a and b in the direction of arrow f, and also in giving b a slight twist.

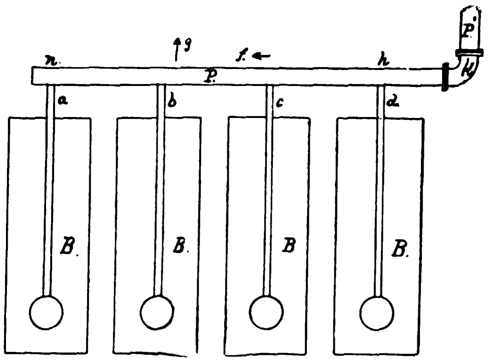

FIG. 3.—HEADER CONNECTIONS.

An engine piped as in Fig. 2 is not likely to give trouble on account of leaky joints, but if piped as in Fig. 1 it almost surely will if there is a considerable difference between the lengths of sections a and b.

In such cases as the foregoing, where one engine is connected with one boiler, it is more difficult to run the piping so as to be injured by expansion than to so dispose it as to be unaffected; when, however, a number of boilers or engines, or both, have to be connected in one general system, as is illustrated by the diagrams, Figs. 3 and 4, the conditions become reversed, and unless the piping is planned by one who is familiar with the laws of expansion, and has due regard for them, serious results are almost sure to follow. In Fig. 3 the boilers B, B, B are connected with the main steam pipe P by the pipes a, b, c, d. Studying this diagram we can see that pipe P will be elongated by expansion, and if held immovable at the end from which P′ leads, its elongation will result in bending to the left all the pipes leading from the boilers. The pipe d will be bent only a small amount, as it is only affected by the expansion of the length, h k, but pipe a will be bent much more, being acted upon by the expansion of the entire length of pipe P from k to n. Unless the pipes a, b, c and d are of considerable length, the movement of a may be more than its elasticity will permit, and the result will be that it will soon leak at the joints. From this it can be realized at once that it would be impracticable to move the pipe P down to the point where the small pipes tap the boilers, and make a direct connection, for under such conditions the expansion would either cause the boilers to move bodily, or else it would break off the connections between them and the steam pipe. Not only must the pipes a, b, c, d be provided, but their length must be so proportioned with reference to the length k n of pipe P that the displacement of a will not be enough to strain the metal beyond the elastic limit. The expansion of the pipes a, b, c, d will move the main pipe P in the direction of the arrow g; therefore P′ must be so arranged that it can move endwise as much as may be necessary to provide for the expansion of the small pipes.

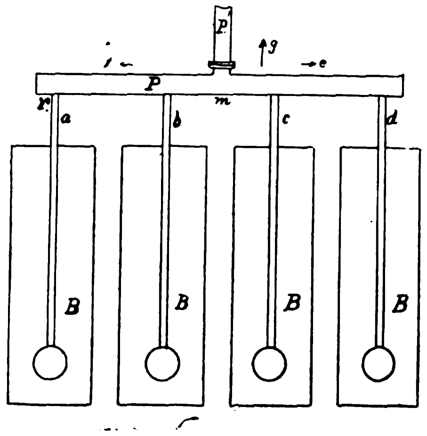

FIG. 4.—HEADER CONNECTIONS.

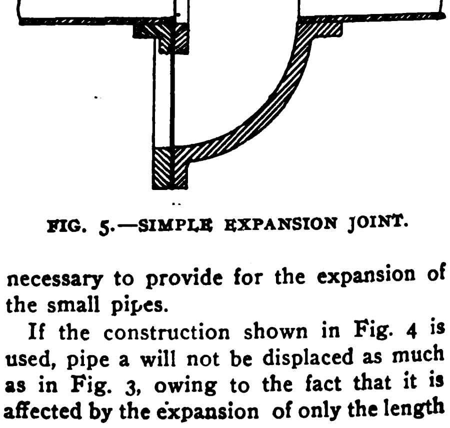

FIG. 5.—SIMPLE EXPANSION JOINT.

If the construction shown in Fig. 4 is used, pipe a will not be displaced as much as in Fig. 3, owing to the fact that it is affected by the expansion of only the length m r of P, which can be less than one-half of k n in Fig. 3. Since the displacement of a is very much less, the length of the connecting pipes a, b, d, c can be greatly reduced, and as a consequence the displacement of P in the direction of arrow g will be reduced. The transfer of P′ from the end of P to the center, as shown by the foregoing, will render possible the reduction of the length of the pipes a, b, c, d, and in addition, will reduce the displacement of P, and thus make it easier to compensate for expansion beyond this point.

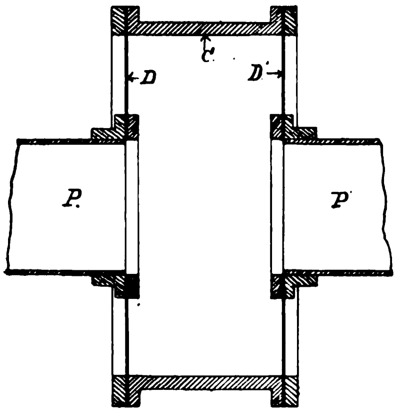

FIG. 6.—DOUBLE DIAPHRAGM JOINT.

From a superficial glance anyone would be able to see that the arrangement of Fig. 4 is superior to that of Fig. 3, but it is not until we investigate carefully that we are able to note the decided superiority. As in Fig. 4 the side displacement of a is less than one-half as much as in Fig. 3, the length of the pipes connecting the main pipe with the boilers can be cut in two, and this not only reduces the piping to a more compact form, but also reduces the displacement of P in the direction of arrow g to one-half, which means that the movement in P′ to be provided for is one-half as much as in Fig. 3.

When the number of boilers is not over four or five, and the size of the pipes a, b, c, etc., not over 4 ins., the construction shown in Figs. 3 and 4 can be used; but when there is a long string of boilers, or when their size is such that the pipes a, b, c, etc., are larger while the length has to be reduced, then the expansion cannot be taken care of by the side springing of the pipes. In such cases it is necessary to provide some form of expansion joint. In some cases the piping may be so arranged that the greater part of the expansion can be provided for by the displacement of the pipes, so that one joint will be sufficient; in other cases, however, it may be necessary to provide several expansion joints. A simple form of expansion joint is that in which one pipe slips inside of the other, a stuffing box similar to that used on the piston rod being provided to make a steam-tight fit. For small pipes this answers very well, but for large ones it is expensive and more or less troublesome to keep in good order. Figs. 5 and 6 show modifications of simple diaphragm expansion joints, that are well adapted to many cases, particularly where the movement to be provided for is not very great. In Fig. 5 P and P′ are the two parts of the pipe joined by the expansion joint. Upon the end of P is secured the flange b, and upon P′ the casting c. A diaphragm, D, is secured to flange b by means of the ring a and suitable bolts; and to the casting c, by means of the ring e. This diaphragm is generally made of copper, and is corrugated in circular lines so as to increase its flexibility. When one diaphragm is not sufficient to provide all the movement necessary, the construction of Fig. 6 is used, in which, there being two diaphragms, the movement is doubled. Neither one of these designs is well adapted to high pressure, owing to the fact that unless the diaphragms are thin they cannot spring to any extent, and if thin they will not withstand much pressure unless the diameter inside of casting c is not much greater than the outside diameter of b. This difficulty, however, can be overcome by resorting to the construction shown in Fig. 7, which differs from Figs. 5 and 6 in being supplied with bridge pieces, s s, which reinforce the diaphragms. These pieces, which are of sectoral shape, as shown at A, are supported at the outer ends by the overlapping edge b of the ring B, and at the inner ends by the overlapping edge a of flange E. The pressure of the steam acting from within forces the diaphragms D against the supporting bridges s s; thus these carry nearly all the strain, and the diaphragms only need be of sufficient thickness to resist the pressure acting over a comparatively short distance near the inner and outer edges, and also to resist the flattening out of the corrugations against s s. As with this construction the diaphragms are relieved of nearly all the strain, and as there is no difficulty in so proportioning the bridges s s that they may carry any amount of pressure, the distance a b spanned may be any amount desired; therefore, the movement obtainable from a single diaphragm may readily be made as much as 1 or 1½ ins. for a joint suitable for a 10-in. pipe.

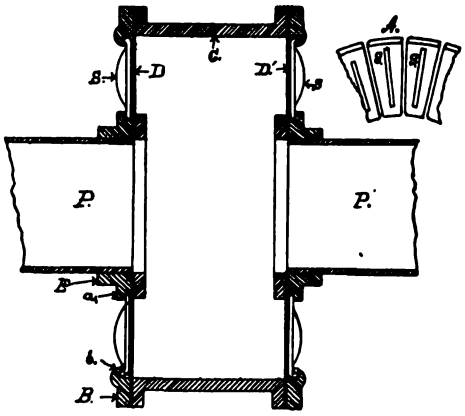

FIG. 7.—REINFORCED DOUBLE DIAPHRAGM JOINT.

In order to obtain the greatest amount of movement from these joints it is necessary that the length of the pipes be such that when cold the diaphragms will be drawn outward at the center to a distance equal to one-half the total movement, then when the expansion reaches one-half the maximum amount they will be in the position shown in the figure.

To be able to determine whether it is necessary to resort to expansion joints or not we must know the rate at which iron expands with rise in temperature, and also the extent to which pipes can be deflected sidewise without weakening the joints. The elongation of steam pipes carrying 100 lbs. pressure may be taken roughly as equal to two-hundredths of an inch per foot of length, and the deflection for pipes under 5 ins. diameter as equal to fifteen-hundredths of an in. per ft., divided by the diameter of the pipe in ins. From these figures we can see that, roughly, a pipe 12 ft. long will expand ¼ in. in length, and if its diameter is 3 ins., equal to 3½ in. outside, the safe side motion will 12 times 15-100 in., divided by 3½, or a little more than ½ in. Applying these figures to Figs. 3 and 4, we will find that if the pipes a, b, c, d are 12 ft. long and 3 ins. in diameter and 10 ft. apart, the expansion of pipe P in the latter figure will not be more than the permissible side movement of the smaller pipes, but in Fig. 3 it will, for in this construction the length of P from a to d is 30 ft.; therefore, from P′ to n probably 35 ft.; which would make the elongation about 7-10 in., or nearly 50 per cent more than pipe a could safely withstand. Hence, to make this construction perfectly safe it would be necessary to increase the length of the small pipes, or if this cannot be done from lack of room or any other cause, to place an expansion joint in P between pipes c and b.

◆

AMERICAN TELEPHONE PRACTICE.

LUMINOUS SIGNAL SWITCHBOARDS.

BY KEMPSTER B. MILLER.

In the last two articles in this series a somewhat detailed description was given of the various types of so-called self-restoring switchboard drops. In all of the telephone exchange systems so far outlined the various signals for attracting the attention of the operator have been given by some form or another of electro-mechanical annunciators, of which those of the self-restoring type represent the highest development. An entirely different class of signals has recently come into very general use, especially by the Bell Company, namely, the incandescent lamp or luminous signal, as it is termed. The use of the incandescent lamp as a signal in telephone work was, so far as I am aware, first proposed by Mr. J. J. O'Connell of Chicago. Luminous signals and, in fact, incandescent lamps, had however been used at an earlier date for signaling in other lines of work.

The advantages of the incandescent lamp over the electro-mechanical signal are many, and among them may be mentioned the following: First, they are capable of attracting the attention of an operator with much more certainty than the ordinary mechanical shutter; second, they are entirely free from mechanical complication, and therefore unlikely to get out of order or to fail in action, unless entirely destroyed; third, they are much more compact than even the simplest electro-mechanical signals; fourth, they are entirely automatic in their operation, being always restored to their normal condition by a cessation of the current through them; fifth, by the use of various colored glass in front of them they may be used in the same board as indicating separate kinds of information; sixth, they are easily replaced when destroyed; and seventh, they are as cheap, if not cheaper, than the high-grade tubular drops now in such common use.

Obviously there two different methods of associating incandescent lamps with the circuits of the subscribers' lines. The first of these and, without mature consideration the most desirable, is to place the lamp directly in the circuit of the subscriber's line and operate it automatically by a change in resistance in the line, brought about by the removal of the subscriber's receiver from the hook. The second is to have the lamp in a local circuit controlled by a relay directly in the line circuit, which relay may be operated by an ordinary subscriber's magneto generator or by a source of current at the central office thrown into action by a change of resistance at the subscriber's station.

A system using the first method is shown in Fig. 1, in which the subscriber's apparatus is shown at S and the central office apparatus at C. The line wire 2, forming one side of a metallic circuit, is connected with the tip spring t of the jack J, and passes through an incandescent lamp, l, and through an inductive resistance, h, to one pole of a battery, i. The other side, 3. of the metallic circuit passes through an inductive resistance, g, to the other pole of the same battery. When the subscriber's receiver is on its hook the circuit at the subscriber's station between the two sides of the line wire is completed only through the high resistance call-bell, e, and as this bell has a resistance of about 1000 ohms, the current from the battery, i, through the line circuit is not sufficient to illuminate the lamp, l. When, however, the subscriber's receiver is removed from its hook a circuit of low resistance is closed in parallel with the bell magnets, e, this circuit including the secondary winding, c_2, of the induction coil, and the receiver, b, in series. As this circuit may readily be made less than 40 ohms, sufficient current will be allowed to flow from the battery, i, to illuminate the signal, and thus attract the operator's attention. Another feature of this system and one which it was not the purpose of this article to illustrate, but which, owing to its extreme ingenuity, should be mentioned in passing, is the peculiarity of the arrangement of the battery, d, with respect to the circuits of the subscriber's station. It will be obvious that whatever current passes through the bell magnets, e, from the battery, i, at the central office, must also pass through the battery d. This consists of two cells of storage battery of the Plante type. Whenever the apparatus at the subscriber's station is not in use this battery will therefore be receiving a charge from the central office source, the strength of the latter and the resistance of the circuits being so proportioned that the storage cell will receive a constant charging current of about .02 of an amp. When the subscriber's apparatus is put in use, however, the battery is thrown in a local circuit including the primary winding, c^1, the transmitter, a, and the contact point, f^2, and will then perform the functions of an ordinary primary battery in connection with the transmitter. The chief novelty in this system consists in the alternative function which this battery, d, may perform. It is well known that if a storage cell of the Planté type becomes almost or quite discharged it will develop a counter e.m.f. when a current is sent through it in the direction necessary to charge it, and that this counter e.m.f. will be very nearly equal to the e.m.f. of a similar cell fully charged. Supposing, now, that from some cause or other the cell, d, becomes discharged to such an extent that it is incapable of furnishing enough current to operate with the transmitter, a, in the usual manner. In this case, when the receiver is raised, the current from the battery, i, at central, which tends to pass through the storage battery, will meet with a considerable counter e.m.f., which will compel most of the current to pass through the secondary c^2, receiver b, wire 4, wire 6, contact f^2, wire 5, transmitter a, primary coil c^1, and to the line wire, 3. The transmitter, a, will therefore receive current from the battery, i, sufficient to operate it, and yet it will be operating with all the advantages to be derived from a local circuit and induction coil; for, although the current operating it comes from the central office, any fluctuations in this current caused by the transmitter, a, will pass through the low-resistance battery, d, which will act in this case very much in the same manner as a condenser. This system is the invention of Mr. C. E. Scribner of Chicago.

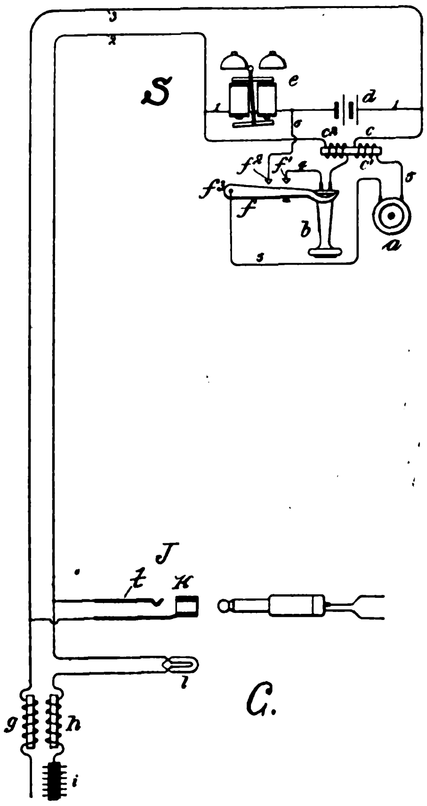

FIG. 1.—CONNECTIONS FOR LUMINOUS SIGNAL.

To return now to the luminous signal feature, we find ourselves confronted with several rather serious objections; in the first place, the resistances of no two subscribers' circuits are the same, owing to the differences in the lengths of these circuits and other causes, and therefore either the resistances, g or h, or that of the bell magnets, e, will have to be varied in each case in order to insure the proper amount of current passing through the lamp, l. This is a feature easy to overcome, and a much more serious one is that arising from crosses between two line wires from any source whatever, such a cross, of course, always subjecting the lamp to an undue amount of current, and therefore burning it out. This latter objection has proved so serious as to cause the abandonment of the plan of including the lamp directly in the line circuit in nearly every case where it has been tried. Of course, for underground systems this objection is not such a serious one.

Passing now to the second method of associating the lamp signal with the line circuit, reference will be made to Fig. 2. This shows the circuits of three subscribers' stations, S, S^1 and S^2, these circuits being connected with the central office by the metallic circuits, 1, 2. The line wire, 1 in each case passes to the sleeve spring, d^2, of the spring-jack, J, and thence through the relay contacts c^1, to the ground. The line wire, 2, passes in a similar manner to the tip spring, d, thence through the relay contacts, c^2, the winding of the relay, b, and the battery, a, to the ground. The signal lamp, e, is in each case included in a local circuit containing a battery, f, common to all lamps, and the contact, 4, of the relay, b, belonging to its line. The relay, c, of each line which controls the contacts, c^1 and c^2, is known as the cut-off relay, and is included in a local circuit through the jack thimble, d^1, and the plug contact, m, with the battery, n, whenever a plug, l, is inserted into a jack for making connection with the line. The two sides of the line at the subscriber's station are permanently closed through a high-resistance bell, B, and a condenser, C, the latter being of considerable capacity, so as to allow the alternating currents from the calling generator at the central office to pass through it and operate the call bell in the usual manner. The high impedance of the call-bell magnets, however, prevents the short circuiting of the voice currents when the receiver is removed from its hook. The call-bell circuit therefore presents an open circuit to the direct current from the battery, a, thus normally insuring a condition of no current upon the line wire. When, however, the receiver at the subscriber's station is removed from its hook, a path of comparatively low resistance is formed between the two low line wires, and a current proceeds from the battery, a, through the relay, b, contact, c^2, line wire, 2, to the subscriber's station, back by line wire, 1, through relay contact, c^1, and by ground to the opposite terminal of the battery, a. This current is sufficient to operate the relay, b, and unlike the case where the lamp was used directly in the line wire, a considerable variation in the amount of this current is allowable. The operation of the relay, b, closes the circuit of the lamp, e, through the following path: From the battery, f, through the relay, g, wire, 5, common wire, C, lamp, c, wire, 3, relay armature, 4, and back by ground to the opposite pole of battery, f. For the purpose of clearness the relay, g. need not be considered at all at present, as it has nothing to do with the operation of the lamp, e, and we may therefore consider one pole of the battery, f, to be connected directly to the common wire, C. The closure of this circuit illuminates the lamp, e. The next step in the operation of the system is the insertion of the plug, l, into the jack of the line on which the signal is displayed. The insertion of this plug closes the circuit through the relay, c, over the following path: From the battery, n, wire, 10, plug sleeve, m, thimble, d^1, wire, 9, relay coil, c, to ground and back to the opposite pole of the battery, n. This causes the relay to attract its armature and break both of the contacts, c^1 and c^2, thus accomplishing a double purpose, the first of which is to break the circuit through the relav, b, and thus cause it to release its armature, 4, breaking the circuit through the lamp, e; and the second of which is to cut off both sides of the line circuit, 1, 2, beyond the spring-jack, J. This latter feature is a very important one, since it removes all difficulty from cross talk and other troubles in the auxiliary circuits of the central office.

The circuits illustrated in Figure 2 are substantially those in common use by the Bell Company in their lamp signal exchanges, so far as the circuits of the relays and lamps are concerned. Several different modifications of the circuits at the subscribers' stations have, however, been used. The subscribers' stations may or may not include local batteries, and the tendency of practice is now to do away with these entirely and to supply current from central office for the operation of the transmitters as well as for all signaling purposes; this feature, however, will form the subject of subsequent articles.

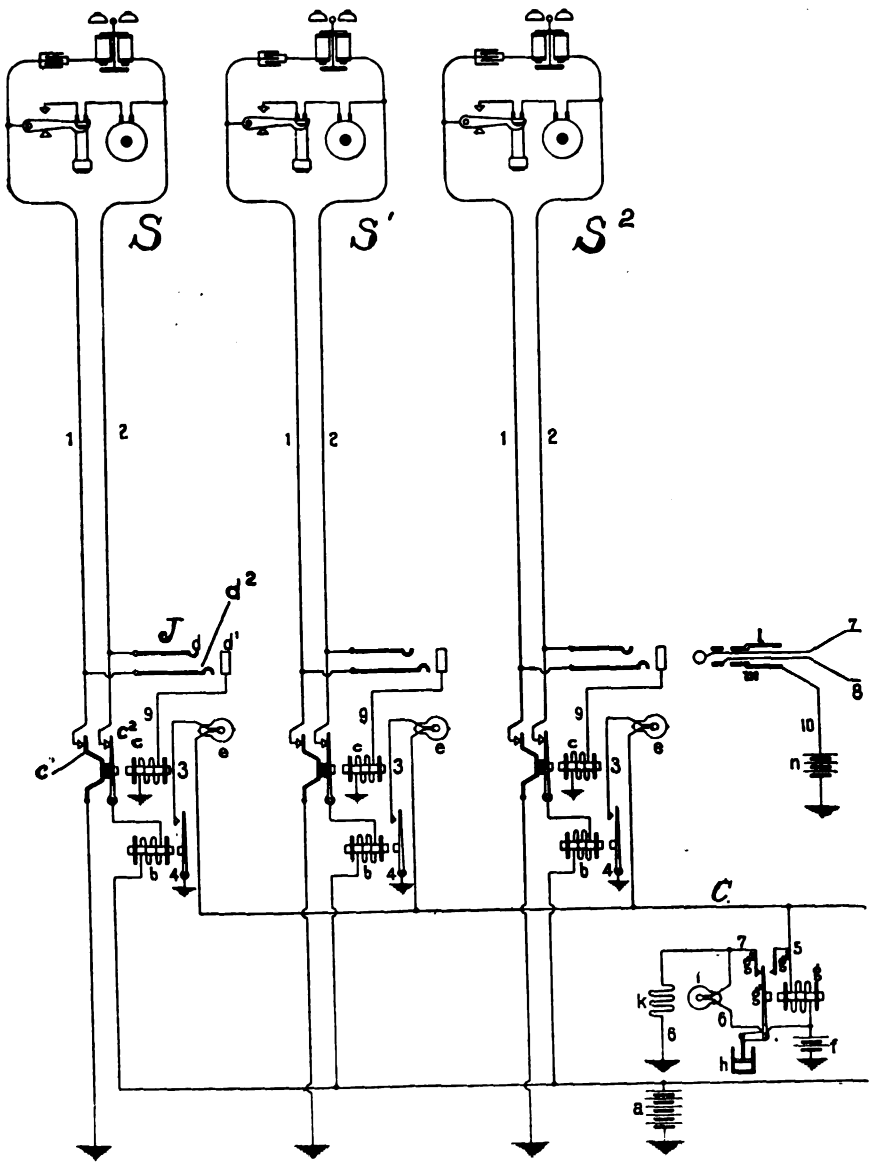

FIG. 2.—SECOND METHOD OF LUMINOUS SIGNAL CONNECTIONS.

The relay, g, and its associated apparatuses form a very interesting addition to the system as outlined. It is found desirable to use what are termed pilot lamps for certain groups of line lamps, for the purpose of attracting the operator's attention more surely to a signal on her board. If two or more signals are displayed at once, but one of them may attract the attention of the operator, who might therefore neglect the other. Pilot lamps are used in such connection that they remain lighted as long as any one of the line lamps in their group are lighted, and as they occupy a very conspicuous position and are as a rule brighter than the others they cannot escape the operator's attention. Obviously it would be a serious objection to put a relay for operating such a pilot lamp in the common wire, C, of the local circuits of the lamps, e, for the reason that the fall of potential or drop through such a relay would vary, according to the amount of current passing through it, and if several of the lamps, e, were operating at the same time, they would probably not therefore receive enough current to properly illuminate them. The relay. g, is therefore included in circuit with battery, f, and means are provided whereby its resistance will be short circuited the instant it is operated. To accomplish this, the armature, g^1, makes contact with the point, g^2, as soon as it is attracted, thus short circuiting the resistance of the coil, g. At the same time it breaks contact with the point, g^3, and thus allows the current to flow from the battery, f, through the lamp, i, and resistance, k, thus illuminating the lamp. In order that the armature, g, may not fall back against the contact point, g^3, as soon as the coil, d, is de-energized by being short circuited, a small dash pot, h, is provided in connection with the armature to render its movements sluggish. Thus before the armature, g^1, has time to move very far away from the point, g^3, owing to its sluggish action, it will be at once attracted again, and the interval during which the resistance coil, g, is in circuit with the common wire, C, and the lamps, e, is so small that it does not have time to affect these lamps. This system is also due to Mr. Scribner, and both it and the one shown in Fig. 1 form interesting examples of the highly skillful manner in which he always solves his telephone problems.

The incandescent lamps commonly used for signaling purposes and telephone work are of the type shown in Fig. 3; the lamp is about ⅜ of an in. in diameter, and 1¼ ins. long over all. They are commonly built for 10 or 20 volts pressure, the tendency being rather to increase the voltage than to decrease it. At first lamps of 2 and 4 volts were used, but for various reasons, not the least among which was the trouble of securing proper contacts at the relay and switch points for such low voltages, the voltage was gradually increased to the above mentioned figures.

Mr. A. H. Abbot of Chicago has recently given some interesting figures concerning the life of incandescent lamps in switchboard work, and mentions one case where a lamp was flashed over a million times without showing serious signs of deterioration. His tests seem to indicate that for general service in switchboard work the average lamp will live for a period of about 1200 hours, although in laboratory tests a much longer life has proved possible. He points out, as a result of his observations, that, according to theory, the lamps used in subscribers' line circuits should last about 25 years and those in the cord circuits used as "supervisory" and clearing-out lamps, for from one to two years. He also says that such a life has already been obtained in the cord circuit lamps, but that it is doubtful if the theoretical limit for the line lamps will ever be closely approximated.

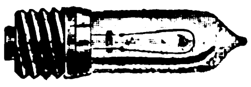

FIG. 3.—SIGNAL LAMP

LESSONS IN PRACTICAL ELECTRICITY

HOW TO DESIGN A DYNAMO.

We must now make some preliminary calculations to see whether or no the armature we have designed in the last section will overheat.

There are two sources of heat in an armature under load, viz., the core loss and the wire loss. The core loss, in turn, consists of two parts, that due to eddy currents and that due to hysteresis. The loss by eddy currents it is impossible to calculate. It depends upon the specific resistance of the metal, the degree of lamination of the core, the quality of insulation of the laminations, conditions which it is very hard to determine; and, even if they be known, the formulæ will be highly empirical. Fortunately, eddy current losses are usually slight.

Hysteresis, on the other hand, is very readily calculated by the aid of appropriate tables. These tables, which are to be found in many reference books, usually give the loss in watts, per cycle, per second, per cubic inch of iron, for the various densities of magnetization. We must, therefore, calculate the number of cubic inches of iron in the various parts of our armature and determine the magnetizations to which they are subjected. The teeth we already know to be substantially trapezoidal in section, with an altitude of 695.8 mils, and we can readily compute the average width, which we will find to be 211 mils. This gives a section of .1466 square ins. Multiplying this by 11, the length of the armature, we obtain the volume of one tooth, and by 42, we obtain 67.75, the volume of all the teeth in cubic inches. To find the maximum flux to which these teeth are subject it is necessary to compute the area of each tooth at the root. The dimensions, as we already know, are .1585 ins. wide by 11 ins. long. We must now assume a polar arc in order to find how many teeth are doing duty in carrying the flux. The poles are commonly supposed to cover two-thirds of the armature, the remaining one-third being split up into gaps between the pole tips. Therefore one-third of the teeth are carrying the total flux—that is, practically 14 teeth are carrying the total flux of 3,095,240. The effective area of the roots of the 14 teeth is 24.4 square ins., and hence the density is 126,500 lines per square inch. Referring to tables, we find that the number of watts lost per cycle per minute in a cubic inch of iron at that density is .00047.

We have 67.74 cubic ins. of iron, and as we are running at 1500 revolutions we have 1500 cycles per minute, the total watt loss due to hysteresis in the teeth is 67.74 × 1500 × .00047 = 47. 7 watts.

We now come to the hysteresis in the armature body proper. That was designed with iron area to carry 70,000 lines per square inch. The iron carrying this flux is a hollow cylinder about 5.1 ins. in external diameter by 1¼ ins. in internal diameter. Its volume is therefore, 211.3 cubic ins., and, applying similar methods, we find the loss in this part of the core to be 63.4 watts.

We now pass to the calculation of the wire loss. The length of each turn consists of a loop, the sides of which are each 11 ins. and the ends about 7½ ins. Although the armature is 6½ ins. in diameter, we must add a certain amount on account of overlapping of the ends. This makes the total length of loop 37 ins. We have 84 such loops, giving a total length of wire on the armature of (84 x 37) or 3108 ins. We selected in the first place No. 8 Brown & Sharpe wire, and the resistance of such a piece of wire, computed from the wire tables, is .163 ohms. The current circulating in this wire at full load is 27½ amps., and the loss in watts is obtained by squaring the current and multiplying by the resistance, and will be found to be 123.1 watts. We now must refer to practical experience, and that tells us that if the armature losses do not exceed one watt per square inch of radiating surface there is no danger of overheating. The armature consists of a cylinder, which in its completed state will be about 12 ins. long and 6½ ins. in diameter. The surface of such a cylinder is 312 sq. in., giving a radiation of about .75 watts per square inch. This shows that the armature is very suitably designed for its work; in fact, it would carry a substantial overload without trouble.

We must also remember that we have figured very liberally in making this calculation. We have, for instance, assumed for the total density throughout the teeth that at the narrowest section, which is not strictly the fact, and we have also figured the armature as a solid mass of iron, whereas it is made up of laminæ, and the assumption that it was solid erred perhaps within 5 or 6 per cent, according to the thickness of the insulation between the plates. It is, however, always best to figure in this way, for calculations on hysteresis loss are apt to be thrown many per cent astray, due to the fact that iron is not at all uniform in this respect. In fact, it may easily be that of two samples, apparently similar, one will consume twice as much energy as the other, when subject to a certain cycle of magnetization.

It is not the purpose of these lessons to take up mechanical points in design and construction, but simply to show how to determine magnetic and electrical dimensions. We may now summarize the following for our armature:

Core disc, external diameter	6½ ins.
Core disc, internal diameter	1¼ ins.
Number of slots	42
Width of slot	225.5 mils.
Depth of slot	695.8 mils.
Thickness of slot insulation	35 mils.
Size of armature wire	No. 8 Brown & Sharpe
Number of wires per slot	4
Total number of wires	168
Number of bars in commutator	42
Length of core	11 ins.

Before finally accepting this design we must make one more precautionary calculation, that of the peripheral speed. To do this we, of course, multiply the circumference in feet by the number of revolutions per minute, obtaining a peripheral speed of 2550 ft. per minute. A conductor velocity under 4000 feet per minute is permissible in such an armature, and hence we may regard the design as satisfactory and proceed to the field magnet calculation.

In calculating the field magnet we must first determine what material shall be used; something about its magnetic permeability, and similar matters. We must further determine what is known as the leakage coefficient. It is a fact that of all the lines generated in a field magnet frequently one-third, or sometimes as much as one-half, are lost in leakage; and the ratio of the total flux to the useful flux is known as the leakage coefficient.

There exist a great many empirical formulæ for calculating this leakage coefficient beforehand, and they are moderately reliable, though somewhat complicated in their application. A practical designer is usually well acquainted with the leakage coefficients of the various types of field magnet, which he is wont to adopt and can make a very shrewd guess as to what the average leakage coffiecient will be. Moreover, in designing a field magnet, a margin is always allowed for rheostatic control, and this margin ought to exceed any error in leakage coefficient determination. For the purpose of this article it is sufficient to select the leakage coefficient from the table of average values given in the August number. For a 5-k.w. machine this is 1.6. It therefore follows that we must generate in the field magnet 1.6 times the number of useful lines we use in the armature, which will amount to 4,952,384 lines of force. We will further assume that the field magnet be a steel casting, which can be comfortably worked at 90,000 lines to the square inch, without using excessive magnetizing power. The area of the field magnet waist must be therefore 55.02 sq. ins., and if we assume this area to be circular it will have a diameter of 8.36 ins. The next question is the length of this magnet waist.

From a theoretical point of view, this magnet waist should be just long enough to allow the requisite number of ampere turns to be wound upon it, for any added length increases the length of the magnetic circuit. Practically speaking, such a construction is a mistake, because it is frequently desirable to rewind the field magnet and frame for other voltages and capacities, and some flexibility in the size of the bobbin that may be put on is highly desirable. Moreover, the reduced length of the magnetic circuit, obtained by careful calculation, would only diminish its reluctance a very few per cent, and the gain in magnetizing energy would be almost microscopic.

We may take as a reasonable assumption, for the purposes of preliminary calculation, that the total reluctance of the magnetic circuit is equal to double the reluctance of the gap space. This proportion obtains in good dynamo design. The reluctance of the gap space has already been determined by our previous assumptions. Its area is practically equal to the area of the polar faces, and its length is the minimum length that mechanical conditions will permit, and may in this machine be as close as one-twentieth of an inch. If, therefore, we multiply the total number of lines of force by this length in inches and divide it by the area and multiply that result by .3132, a constant which transforms c.g.s. magnetizing force into ampere turns, and also takes into account English measures, we shall obtain the number of ampere turns necessary to force the flux through one of the gap spaces. As there are two gap spaces we must double this amount. The calculations are shown below:

$$\text{Area of pole piece} = \frac{6.5 \times 3.1416 \times 11}{3} = 75$$

$$\text{Ampere turns} = \frac{3{,}095{,}240 \times .05 \times .3131}{75} =$$

648 for one gap

Ampere turns both gaps = 1396.

If we take double the ampere turns necessary for the gap spaces we shall find the total ampere turns to be 3792, and we are ready to determine approximately the size of the shunt wire necessary to produce this magnetization, and from that to gain an idea of the size of the field coil.

It is to be understood that these calculations are preliminary, and, having thus obtained the dimensions, it will be necessary to review the latter carefully and modify them where they are objectionable. Such methods as this are frequently used in dynamo design, and in all other cases where results that are opposed to each other are desirable. Thus it is desirable to have low speed, small exciting current and minimum armature reaction. Low speed demands strong field and many armature conductors. Small armature reaction, on the other hand, requires few armature conductors, and strong field requires large exciting current. It will be necessary, therefore, to subsequently adjust these conflicting conditions to a happy medium.

Letters on Practical Subjects

Hardening Machine Tools.*

To the Editor of American Electrician:

Sir: There are two things of vital importance in hardening milling cutters or other tools that have to be hardened all over: First, heat evenly and not too hot; second, cool evenly and quickly. Do not try to heat the cutters in too small a fire. Build up a good big fire of charcoal, so that the cutters (or other articles) are surrounded on all sides by a mass of glowing coals of uniform temperature. A moderate natural draught is much to be preferred to a blower blast. If there is no natural draught it may be necessary to use the blower, but this should be done with the utmost caution, as it tends to make an intensely hot spot directly over the tuyere, surrounded by zones of successively lower temperature, which may render it impossible to do good work or even cause the work to crack when it is dipped. There is no advantage in heating very slowly; in fact, it is better for the steel not to keep it in the fire any longer than is necessary to bring it to the proper heat all over, without overheating any part.

When the cutter has reached the proper temperature for hardening (which varies somewhat with different brands of steel, most kinds requiring a cherry red, but some hardening at a blood red), it should be removed and dipped.

If it is bad to use a small fire, it is worse to use a little water. Do not try to harden a big cutter in a little pail of water. Have a tub made from half a whiskey barrel, at least. A whole barrel with one head removed is still better for large work, on account of the increased depth. Fill the tub or barrel with strong brine. The salt raises the boiling point, thereby increasing the cooling action.

Lift the cutter by means of a small rod with a hook bent on the end, inserted through the hole. Do not use a rod that fills the hole, as the brine should have free access to the interior. Hold the cutter over the center of the water and immerse by a quick but steady motion, perfectly straight down. Do not go in with a splash, and do not hesitate. Do not stop and hold the cutter still as soon as it is immersed, but lower it to the bottom, and then pull it up again. Keep it moving until it is cold.

A cutter of large diameter and small width, that is, disc shaped, should be immersed edgewise. If the axial dimension is considerable, that is, if the shape is cylindrical, the cutter should be immersed end first. Some prefer to finish the cooling in oil, as less liable to crack the work. As soon as the work has cooled sufficiently to become black on the outside, remove it from the brine and immerse in a tank of oil, keeping up a lively motion until it is cold.

When the cutter is cold, polish a few teeth with emery cloth so as to observe the colors in drawing the temper. Draw to a light straw color and cool off in water or oil. It is essential that the heat should be perfectly uniform. An excellent way to draw the temper of a cylindrical cutter is to put it on a red hot iron rod which nearly fills the hole held horizontally, and keep it turning slowly. Small cutters may be drawn in the gas, and large ones of any form drawn on a hot iron plate, turning them over and over all the time. They may also be drawn by direct exposure to the fire, but this requires much greater care to secure good results.

TOWNSEND WOLCOTT.

Some Electrical Sport.

I take the liberty to review for the edification of your readers two experiences which are along the line of the electrical sport which has appeared from time to time in your columns, and which may amuse your readers. It requires practical experience in such matters, however, to appreciate them fully. The first of these "jobs" entailed the doctoring of door knobs. Quite a number of the street urchins used to be in the habit of visiting the station. They would prowl around into every room and peek into cupboards where they had no business whatever. We could not watch them all the time, and to lock up every door proved so great a nuisance that it was abandoned.

Finally all the door knobs which were metallic concerns were connected up, having first been fitted with contact points so arranged that if the knobs be turned more than the stated distance in either direction a circuit would be closed which contained the intruder's body as a part thereof. By turning the knob just far enough to move the bolt contact would not be made, and doors and cupboards could be opened at will without danger or even discomfort.

An excellent magneto was in the station; this instrument was permanently connected up and driven by a belt which ran continuously. One side of the magneto was grounded, the cement floor of the station offering an excellent opportunity for the door knob business. Each knob and cupboard catch was then connected up as described. The result was that every street urchin received a severe shock, but none of them ever got a second one.

Another case of sport for the operator, but decidedly not for the victim, has just come to light in a town not 1000 miles from New York City. The day engineer of the station got into the habit of returning to his boarding house at very unseemly hours, very close to if not past midnight.

The worst of it was the exceeding slyness with which the engineer entered his boarding house. He was determined that no one should know when he came in or where he came from. To this end he always removed his shoes as soon as he entered the hall, and groping in the dark he would find the stairway and ascend with scarcely a sound.

One night the boys determined to know when the engineer came in and to permanently cure him of his nocturnal proclivities. To this end a little wiring was done on the sly around stairway and hall. A door at the foot of the stairs opened outward into the hall. This was used in place of a switch, and a half dozen incandescent lamps were hung on the stairs and in the hall and connected up so that opening the door would turn on the current.

Two or three electric door mats were borrowed from an adjoining drug store and placed in the hall and connected with bells in the rooms occupied by the would-be jokers. Screw eyes were inserted into the base boards on either side of the hall and a dozen lengths of string were tied across 6 ins. from the floor, or just about ankle high.

A bushel basket was filled with old tomato cans and balanced on top of the stairs so that the least touch would precipitate it rattling down into the hall below. A string made connection between the closed doors and the basket handle. To make the matter still more interesting, half a dozen sheets of tangle foot fly paper were procured and cut into two pieces each. These pieces were scientifically distributed along the hallway on the floor.

At just about 12:02 that night a terrific ringing of bells woke everybody in the house. Simultaneously with the ringing came a flash of light in the hallway and on the stairs a crash of a heavy body falling into the hall, then after a brief interval a few half-smothered swear words came up stairs and the basket of tins went down to meet them.

By this time everybody had reached the stairway, and there at the bottom on his hands and knees was the engineer. His hands, feet and head were ornamented with sticky fly paper, and the tableau was ludicrous in the extreme. I will not discuss it further. It can easily be imagined.

L. S. Carson.

The Resistance of Magnets.

To the Editor of American Electrician:

Sir—I note a query from C. M. in the July "Electrician," asking what the resistance of nineteen magnets should be to work in series with twenty-five dry batteries, and would reply as follows: I assume that the working conditions of the magnets are for maximum effect, therefore the resistance of the magnets should be equal to the internal resistance of the batteries. For simplicity, the line resistances will be assumed zero. The electrical dimensions of a dry cell vary, but a safe assumption is 2 ohms and 1.5 volts. We then have the following:

$$\frac{25 \times 2}{19} = 2.631,$$

which is the resistance in ohms of each magnet. The current flowing under the above conditions will be:

$$C = \frac{Ne}{NR + r} = \frac{25 \times 1.5}{25 \times 2 + 19 \times 2.631} = .375$$

amps. In this case N equals the number of batteries. No. 25 B. & S. gage is a very convenient size for magnet winding, providing the magnets are not too large. Each magnet will contain 7281.2 ft., the temperature being assumed to be 75 degs. F. The nineteen magnets will contain 11.5 lbs.

Jas. T. Jennings.

ELECTRICA CATECHIS

236. What is the general principle upon which electromagnetic instruments are based?

Electromagnetic instruments, which include nearly all ammeters and voltmeters, depend upon the fact that every current is surrounded by a magnetic field which reacts against any other magnetic force in the same field. This is illustrated by Fig. 1, which shows the effect of a wire carrying a current through the field of a magnet. The lines of force, which formerly went from one pole to the other by straight lines or short curved ones, as shown in Fig. 2, now are stretched by the effect of the current, and the wire must move in toward the magnet poles in order to relieve the tension. In the figure the current is shown as going down or into the paper; if the direction of the current had been opposite, the current would have been repelled, since the lines of force would then have been crowded together closer on the inside toward the magnet.

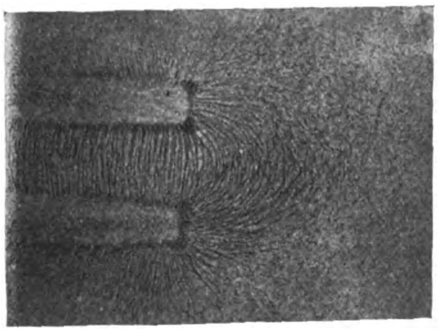

FIG. 1.—FIELD OF FORCE.

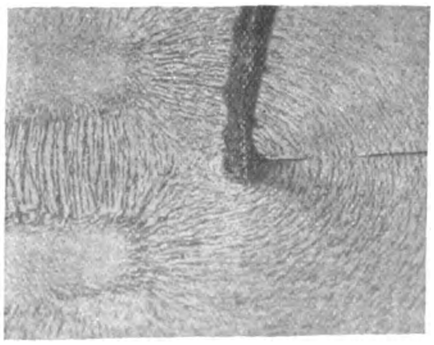

FIG. 2.—DISTORTED FIELD OF FORCE.

237. Does the whole current pass through the coil in an ammeter of the d'Arsonval type?

Only in those for very small currents. In order to be sensitive, the hair springs must be small and not be allowed to carry much current, or they may get hot enough to lose their temper. A voltmeter takes so little current that the whole of it can safely pass through the delicate hairsprings without danger, but only a small fraction of the current through an ammeter can pass through the springs.

238. How can the ammeter be made to measure correctly when only part of the current goes through the coil?

The coil is arranged so that a definite proportion of the whole current passes through it. A large conductor of low resistance is connected directly between the two terminals or binding posts of the instrument; the coil is connected as a shunt around a definite part of this main conductor; then, since the two are connected in multiple and each branch has a definite resistance, the current divides between the two branches directly in proportion to their relative conductivity, or inversely, according to their resistances. The coil, therefore, takes a definite part of the whole current, and the force moving it and its pointer away from the zero position is directly proportional to the whole current.

239. What is the construction of the Weston switchboard ammeters, in which the instrument is connected only by small cords like lamp cords?

In these instruments, as with all their instruments for very large currents, the "shunt" is arranged for connecting directly into the bus bars, while the rest of the instrument may be placed wherever desired. The part usually thought of as the instrument is really a d'Arsonval galvanometer, practically the same thing as the voltmeter, and contains a permanent magnet with a coil mounted on pivot bearings and controlled by hair springs, which also carry the current into the coil. The coil with its hair springs and the connecting cords have a definite resistance; when these are carefully connected to the "shunt" in the bus bars, a small but definite portion of the whole current goes through the cords and the galvanometer, which thus measures the whole current.

240. What advantage is there in this kind of instrument?

It saves considerable expense in building the switchboard, since the bus bars do not have to be carried to any particular place to suit the instrument. Also if desired, a number of galvanometers may be connected around the shunt, so that the current may be read from different points. It is also possible to do away with the regular shunt entirely and connect the galvanometer cords to points on the bus bars themselves (which points must be found with care), and so do away with the two joints in the bus bars otherwise necessary. It is also possible to use the same galvanometer for measuring the currents in several different circuits.

QUERIES AND ANSWERS

Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied. The privilege of this department only extends to subscribers, and queries must be accompanied by name and address to secure attention.

How is it that the shifting of the brushes on a closed coil machine increases and decreases the number of active conductors in the armature?

The field magnet of the machine divides the armature into bands of conductors having e.m.fs. in the same direction. If the brushes are placed to commutate on these division marks between these different bands of common direction the current in the wires will agree with the e.m.fs. and the number of effective conductors will be a maximum. If, however, the brushes are shifted to some other position, the current which traverses the armature will flow through some of the conductors whose e.m.fs. are opposed to the direction of the main current. This diminishes the total effective e.m.f. in proportion to the magnitude of the e.m.f. in the conductors thus cut out of position.

Can an efficient accumulator per pound weight be made with sheet lead plates, the surfaces of which have been roughened by hammering with a coarse file; the plates to be coated with litharge paste and enveloped in three thicknesses of cheese cloth, the bundle of plates being loosely bound together with rubber bands? R. E. K.

The construction you describe is a common one used in making amateur storage cells. The internal resistance is rather high, thus making the weight efficiency low, and, moreover, it is not of a very permanent character. The paste for the positive plates should be made from peroxide of lead, Pb_3O_4, not litharge, the symbol of which is PBO. Litharge may be used for the negative plates. The paste may be made by wetting up the peroxide with a solution of very dilute acid. It is not very adhesive and must be secured in place by some means such as you have described.

1. Is chemically pure sal ammoniac better to use in batteries, both dry and liquid, than commercial, or is it different in its use from commercial NH_4Cl?

2. Are carbons made for electric light purposes as good for battery use as regular carbon plates. H. B.

1. The difference, if any, is not worth the added cost of the pure sal ammoniac. Lump sal ammoniac, such as is used for soldering, contains iron and should be avoided.

2. The electric light carbons are a little soft, but will answer for battery purposes, provided their copper coating is removed by treatment with dilute nitric acid.

1. Is ozone produced by direct or alternating current?

2. When decomposing water by current, and thus producing ozone, will water heat to more than 140 degs. F.? W. P. S.

1. Ozone is produced by electrostatic discharge, which is of an oscillatory character. Neither alternating or direct currents of ordinary commercial voltages will answer; the discharge should be produced by a static machine or induction coil.

2. When decomposing water ozone is not produced, but oxygen and hydrogen are produced, one at either pole. If sufficient current is passed through the water it may be heated to the boiling point, 212 degs. F., but can get no hotter.

What is the best way to permanently magnetize steel? A. K.

Heat the steel to cherry redness in a strong magnetic field and harden it glass hard by raising a bath of water or oil up around the steel, not removing it from the magnetic field. The steel needs to be carefully selected and some of the approved brands of imported steel are said to be the best.

In the February and March issues of the "American Electrician" is an article on designing small motors, by Cecil P. Poole. In the issue of February, 1898, is tabulated the following:

		Density.	Total length of path.	Ampere turns.
Air-gap..............	$\frac{77,000}{5 \text{ ins.}} =$	15,000	⅛ in.	603
Pole pieces (cast)...	$\frac{97,000}{5 \text{ ins.}} =$	19,400	3 "	21
Field cores..........	$\frac{107,800}{1.48} =$	72,838	6 "	98
Yoke (wrought iron)	$\frac{90,000}{1.25} =$	72,000	3¾ "	57

1. What does the 5 ins. in the fraction in the first two lines mean, and where is it measured, and the decimal 1.48 and 1.25 in the third and fourth, respectively? How is the 3-in. length of path in the pole pieces and the 3¾ in. in the yoke measured?

2. What kind of primary battery would you recommend for a 1-6 h.p. motor to deliver about 6 volts?

1. The explanation of the fractions is as follows:

Total flux....	77,000	97,000	107,800
Area of path.	5 sq. ins.	5 sq. ins.	1.48 sq. ins., etc.

The area of the path is measured, of course, at right angles to the direction in which the magnetic lines are supposed to flow. The 3 ins. length of path in pole pieces is measured from the curved surface of one pole piece to where the core takes the flux, and doubled, there being two pole pieces. The length of path in the yoke is from center to center of the cores if they are butted to the yoke; when they are set in the yoke the length of the path in the latter should be measured from edge to edge of the cores.

2. For intermittent service some type of bi-chromate battery is best. For constant service something on the Bunsen or Grove style will answer. It will require four or more cells in series, according to the size of the cells and the efficiency of the motor.

What is the resonance in a line or transformer, and what causes it? A. W. B.

In every electrical circuit there is a certain frequency of alternation, which produces an effect known as electrical resonance. It is a function of the inductance and capacity of the circuit. If these are adjusted in a certain way the result will be an enormous rush of current, which usually produces disastrous results. It is akin to acoustic resonance, in which a tube or pipe will take up a certain vibration and respond with a volume of sound, but will be silent to other vibrations of slightly different frequency.

I have some transformers—1000-volt primary and 30-volt secondary—and I wish to change the secondary voltage to 100. What would be the necessary change in winding? Would the same iron core answer? F. B. H.

The same iron core will do. Remove the secondary and carefully count the number of turns as they are unwound. Rewind with a wire of 1/3 the size in circular millage, and using 3 1/3 times as many turns.

1. Are any of the fan motors used on alternating currents shunt and series wound? If so, can they be used on direct currents?

2. Can such motors be used on any number of alternations?

3. Can an induction motor run on single phase circuit?

4. If small shunt and series motors run on alternating current, why are not larger machines of this class run with it?

5. I have a direct current 10-h.p. motor loaded to its capacity. If I decrease the field strength to make it run faster, will it give as much power or will it give more?

1. Some alternating current fan motors are simply series motors. The shunt motor is not applicable because the current in the field magnets would not be in phase with the current in the armature. They will run with direct currents, if supplied at the proper voltage.

2. Such motors are to an extent independent of frequency, but there is a certain frequency at which they will operate best.

3. An induction motor can be run on a single phase circuit, when once up to synchronism, but it requires some extraneous means of starting. The monocyclic motor is practically a single phase induction motor with a polyphase winding for use on starting.

4. Series motors are very unsatisfactory on alternating current circuits, as they produce a heavy inductive load, and are therefore permissible only in small sizes.

5. If you reduce the strength of the field of your motor it will run faster, provided you do not reduce it too much. It will give out more power, but it will call for more current to do this and may burn out your armature.

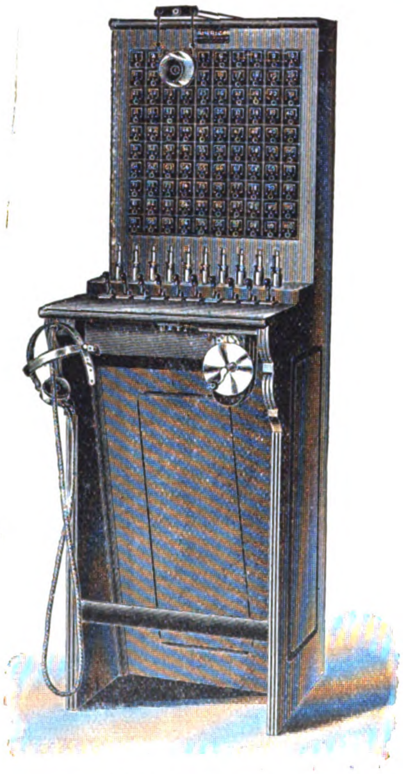
What is a suitable material to be used for a making and breaking contact in a mercury cup? We use a copper wire, which is very quickly eaten away by the mercury. R. R.

If there is considerable current to handle and the circuit is frequently broken, almost any wire will be gradually consumed. Aluminum and iron, however, are practically unaffected by mercury, and either could be profitably used.

New Apparatus and Appliances.

A COMPACT EXPRESS SWITCHBOARD.

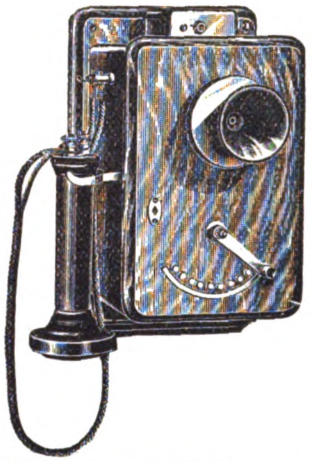
The accompanying cut shows a 100-drop express switchboard of the American Electric Telephone Company, Chicago, which is wonderfully compact and efficient. The details of the drop and jack were explained in a technical article by Mr. Kempster B. Miller in the August issue of this paper. This board is built for metallic lines, is built with self-contained jacks and drops. The drops are mechanically restored by the plugs. There are no drops in the cords, the ringing off being effected through the main drops, which are restored on pulling out the plugs as well as upon pushing them in. Ringing cams are also dispensed with, the ringing being accomplished by pushing the plug in the jack deeper than its normal position. Among the interesting features of this board is the mounting of the combined jacks and drops, each set being entirely self-contained and constituting a small draw, which is removable from the front of the board and is firmly fastened in place on the back of the board by screws and nuts. These nuts make the line contact and the connected line wires are soldered to lugs, but it is not necessary to unsolder them in order to permit of the removal of the jack. Another board made by the same company, known as the "Universal" board, is also finding favor. This has the jacks in a separate panel over the drops, the latter being restored manually by means of a common drop-lifter. This company is using the Burns two-pole receiver with double-area gaps on all their instruments, and a solid-backed microphone with carbon gap and carbon plate.



EXPRESS SWITCHBOARD.

AN INTER-COMMUNICATING TELEPHONE SWITCH.

The chief drawback to the universal use of warehouse telephones in business houses, factories, schools and similar institutions has been due to the lack of proper means for obtaining connections between the different stations and restoring them without the aid of a central office, which, when comparatively few instruments are employed, is costly to maintain and requires constant attention. The ordinary manual switch has been used, but after making connection with it, it is necessary to return it by hand to its home point so that the instrument will be in proper position to receive and answer the next call. It has proved to be the case that people will neglect to turn this switch back, and no device has seemed to be able to cause them to properly restore the connections, and the result is a most unsatisfactory service. The switch herewith illustrated is designed to overcome the difficulty. It is operated the same as an ordinary switch, being turned around until the lever rests upon a point corresponding to the instrument desired. A slight pressure upon the knob of the switch rings up the instrument wanted without calling any of the others, and when the conversation is finished, the hanging up of the receiver automatically restores the switch lever to its normal position. The device is very thoroughly made. The working parts are made of case-hardened tool steel, and the workmanship is excellent throughout. It is covered by broad patents and manufactured in different forms for both wall and desk use, by the Holzer-Cabot Electric Company, of Brookline, Mass.

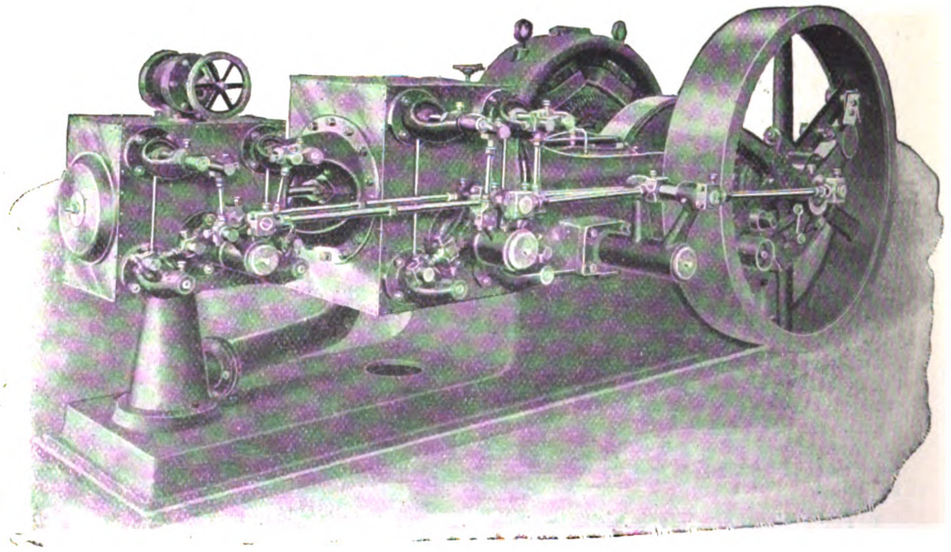


SELF-RESTORING TELEPHONE SWITCH.

A NEW CORLISS ENGINE.

We illustrate herewith the new horizontal tandem compound engine designed and built by the Ball & Wood Company, of New York. It is believed that in this engine are embodied all the best features of the well known Corliss type, together with a number of important and interesting improvements designed by the engineers of the Ball & Wood Company, with the object of obtaining the best possible distribution of steam, close regulation and high efficiency.

The valve gear is generally Corliss in type, but is without the usual Corliss tripping devices or dash pots. Instead of this the admission valves are operated by an independent wrist plate. The exhaust valves are actuated by a second wrist plate by means of an adjustable eccentric, and both wrist plates are connected by the Ball & Wood inertia governor, which is well known to be one upon which extremely small variations of speed have an immediate corrective effect. The valves are multiported on both steam and exhaust cylinders, thus insuring quick and full admission of steam into the cylinders and prompt release at completion of stroke. The exhaust motion is very rapid, and by means of the independent eccentric any desired adjustment is obtainable. The steam valves have large openings, and being operated



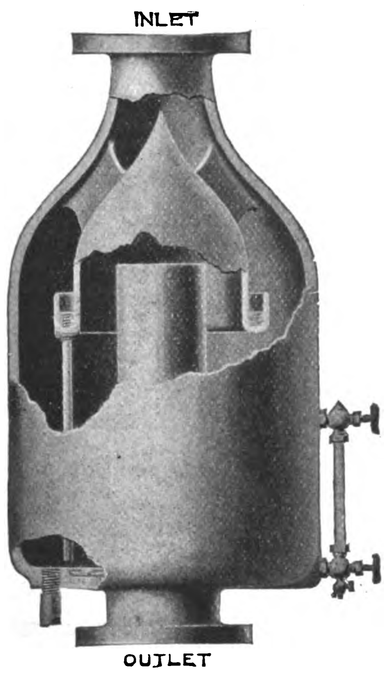
A NEW CORLISS ENGINE.

by the Corliss plate quick angular motion is obtained.

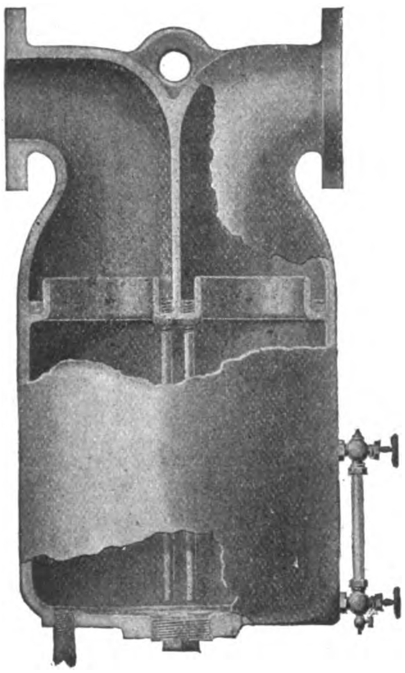
It is evident that the economy of this type of engine should be exceedingly good, and its regulation as nearly perfect as is possible to attain in engine practice. These new engines are manufactured in large and small sizes, for railway and lighting service, and in connection with the vertical and other types built by the company enable the latter to furnish to customers practically any type of engine desired.

A NEW STEAM SEPARATOR AND OIL ELIMINATOR.

In the accompanying cuts are shown two types of a steam separator and oil eliminator, which have recently been put upon the market. It is believed that their design is entirely new. In previous designs an effort has been made to cause the steam to take on a centrifugal, zigzag, or similar tortuous motion in its passage through the separator, and cause the entrained oil and water to be thrown off by centrifugal force. In the separators shown in the cut the object is to reduce the obstructions to the flow of the steam. In both of the separators shown the steam inlet gradually enlarges into a chamber, which is ten times the area of the pipe, and the outlet is gradually reduced to the original area. The entrainment is intercepted by gutters, which are kept partially filled with water. It has been found that these gutters, so filled, very effectively cut off the entrained water or oil, the channels being so arranged as to guard both inlet and outlet of the separator. In the vertical separator the steam enters the top; the entrainment follows the interior surface and will pass along that surface to the bottom of the separator, where it will be intercepted by the water at the bottom. Any water or oil in the steam which escapes the separation will strike the exterior of the cone at the top, and, spreading over this surface, will be caught by a gutter at the bottom of the cone and carried off by pipes provided for that purpose. In the horizontal separator, the steam may enter at either side, as both are alike. In its path through the separator it passes by two gutters which effectively catch the entrainment and carry it down to the bottom of the separator, where it is trapped off in the usual manner. All the separators for pipes above 8 ins. are built of flanged steel. They are manufactured by the Hoppes Manufacturing Company, Springfield, Ohio.



VERTICAL SEPARATOR.



HORIZONTAL SEPARATOR.

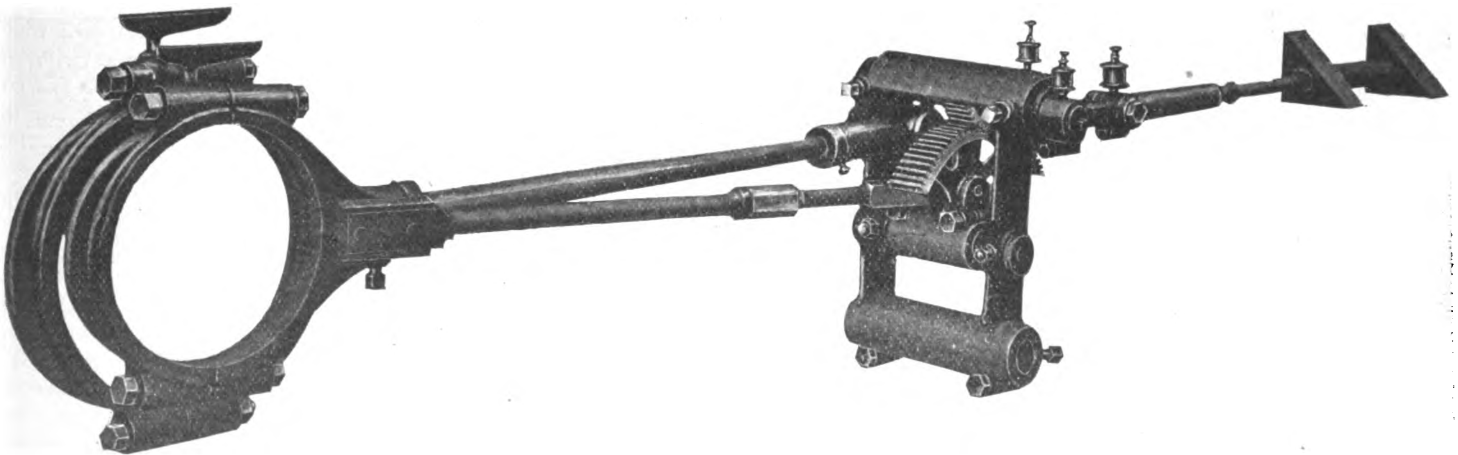
AN INGENIOUS VALVE GEAR.

The problem of properly distributing steam to either end of an engine cylinder by means of a simple valve gear has received a great deal of attention from engineers and manufacturers. It has generally been admitted that a simple eccentric motion cannot achieve the best results. The Corliss valve gear and its modifications does reach this desirable steam distribution, but at the expense of considerable complication.

In the accompanying illustration is shown a device for obtaining superior steam distribution with a single balanced valve.

This one valve performs the function of four separate valves by employing means to impart to it an intermittent motion, giving the valve a very high speed at the opening and closing of the port, and a lower speed during expansion. The valve opens rapidly and then moves slowly until the point of cut-off is reached; a quick movement then closes the admission port. This action gives the steam free admission and a level admission or steam line, and by its quick closing avoids wire drawing and secures all the advantages of the sharp cut-off. This mechanism also enables the exhaust to be opened promptly at the extreme end of the stroke, thereby allowing the steam to remain in the cylinder and expand to its fullest extent, giving unusual freedom of exhaust and avoiding undue compression.

The mechanism employed to produce these movements provides the ordinary automatic governor connected by the usual eccentric rod to the rocker arm or valve cross-head. In the upper end of the rocker arm is an eccentric shaft carrying a pinion; in mesh with this pinion is a toothed sector, which is also pivoted on the rocker arm, and is actuated by a fixed eccentric on the main shaft. The geared eccentric shaft carried by the rocker arm is connected to the valve stem by a simple connecting rod. The fixed eccentric is set nearly opposite but slightly in advance of the governor eccentric, that is to say, it



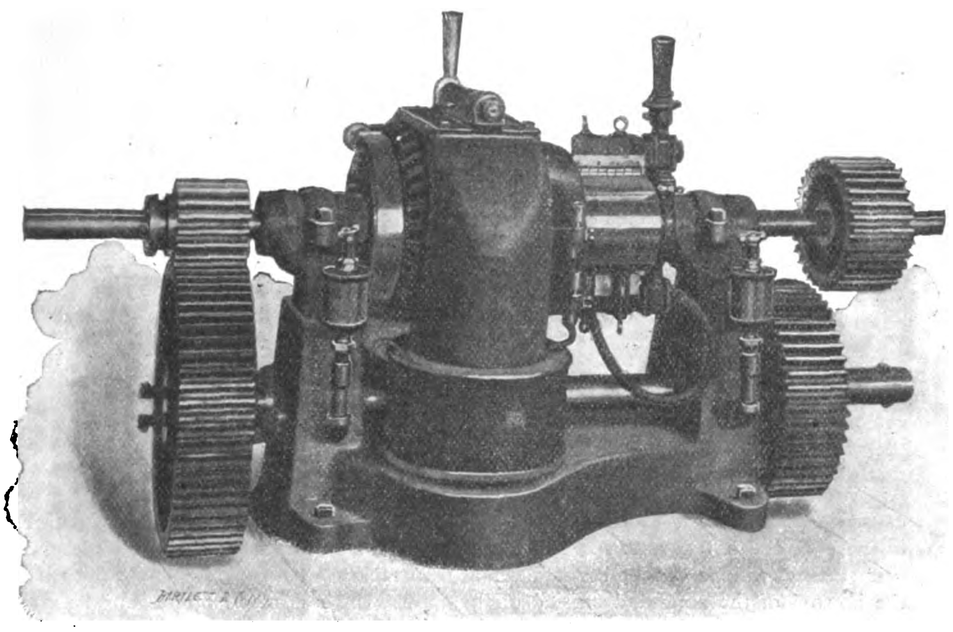
AN INGENIOUS VALVE GEAR.

is given a few degs. lead ahead of 180 degs. The sector will, therefore, move in one direction while the rocker arm moves in the opposite direction, thereby imparting through the pinion an oscillating motion to the eccentric shaft, giving the latter at shortest travel a little less than one revolution and at greatest travel a little more than one revolution. When the eccentric shaft is on either center the valve is in position of admission, and the movement of the latter will be due to the rocker arm and augmented by the rotation of the eccentric shaft in the same direction. At the completion of the stroke the return is similar, closing the valve by the time the eccentric shaft has returned to its center. During the next half revolution of the eccentric shaft its motion is opposed to that of the rocker arm and the valve's movement is retarded. The two movements are so timed that the valve comes practically to a standstill until at a predetermined point in the stroke the valve travel is accelerated, closing the exhaust in time for the desired compression, releasing at the opposite end and again admitting steam. The results are said to be equal to those obtained by the Corliss valve gear and to exceed the results accomplished by four valve types which do not use the detaching gear. It may be run on engines as high as 300 r.p.m., which is a decided advantage, as the limit for Corliss valve gears is about 100 r.p.m. As a result of the higher speed at which this valve gear may be operated the cylinder may be made shorter, thus increasing the number of admissions and obtaining thereby a higher cylinder temperature. By avoiding one set of ports a much reduced clearance is obtained, and by a much later compression together with higher initial and a later release, the economic results would appear evident.

Patents are being taken out on this movement in the United States and all the advanced foreign countries of the world by Mr. J. B. Allfree, and it is now being applied on engines built by the J. B. Allfree Manufacturing Company, of Indianapolis, Ind., who will take pleasure in giving any further information concerning it.

AN IMPROVED BRAKE MOTOR.

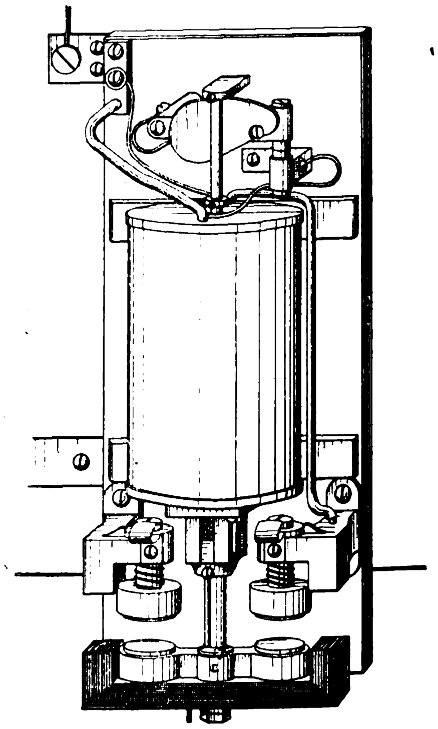
The accompanying illustration shows a comparatively new device, consisting of an electric motor provided with a braking attachment, which becomes operative the moment the current is shut off and quickly brings the motor to a stand-still. These motors are very useful and applicable to almost all machinery where prompt and accurate control is required, for example: Elevators and hoists, where it is important to provide adequate means for holding the load when hoisting; and also printing machinery and other devices where it is important to secure an instantaneous stoppage, without waiting for the machine to slow down. Heretofore, motors have been provided with separate means for doing this which are very cumbersome and require additional levers to operate the brake. In the motor shown the brake is arranged to grip the armature firmly as soon as the current is cut off. This motor is made in two forms. The standard motor has a single brake, which grips more strongly when the armature is revolving in the standard direction. This is sufficient for most requirements, but in addition a reversible form is provided, which grips the armature equally well with either direction of rotation. Most motors drive machinery of moderate speed: to do this gearing is required to supply the desired reduction. These motors are supplied with counter shafts arranged in their bases, and in the cut shown the motor has two sets of gears whereby two sets of speed may be obtained by throwing either the one or the other into operation. These motors are made by Crocker-Wheeler Electric Company of New York.



AN IMPROVED BRAKE MOTOR.

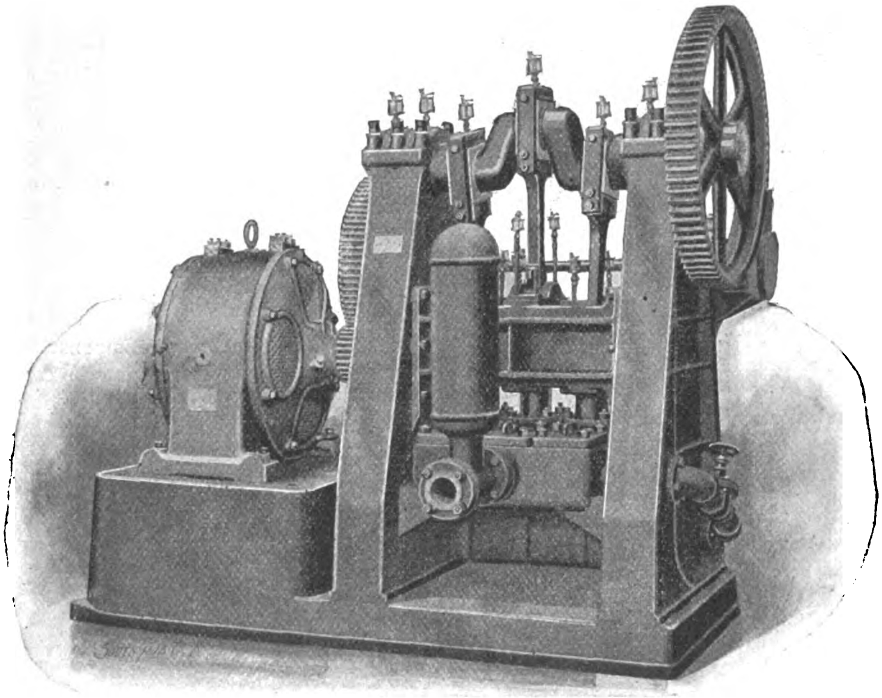
A NEW SECTIONAL RAIL SWITCH.

The accompanying illustration depicts a new automatic switch, which is to be used by the Safety Third Rail Electric Company of New York for heavy traffic. Their system, it will be remembered, has created a great deal of comment among electric railway men, as being one of the few sectional conductor systems which gives bright promise of success. The switch depicted in the illustration has been designed with reference to its current carrying capacity. The lower rectangular jaws are of laminated copper and can readily carry 300 amperes, while their momentary current-carrying capacity is undoubtedly between 600 and 700 amperes. These copper jaws are supplemented with carbon breaks, which successfully withstand the deflagrating action of any arc that might occur there. It is to be added, however, that the system of the Safety Third Rail Electric Company is such that no arcs occur at the switch jaws of the automatic circuit closers. This is accomplished by having one of the coils which acts on the plunger in series with the switch. It therefore follows that this coil will not allow the switch to open until the current in it has ceased, when the switch will fall open for lack of magnetic power to hold it up. At such times as this, however, there being no current to break, there can be no arc. When it is remembered that this difficulty of arcing is what has blasted the hopes of many a surface contact electric railway system and rendered it inoperative, this ingenious way for avoiding the trouble will be greatly appreciated. The action of the switch can be briefly reviewed in a paragraph. An iron-clad solenoid carries two bobbins wound on the same spool. One is a fine wire bobbin, which connects with the sectional rail and also with the ground through circuit breaking contact on the top of the switch. The other connects with the sectional rail through the switch



SECTIONAL RAIL SWITCH.

jaws to the feeder main. As gravity holds the switch open at times when the latter is inoperative no current can escape from the feeder main to the section, which is therefore insulated. When the car approaches the collecting trolley impinges upon the sectional third rail and immediately sends a current through the fine wire bobbin to ground. The plunger rises, closing the lower and breaking the upper circuit. The fine wire circuit is now open, but, as the motor is drawing current from the coarse wire circuit, the switch holds up and remains closed until the car has ceased to draw current from that section, when gravity pulls it open again. The switch is remarkably compact and requires only three electrical connections to the system. Two of these are made by simply screwing the switch against the bus bars in the switch vault, and the third, a light connection of flexible wire, is screwed into an appropriate binding post. The method of the whole installation is so obvious and simple that the ordinary laborer can hardly go astray. The Safety Third Rail Electric Company have offices in the Temple Court Building on Beekman Street, and have been very active in developing their system. They will doubtless be frequently and favorably heard from in the near future.



TESLA MOTOR AND TRIPLEX PUMP.

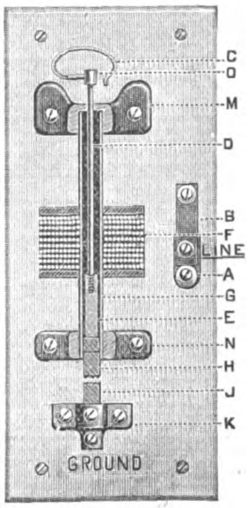
THE INCREASING USE OF ALTERNATE CURRENT MOTORS.

The prejudice against the alternating current motor is becoming historical, and it is interesting to note that this motor has now demonstrated its superiority over its direct current rival in a number of peculiarly trying applications. Among the original promoters of the use of alternating apparatus, the Westinghouse Company have been pre-eminent, whether in monophase or polyphase systems, and their Tesla Type C induction motor is universally admitted to represent one of the highest developments of the art. The motor has been frequently described in these columns, and the essential feature—that is to say, the absence of any connections between the line and the rotating parts—is familiar to every electrical engineer. These motors have shown their fitness for a peculiar line of service in an extensive installation at the factories of the Silver Springs Bleaching and Drying Company, of Providence, R. I. This company has been a pioneer in the use of electrical apparatus for mill purposes, and very early in the history of the industry purchased two direct current dynamos, which were used for lighting and power service until 1895. At this time the necessity for extensions induced the company to investigate the more modern developments in lighting and power service; and, after a most thorough investigation, Mr. E. C. Myrick, the company's engineer, recommended the adoption of the Westinghouse three-phase system, at 3000 alternations per minute for both lighting and power. This decision was at the time the subject of severe criticism by contemporary mill engineers, but the results of two years of active service, under the worst imaginable conditions, have demonstrated the soundness of the engineering judgment.

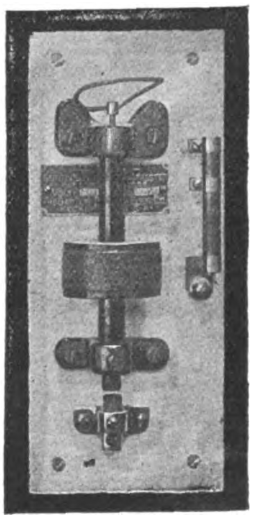
In addition to lighting the entire plant, some thirty Westinghouse induction motors, of from 3 to 75 h.p. have been installed. These motors are ample for driving the washing machines, ironing machines, triplex pumps, elevators, ventilating fans and similar contrivances. Some of the motors operate continuously in a cloud of steam that would stall a direct current motor in five minutes. Many of them are subject constantly to the action of chloride fumes, which are so corrosive that the copper parts of the motors and switches are green from their influence. In many of the operations enormous starting torque is required, the initial torque being in some cases four times the normal torque of the motor. The plant has proven so satisfactory that it has recently been extended by ten or more of the Tesla Type C motors made by the Westinghouse Company.

AN INGENIOUS LIGHTNING ARRESTER PRINCIPLE.

The principle of the well-known Garton-Daniels lightning arrester is well illustrated by the following cross-sectional view of their device. It consists of a tube, in which is a solenoidal plunger resting on a carbon contact. The contacts shown in the lower part of the figure are very near together but not quite touching. The discharge enters the arrester by the binding post A, and from thence crosses the non-inductive resistance B, which is in multiple with the coil F, through conductors which are bedded in the slate base of the arrester. From thence it passes to the flexible cord C and across the spark gap to ground. The discharge, it will be noted, takes its path through the non-inductive resistance in multiple with the coil. If the dynamo current tends to follow, it will pass for the most part through the coiled bobbin F, which is thereby energized, drawing up the iron armature E, and introduces a second air gap into the circuit to such an extent that the arc immediately goes out. The current in the bobbin then ceases, the



SHOWING PRINCIPLE OF ARRESTER.

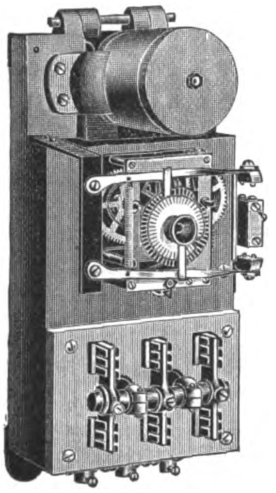


ADAPTATION FOR RAILWAY CIRCUITS.

plunger drops, and the arrester is ready for another discharge. This arrester is exceedingly effective, and there is no reason why it should not be. The arc occurs within a tube which is very nearly air tight. The oxygen is rapidly consumed, which assists in extinguishing the arc. The air gap can be made very much smaller than in the case of the non-arcing arrester, and hence the discharge is more certain to follow the path that was intended for it. As there is but one moving part, the arrester is simplicity itself and not liable to get out of order. In the second figure the arrester is shown as used on railway circuits. It is manufactured by the Garton-Daniels Electric Company, Keokuk, Ia.

AN AUTOMATIC ELECTRIC TIME SWITCH.

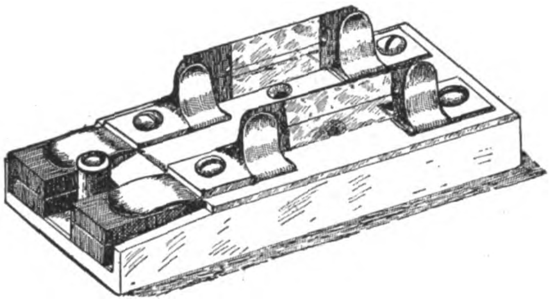
It is only recently that the demand for a good electric time switch has been appreciated by makers of electrical apparatus, and the accompanying illustration depicts a switch of this character, which, it is claimed by the makers, embodies features of marked superiority. The general design is clearly shown in the cut. It consists of a two or three pole, double break, knife-blade switch, which is operated by an electromagnet in conjunction with a lever and spring, which makes the opening and closing of the circuit practically instantaneous. The operating current is controlled by an eight-day clock movement. Two discs are mounted on the hour stem of the clock movement and are held in position by an adjustable thumb nut. These discs are divided into twenty-four sections, each representing an hour of the solar day. Each dial has a zero point notched in the periphery, which allows the lever or contact arm to drop. When the time of switching arrives the contact arm closes a circuit through one of the magnet coils, which in turn closes the knife switch. When the time of cutting out the lights arrives the other dial operates its contact arm, which again energizes the magnet and opens the knife switch. The operating current is only used at the times of switching on and off, and then only for a brief period. There is, therefore, no continuous consumption of current in the magnets and no danger of overheating them. These switches are very carefully made and rigidly tested in the factory before being offered to the consumer. They are manufactured by the Cleveland Electric Company, Cleveland, Ohio.



AUTOMATIC TIME SWITCH.

A COMBINED TELEPHONING FUSE AND LIGHTNING ARRESTER.

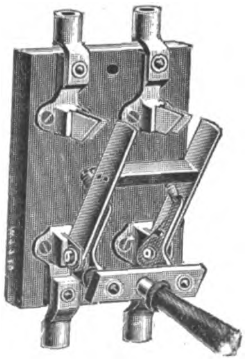
In the accompanying cut is depicted a combined lightning arrester and fuse for telephone lines. The foundation of this apparatus is a porcelain base, upon which are mounted two carbon blocks separated by perforated mica. One of the blocks rests on the ground plate and the other is directly connected on to the line, the idea being to produce an arrester on the gap principle. The perforations of the mica are, of course, liable to become partly filled with carbon dust after continuous use, and to anticipate this difficulty the blocks are made removable, can be pulled out and the carbon dust blown out of the mica separator, and by replacing them the arrester is in working order again. The fuses are the ordinary copper field fuses about 2 ins. long, and rest between clips, as shown in the cut. The combination is said to be very effective and satisfactory. It is made by the Electric Appliance Company, Chicago, Ill.



COMBINED FUSE AND LIGHTNING ARRESTER.

IMPROVEMENTS IN SWITCH CONSTRUCTION.

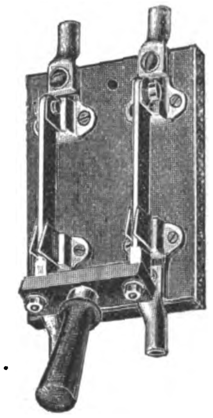
The accompanying illustrations depict several types of jack-knife switches, which are finding favor among constructing electricians. The first is a quick break switch. In this switch the handle strains on a spring and the switch jaws will not pull out until the spring is sufficiently strained to throw them out with a snap. The breaking in this respect is not under control of the operator; is exceedingly prompt, and minimizes the arcs.



QUICK BREAK SWITCH.

In the second cut is shown a very desirable switch for switchboard work. Its claims for excellence are in its workmanship, the contacts being made with the greatest care, and the joints and machine work being very substantial.

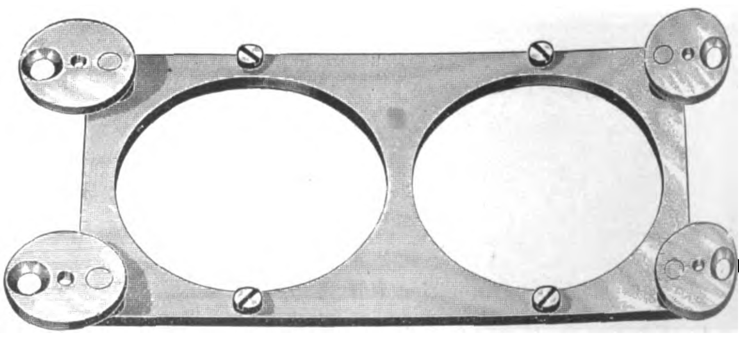
These switches, together with several other new and desirable types, are manufactured by the Warren-Medbery Company of Sandy Hill, New York.



PANEL SWITCH.

IMPROVEMENTS IN ELECTRICAL HARDWARE.

To meet the demand for artistic and ornamental electrical hardware for use in public buildings and the better class of private residences, the Hart & Hegeman Manufacturing Company, 52 High Street, Hartford, Conn., is manufacturing a line of plates for single flush switches, or gangs of flush switches, and claim that for quality of material, workmanship and style of finish they will meet the most exacting demands of architects and others. Any finish in hardware can be duplicated in these plates, which are made of any size, from one-switch capacity up to one hundred or more. To enable them to fill orders promptly this company keeps constantly in stock a line of plates ranging in capacity from two to eight switches. Among the finishes always on hand are nickel, bronze or polished brass. While these sizes and finishes are found to answer all ordinary requirements, the company is prepared to furnish other sizes and special finishes on short notice. We illustrate herewith a Hart gang back plate for two switches.

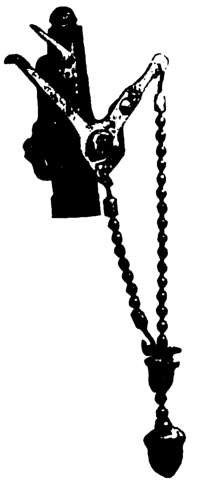


GANG BACK-PLATE.

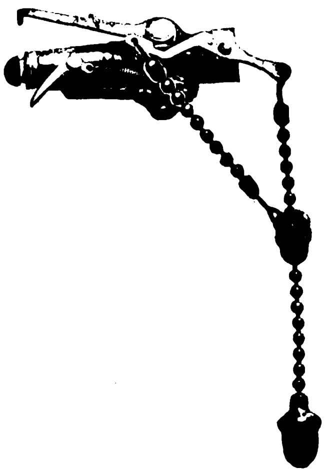
The openings in these back plates are all of the same size, enabling them to accommodate single-pole, double-pole, three-way, four-way or electrolier switches, as may be desired. Hart gang plates and gang switches are carried in stock by almost all dealers in electrical supplies, and therefore can be procured in any part of the country without delay, and any desired combination of plates and switches made.

ELECTRIC GAS BURNER ATTACHMENTS.

The accompanying illustrations show gas burners electrically lighted on the pendant plan. The manufacturers state that they may also be operated by a stiff rod, and that the parts are specially designed to prevent short-circuiting. It will be noted that both contacts are held well out of the flame and cannot lose their tenacity and springiness, or become oxidized by reason of the heat. The valves have easy attachments for removing them for cleaning, and show by the position of the balls on the chain whether the gas is on or off. The springs are of phosphor bronze, and the burner is highly finished from solid brass rod stock. The valves are well proportioned, and ground in the stem and seat to make a perfect fit. These attachments, which are also adapted for horizontal gas jets, such as are used on billiard tables, are manufactured by Rousseau's Electrical Works of New York, which are also placing on the market a new line of window and door springs for electric alarms. These springs are thoroughly insulated with rubber, with the exception of the exposed parts, which are insulated with mica. They can be easily put in place with simple tools, and are said to be very effective. The company states that it has purchased all patents, tools, etc., for the manufacture of the above and other specialties, from David Rousseau, who formerly manufactured them for his own use. The new company will do no contract work, but will manufacture these specialties exclusively for the trade, and is arranging with all supply houses to handle its goods for the greater convenience of its customers.



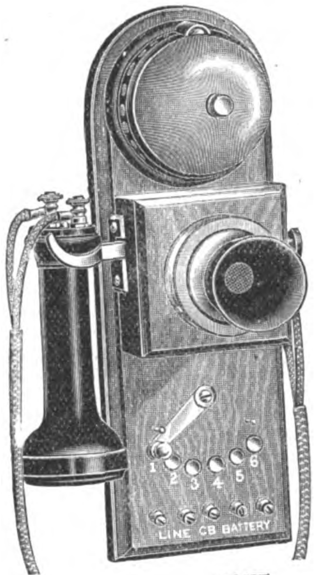
PILLAR BURNER CLOSED.



BILLIARD BURNER OPEN.

A NEW TELEPHONE.

In the accompanying illustration is depicted an intercommunicating telephone, which is exceedingly compact and simple, and has withal a very important improvement over the ordinary instrument of this type. In most intercommunicating systems it is necessary to throw the switch lever to the home station when the party is through talking, for otherwise it is impossible for the instrument to respond to an incoming call from the other station. To improve this some makers have used automatically restoring switches, actuated by the hanging up of the receiver. In the device illustrated the scheme of connection is such that the position of the switch lever matters not, as far as incoming calls are concerned, thereby obviating special devices. This system is adapted for key or plug boards, and also for common return and metallic circuits. The calling battery consists of but three cells, placed in a central location. The instrument is fitted with a granular transmitter and an improved English standard receiver, and the workmanship is first-class. It is manufactured by the Connecticut Telephone and Electric Co., Meriden, Conn.



A NEW TELEPHONE.

PERSONALS.

MR. KEMPSTER B. MILLER has severed his connection with the Western Telephone Construction Company and has moved to Scranton to assume charge of the courses in Telephony and Telegraphy of the International Correspondence Schools at that place. As Mr. Miller is an authority on these subjects, the International Correspondence Schools are fortunate in securing his services.

MR. F. E. DRAKE of the Walker Company has been selected as electrical adviser to Commissioner General Ferdinand Peck of the United States to the Paris Exposition of 1900. Mr. Drake will sail for France with the Commissioner General and party on the steamer La Touraine from New York on Sept. 3. He expects to return to this country about the middle of October and will then resume his duties with the Walker Company.

MR. E. J. WESSELS, former managing director of the Standard Air Brake Company, now owner of the illustrated weekly newspaper, "The Universe," has just purchased all right, title and interest in "Sunbeams Magazine." This publication has been in existence for seven years. It enjoys an excellent advertising patronage, and has a large subscription list. Mr. Wessels will merge "Sunbeams" in "The Universe." The publication office will be at 150 Fifth Avenue, New York City. "The Universe" has rapidly worked its way into favor, and now goes to all parts of the world.

TRADE PUBLICATIONS.

THE CONSOLIDATED SAFETY VALVE COMPANY, New York, has issued a neat catalogue of its goods. It is handsomely illustrated and describes their goods most completely, and numerous pictures of their works at Bridgeport give an idea of their facilities and their ability to fill large orders on short notice. Copies will be sent to applicants mentioning this paper.

THE JOSEPH DIXON CRUCIBLE COMPANY, of Jersey City, N. J., has issued a catalogue on the subject of graphite as a lubricant. The book is replete with technical tests and professional opinions on the subject, and, as is to be expected, advertises the admirable graphite and graphite compounds of the company. It forms very interesting engineering reading matter.

THE HAYDEN & DERBY MANUFACTURING COMPANY, New York, is now mailing an extensive catalogue on its injectors and ejectors. It is thoroughly illustrated, and the apparatus is completely described, and the essential dimensions are given. The catalogue is valuable as a reference to anyone who is using the goods of this company and the prospective buyers of such apparatus. Applicants for the catalogue, mentioning this paper, will receive a copy.

THE CROWELL APPARATUS COMPANY, of Indianapolis, Ind., is circulating an interesting little pamphlet describing their goods, which consist of experimental devices for school and for students' use. It illustrates many experiments, which can be performed with simple materials. To the instructor in physics and to the student, this book is well worth writing for, for many of the experiments are decidedly unique, and show to excellent advantage the principles of physics illustrated therein.

THE CROUSE-HINDS ELECTRIC COMPANY, Syracuse, N. Y., has issued a catalogue which describes in detail the construction of their jack-knife switches, panel and fuse boards, and switch parts. This little catalogue is valuable to all who have to do with switchboard contracts of any kind, as experience has shown that in making up a switchboard there are many parts that can be purchased much cheaper than they can be made, due to the fact that manufacturers like the above-named firm make a specialty of such parts, which are turned out in large quantities by special machinery.

THE RELIABLE ELECTRIC MANUFACTURING COMPANY, Worcester, Mass., has recently sent out to the trade a new catalogue replete with handsome illustrations showing their telephone apparatus as well as their various electrical supplies and specialties. The company claims that only the best workmanship and material are employed in their telephone apparatus, of which they make a specialty and which, it is stated, is of the latest design, and is built upon correct electrical and mechanical principles. The offices of the company are at 86 Foster Street, to which applications for this catalogue should be addressed.

THE MICA INSULATOR COMPANY of Chicago and New York have issued a neat and very desirable catalogue. It comprises a short history of mica down from the time of Thales and Mahomet to that of the Anglo-

Indian. It is illustrated, and gives an excellent idea of the mica mines of India. The chief value of the catalogue to the electrical engineer, however, obtains in the tables and information concerning mica and micanite. The tables comprise resistances, break down voltages of a large number of insulators, while very instructive data is comprised under the titles of "Armature Notes and Commutator Construction."

THE CONNECTICUT TELEPHONE AND ELECTRIC COMPANY, Meriden, Conn. have issued a little yellow covered catalogue, which describes in complete detail the numerous forms of telephones that they manufacture. The little book is profusely illustrated, and shows the construction as well as the general appearance of their apparatus. The goods comprise long-distance 'phones, special anti-induction 'phones, desk 'phones, intercommunicating battery call 'phones, both of the block and switch type; transmitters and receivers and magnetos of all sizes. They also have a line of telephone parts, batteries, lightning arresters and central station switchboards.

THE NEW CATALOGUE of the Western Electrical Supply Company, St. Louis, is a very extensive volume, descriptive of the many goods of which they have the agency. It consists of 753 pages handsomely illustrated matter. The apparatus and appliances are exhaustively described, and the purchaser will have no difficulty in selecting what he needs from the illustrations and descriptions. In addition to the description of the goods the catalogue is made of greater engineering value by the addition of numerous tables, relative to the properties of wire, weights, lengths and resistances. The descriptions are ably written and technically accurate. The book is handsomely bound in cloth and is a decided addition to the reference volumes of the contractor or electrical engineer.

THE G. F. HARVEY COMPANY, of Saratoga Springs, N. Y., has issued a little pamphlet on "Vitogen." Vitogen is a substance which is adapted for treating wounds or burns which are difficult to heal, and particularly electric burns. It is an antiseptic dusting powder, is non-irritating, nonodorous and unaffected by light and heat. Those who have to do with or handle large currents appreciate the difficulty with which electric burns heal, particularly those which are due to arcs between brass or copper terminals. They will therefore be interested in this material, and will do well to send for this booklet. The company have received a great many letters from electricians, speaking of the merits of their compound. It is said to instantly allay all pain due to electric burns, even if they be very severe.

THE WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY has issued a booklet, entitled "One-fourth of a Million Horse-power of Polyphase Transmission Apparatus." The book is very artistically gotten up, and concisely describes a few of the many plants of polyphase apparatus which the Westinghouse Company has installed or supplied the machinery. It certainly impresses the reader with the fact that the Westinghouse Company is doing an immense amount of business, and is supplying power transmission machinery to fill widely different electric and mechanical requirements. Another publication by the same manufacturers is entitled, "Electricity for Machine Driving." It is profusely illustrated with excellent half-tones, showing the many applications of the Westinghouse Tesla motor to the operation of machine tools.

THE NEW CATALOGUE of the American Stoker Company, New York, is an interesting dissertation on their apparatus, written from an engineering standpoint. It is handsomely illustrated, with half tones and diagrams. The apparatus of the company is described and illustrated in detail. Following this are shown the methods of applying the stoker to different types of boilers, and beyond are reports of extensive tests. The whole is supplemented by an excellent collection of photographs of numerous plants, in which the company has installed its apparatus. An interesting series of photographs consists of ten different views of the power house of the Shoenberger Steel Company at Pittsburgh. The photographs were taken at intervals of twelve minutes during the busiest part of the day. Nine stacks in all are shown. The six stacks which receive the flue gases of furnaces equipped with American stokers show no smoke whatever, while the three other stacks, which are not thus equipped, are profusely smoking in all of the pictures. Copies of the catalogue will be sent on application.

BUSINESS NEWS.

THE DEARBORN DRUG AND CHEMICAL WORKS, of Chicago, have recently analyzed fourteen boiler feed waters and shipped two carloads of suitable scale solvents to large sugar concerns in the Hawaiian Islands.

THE WESTERN ELECTRIC COMPANY, Chicago and New York, is placing upon the market its new long-burning arc lamp using the name "Midget" in describing it, owing to its size, the lamp being but twenty inches in length. The name "Midget," however, is no longer used by them in describing this lamp, but the name "W. E. Petite" has been adopted.

THE WESTINGHOUSE MACHINE COMPANY has already begun to reap some benefit from the recent brilliant successes of American arms in Cuba. They are advised that their New York office has received the initial order for a complete steam plant, involving a 100-h.p. Westinghouse engine and Westinghouse generator, together with boiler, pump, piping, etc., this plant to be installed in Santiago de Cuba.

THE W. H. ELLIOTT ELECTRIC COMPANY, of Cleveland, has just completed the repair of five 100-k.w. generators, belonging to the Mahoning Valley Railway Company, Youngstown, Ohio, which were badly damaged by lightning. The first generator was received in Cleveland on Wednesday morning, and on the following Monday morning it had been repaired, returned to Youngstown and was again in commission.

THE LINCOLN ELECTRIC COMPANY, Cleveland, Ohio, was burned out on July 15th. The fire originated in the building two floors below, and spread through the elevator shaft into their floor. They have now moved into larger quarters in the World Building, on Ontario Street. They are now in running order, and can handle any orders that may be sent to them. They manufacture slow-speed dynamos and motors, and have special facilities for testing and repair work.

AMONG RECENT SHIPMENTS of Frontier Tandem gasoline engines by the Frontier Iron Works, Detroit, are: One 60 h.p. to Norway, Mich., for a village electric lighting plant of 600 lights; one 40 h.p. to Bay City, Mich.; one 40 h.p. to Ogdensburg, N. Y.; one 40 h.p. to Wichita Falls, and several 25 and 20 h.p. engines of the same type. The company claims for this engine a regulation equal to that of a steam engine, adapting it to electric lighting and similar duty at a decided economy of fuel and attendance.

THE BEACON LAMP COMPANY of New Brunswick, N. J., have been making some very satisfactory tests on their lamps, with a view to bringing out the fact that they will retain their initial candle-power for a large number of hours. The lamp is claimed to retain its initial candle-power for over 300 hours, and the company also claim that, after 300 hours' burning the lamps give more light and use less current than when started, and show no blackening. They make lamps of from 2.75 watts per candle upward, the standard efficiency being 3.5 watts.

DISSOLUTION OF PARTNERSHIP.—The co-partnership heretofore existing between Edgar H. Freeman, Walter H. Tobey and another, engaged in the business of electrical contracting and the sale of electrical supplies at No. 32 North Water Street, Rochester, N. Y., under the firm name and style of "Standard Electric Construction Company," was dissolved by mutual consent on June 23, 1898. The business will be continued under the same firm name and style by Edgar H. Freeman and Burton A. Vandy, who assume all the obligations of the old concern.

THE FAMOUS FILTER COMPANY, St. Louis, Mo., has made the following recent sales of its "Famous" oil filter: The Syracuse Construction Company, Syracuse, N. Y., third order; the Indianapolis Gas Company, Indianapolis, Ind.; the Electric Lighting Company, Mobile, Ala.; the New York Athletic Club, New York; the St. Louis Ice and Cold Storage Company, the Huse & Loomis Ice Company, second order, the Chonteau Avenue Brewery, the Lafayette Brewing Company, the Wellman-Dwyer Tobacco Company, and the St. Louis Cooperage Company. St. Louis, Mo.

THE NEW BRITAIN MACHINE COMPANY, New Britain, Conn., has compiled a new catalogue on its Case engines and has supplemented it with a very complete series of illustrations of its direct connected sets. The Case engine is adapted to connect directly to any dynamo of the proper speed and capacity. It is well known among steam engineers as a standard high speed engine of small capacity. It is thoroughly inclosed and adapted to the severest service. The catalogue gives dimensional drawings of the engines, which will be useful to those contemplating special applications.

"SOME AMERICAN NOVELTIES INTRODUCED INTO AUSTRALIA" is the title of an article printed in the Williamstown Advertiser, a local daily paper of Williamstown, a portion of Melbourne, Australia, which describes devices constructed for the purpose of closing electrical circuits and thereby ringing bells, telephones or fire alarms. Among these novelties was the fire cable of the Montauk Multiphase Cable Company of New York, which was submitted to a highly satisfactory and practical test. It is stated that this cable has been recommended by the Metropolitan Fire Brigade of Williamstown, and will be introduced into the large mercantile houses of that city. The cable can be attached to an electric bell, to a telephone and to a fire alarm. The peculiar property possessed by this cable is that when it is ignited or affected by dangerous heat it will instantly close any circuit to which it may be connected.

THE AMERICAN SCHOOL OF CORRESPONDENCE, Boston, states that the original plan of its electrical course has been enlarged and improved to keep closely in touch with the latest advances in electrical science. The simplicity and accuracy of the thorough course now offered under the supervision of well-known electrical experts will amply repay careful study on the part of the ambitious workman anxious to better his position. The school has been chartered by the Commonwealth of Massachusetts as "an institution of learning in all branches," thus placing it on a level with other high-grade educational institutions. It aims to distribute technical knowledge to a large army of men who could never enjoy the benefits of a college education were it not for the modern correspondence school, and the terms are so arranged that the poorest-paid workman can secure this valuable instruction, thereby increasing his wage earning ability. A handbook, giving complete information, will be mailed to all interested.

THE WALKER COMPANY, of Cleveland, Ohio, which some time ago was awarded a contract for twenty 500 h.p. alternating current generators with other apparatus for the Union Carbide Company, of Chicago, has, through its vice-president, Mr. S. H. Short, secured a duplicate of this contract for the same company. The order as it stands comprises over 20,000 h.p., in generators. The shops of the Walker Company are running night and day on existing orders, and the recent large additions to the plant will be taxed to their utmost to put out the immense amount of work already in hand.

THE FUEL ECONOMIZER COMPANY of Matteawan, N. Y., reports recent sales as follows: Milwaukee Electric Railroad, Milwaukee, Wis., 2000 h.p.; Worcester Bleach & Dye Works, Worcester, Mass., 350 h.p.; Merchants' Cotton Company, St. Henri, P. Q., 600 h.p.; Excelsior Mills, 300 h.p.; Lehigh Valley Coal Company, Wilkesbarre, Pa., 2000 h.p. (two orders); Western Cold Storage Company, Chicago, Ill., 300 h.p.; Cheney Brothers, South Manchester, Conn., 2000 h.p.; Blackstone Mills, Blackstone, Mass., 500 h.p.; La Belle Mill, Water & Power Company, Coldfield, Colo., 1000 h.p.; Dominion Cotton Mills Company, Magog, P. Q., 1000 h.p. (twelfth order); Frick Company, Waynesboro, Pa., 150 h.p.; D. M. Bare & Co., Roaring Springs, Pa., 600 h.p.; Rome Brass & Copper Company, Rome, N. Y., 350 h.p.

DUPLICATE ORDERS.—The Cling-Surface Manufacturing Company, of Buffalo, N. Y., states that the DeLemar Nevada Gold Mining Company, DeLamar, Nev., was so well pleased with the results derived from three barrels of Cling-Surface belt dressing received early in August that on August 20th it placed a duplicate order for three barrels more. Six barrels in one month to one concern is considered by the company as a very good order, and effective testimony to the efficiency of its dressing. The Cling-Surface Company reports that it is behind in its orders, of which it has a large number on hand from all parts of the country, from Maine to Mexico, and from Florida to Washington; also that its business during the past month was the largest in the history of the company.

THE WARREN-MEDBERY COMPANY, manufacturers of inductor alternators, Sandy Hill, N. Y., reports that its works are now running to their utmost capacity, day and night, in order to fill the orders for their apparatus, and that their business has increased over 100 per cent within the last sixty days, the demand for inductor machines reaching far beyond their expectations. They have recently made a large addition to their works, and the new machinery is now being installed, when they hope soon to be able to meet all demands upon them for alternators. They are also manufacturing a fine line of standard white marble switchboards, and a full line of the celebrated "Medbery" and "Standard" switches, so well and favorably known. The "Medbery" insulation and overhead equipment for electric railways is now being manufactured by this company, who are prepared to furnish this high grade material promptly.

MR. JAMES G. BIDDLE, 910 Drexel Building, Philadelphia, reports a very good demand for the new "Jagabi" portable testing set which he is selling for Willyoung & Company. The Philadelphia & Reading Railway Company has ordered several sets for testing the signal systems on its various divisions, and among other recent customers may be mentioned the United States Naval Academy, Central Union Telephone Company, Jenney Electric Motor Company, Ahearn & Soper, J. H. Bunnell & Company, Western Electric Company, Engineer's Office, District of Columbia, etc. The "Jagabi" portable testing set is probably the most compact instrument of its class on the market. It comprises a Wheatstone bridge, rhoestat, D'Arsonval galvanometer, silver chloride battery, and keys for galvanometer and battery, all mounted in a handsomely finished mahogany case. The theoretical range of measurement is from one one-thousandth ohm to over eleven megohms. Descriptive pamphlet No. 295 will be mailed to anyone interested in the subject.

ON JULY 1ST the name of the Burnham-Hall-Chase Company of Boston was changed to the Burnham Electric Company. Mr. Hall has disposed of his interest in the concern to Mr. Emery H. Rogers, a well-known and influential business man of Boston, Mr. Rogers assuming the presidency of the concern. Mr. W. W. Burnham continues as treasurer and manager and Mr. M. B. Chase has charge of the technical end of the business. The company states that its business has grown very rapidly since it was started last January, and that it is sending its storage and primary battery outfits all over the United States and to foreign countries, and that many of the large dental and surgical supply houses are handling these goods. The company states further that it has some flattering testimonials from customers, old and new, some of them having used the "Excello" improved gravity battery for eight years and more, and that favorable reports are being received from telephone companies and fire alarm and railroad signal superintendents, who have tested this battery.

TOURS IN THE ROCKY MOUNTAINS.

The "Scenic Line of the World," the Denver & Rio Grande Railroad, offers to tourists in Colorado, Utah and New Mexico the choicest resorts, and to the trans-continental traveler the grandest scenery. Two separate and distinct routes through the Rocky Mountains, all through tickets available via either. The direct line to Cripple Creek, the greatest gold camp on earth. Double daily train service with through Pullman sleepers and tourists' cars between Denver and San Francisco.

The best line to Utah, Idaho, Montana, Oregon and Washington via the "Ogden Gateway."

Write S. K. Hooper, G. P. & T. A., Denver, Colorado, for illustrated descriptive pamphlets.

THE CENTRAL ELECTRIC COMPANY, of Chicago, reports a brisk trade on lightning arresters, and is issuing some very attractive circulars on the Wurts arrester, also the Garton arrester. It is also sending out a circular on various types of electrically heated cooking utensils and appliances, and will be pleased to send the same to anyone on application. Among its other specialties the Central Electric Company reports a large and continuously increasing demand for the Samson battery, which has attained an enviable reputation as a product for use under conditions requiring the most exacting service. There has been quite recently introduced the new Samson Semi-Dry Battery, which has become very popular by reason of its desirable features. This battery has extra heavy zincs and large carbons contained in a porcelain jar and sealed. Its ampere output is very large, and as it is portable it is adapted for use under conditions where the former type of open batteries could not be used. The company is carrying large stocks of all Samson types, and is prepared to make immediate shipment on all orders.

WHILE IRON AND STEEL ARMORED CONDUIT is being used, to the exclusion of almost everything else, in new conduit work, there is, nevertheless, a great deal of work where iron-armored conduit cannot be used. The most satisfactory substitute under such circumstances is Canvasite Flexible Conduit. This is particularly useful in wiring or rewiring old buildings. The Electric Appliance Company of Chicago is carrying Canvasite Flexible Conduit in all sizes, from ¼ in. to 1¼ ins. The F. & L. push flush switch is another of the most successful of this company's specialties. It is said to be the smallest push switch on the market, the size of the face plate being only 1¾ by 2¼ ins. It also requires a very small opening in the wall, operates with a very slight pressure on

I-T-E
CIRCUIT BREAKERS

CUTTER ELECTRICAL CO., PHILADELPHIA

Few electrical instruments have been received with the same favor throughout the entire world as has been accorded to the Circuit Breaker. The Cutter Electrical and Manufacturing Company, of Philadelphia, pioneers in this field, have, for some years past, devoted almost their entire attention to the important subject of protection to electric circuits and electrical apparatus. The Circuit Breakers are usually placed on the switchboard and, as their name implies, break the circuit automatically should the current reach a predetermined danger limit. The instruments are susceptible of a wide range of adjustment and are instantaneous in their action. They have frequently been called "electric safety valves," as they afford practically the same protection to an electric circuit that a safety valve does to an engine.

The Cutter Company have developed instruments suitable for either direct or alternating current, of any capacity required and for any voltage. The instruments are beautiful in themselves, being made from the most part of polished copper and iron and steel copper-plated, and are mounted on white marble or black enameled slate. Their accuracy in operation on the circuits for which they are intended is absolutely guaranteed, and the many large switchboards thoughout the United States, which are equipped entirely with this form of protection. give evidence of the favor with which these instruments have been received by leading engineers and electricians. A catalogue will be sent upon request.

the keys, and has many other valuable features, not the least of which is the fact that it is sold at a price considerably below the market for a push flush switch. The Electric Appliance Company is also distributing circulars regarding the latest model, known as "Model '98," of the Packard transformers, for which they are general Western agents.

THE GENERAL ELECTRIC COMPANY began work on its new machine shop at Schenectady, N. Y., recently, when ground was broken for what will be a most important addition to the great manufacturing facilities of that company. The contracts were let last week to A. & R. Roberts, of the Pencoyd Iron Works, Philadelphia, for the steel construction, and to J. J. Turner, of Amsterdam, N. Y., for the masonry, etc. The cost of the new building is estimated at $175,000. The new machine shop will face on Central Avenue, opposite Building No. 15. It will be 653 ft. long and 166 ft. wide, and will be divided into three aisles, the central one having a width of 65 feet, the side aisles being each about 50 feet wide. The total floor space of this building will be not less than 144,250 sq. ft. It will contain the machinery necessary to handle the very large apparatus which the requirements of modern practice have rendered necessary. The need of such an addition to the manufacturing facilities of the General Electric Company is realized after a visit to the factory at Schenectady at the present time. The many orders, both for large machinery and for large quantities of apparatus, are severely taxing their facilities. The working of night shifts has been carried on since the beginning of the year, and, according to the superintendent, there are few signs of the practice being abandoned for the present. It is expected that the new machine shop will be completed before the end of this year. The machinery will be driven by the current transmitted from Mechanicville, seventeen miles distant. In addition to the new machine shop the General Electric Company is making several important extensions to other buildings. The new foundry, which was recently begun, is now in position to receive the iron work, the support for the great traveling crane having been erected last week. This building, when finished, will contain the largest foundry under one roof in the world.

New Wabash
Fast Train East.

"The Continental Limited," a new fast train on the Wabash, now leaves Chicago daily at 12:02 noon for Detroit, Niagara Falls, Buffalo, New York and Boston. This train arrives Buffalo next morning at 5 o'clock, New York at 3:30 and Boston at 5:50 P. M. the next day—only one night on the road. The service, including a dining car, is first-class in all respects. Do not fail to ask for a ticket via the "Continental Limited" on your next trip East.

Other trains for the East via the Wabash leave at 8:50 A. M., 3:15 P. M., and 11:30 at night.

For maps, time tables, etc., write to F. A. Palmer, A. G. P. A., 97 Adams St., Chicago.

IT STOPS WASTE

of water; prevents its flying or spattering; obviates the wear and tear by water-hammer or concussion in pipes; reduces the cost of plumbing; saves repairs, and is warranted to maintain the desired pressure with perfect uniformity, regardless of any and all fluctuations in the outside pressure.

A TECHNICAL EDUCATION
50 CENTS A WEEK

THE new instalment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary text-books.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 43 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

THE "CLARK" WIRE

In a Letter from the Inspector of the Boston Fire Underwriters' Union, he states:

"A Thoroughly Reliable and Desirable Wire in Every Respect."

For Switchboard, Railway and Motor use, we make all sizes of Stranded and Flexible Wire and Cables with Clark's Insulation.

The Clark Wire has been before the public and in use for the past nine years, and has met with universal favor. Thousands of miles of this wire have been sold, and are in use throughout the United States and foreign countries, and the demand for it is constantly increasing, because it always gives perfect satisfaction.

The Rubber used in insulating our Wires and Cables is especially chemically prepared and will not deteriorate, oxidize or crack, and will remain flexible in extreme cold weather, and is not affected by heat.

We guarantee our Insulation wherever used, Ærial, Underground or Submarine, and our net prices are as low, if not lower, than any other first-class Insulated Wire.

We shall be pleased to mail catalogues with terms and discounts for quantities.

ELECTRICAL MEASURING AND TESTING

INSTRUMENTS

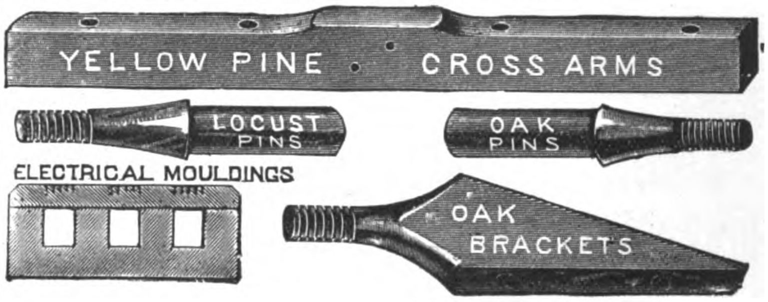
WANTED AND FOR SALE.

ADDRESS

Electrical Apparatus Exchange, Scranton, Pa.

Central Manufacturing Co.,

CHATTANOOGA, MANUFACTURERS AND DEALERS IN TENN.



LOOK HERE!

We are now in the field ready to do business, and we propose to have our FULL SHARE. We can SELL, BUY or EXCHANGE ANYTHING in the way of Electric Railway, Power or Light Apparatus. We can offer you

One 65-light 2,000 C. P. Brush Arc Dynamo, nearly new, self-oiling, for	$575.00
One 30-light 2,000 C. P. Brush Arc Dynamo, good condition	200.00
Two 30-light 1,200 C. P. Brush Arc Dynamos, good condition	175.00
One 50-light 2,000 C. P. "Wood" Arc Dynamo, NEW, great bargain, at	450.00
One 35-light 2,000 C. P. T-H. Ring Armature, good condition	350.00
One 45 K. W. 110-volt Edison Dynamo, nearly new, fine condition	550.00
One 20 K. W. 110-volt Western Electric, fine condition	325.00
One 17 K. W. 110-volt Mather	265.00
One 1,350-light T.-H. Alternator, with instruments and exciter, self-oiler, fine condition	500.00

OVER 600 ARC LAMPS NOW ON HAND.

100 9.6 Amp. T.-H. K. 2, fine condition	7.00 each
100 Manhattan Long Burning 110-volt Lamps, with inner and outer globes	12.50 each

We do not advertise all we have in stock. We have **everything** in the way of Central Station Supplies, and make a specialty of supplies for Brush and T.-H. apparatus. We ship from stock. SEND US A SAMPLE ORDER.

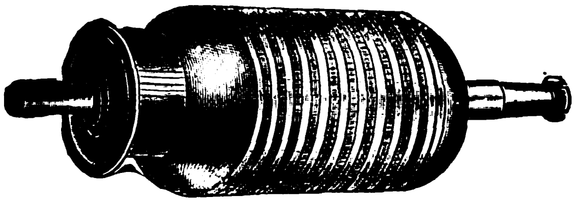
The Cleveland Electric Trading Company,

CUYAHOGA BUILDING, CLEVELAND, OHIO.

THUNDER AND LIGHTNING!!!

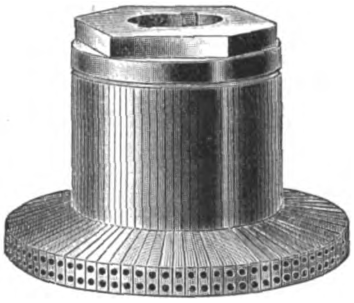
More particularly the latter, damaging the 5 100-K. W. Generators of the Mahoning Valley Ry. Co. of Youngstown. The first two generators reached our shops July 27th and were repaired, returned and again in commission, one in FIVE DAYS and the other in SEVEN DAYS.

WE CAN DO THE SAME FOR YOU.



QUICK AND EFFICIENT WORK.

FULLY GUARANTEED.



We build Commutators and Armatures for every system. Repair Work a specialty One trial secures your business permanently.

LONG DISTANCE TEL. MAIN 2571.

PRICES ALWAYS REASONABLE.

THE W. H. ELLIOTT ELECTRIC COMPANY,

MARINE BUILDING, CLEVELAND, O.

TELEPHONE MEN

will be glad to know that a COMPREHENSIVE TREATISE ON TELEPHONY has at last been produced.

American Telephone Practice,

By KEMPSTER B. MILLER, M. E.,

is now in press and will be ready for distribution in a short time.

This work will include all of the matter published during the last two years in the AMERICAN ELECTRICIAN under the same title, revised and brought strictly UP TO DATE, together with a large amount of matter never before published.

Mr. Miller's experience as telephone expert in the United States Patent Office, and his subsequent experience as chief electrician and superintendent of one of the largest telephone manufacturing companies in this country, has enabled him to write on the subject from its practical as well as its theoretical side.

It will cover the PRACTICAL FEATURES OF TELEPHONE WORK with an attention to detail not found in any other book.

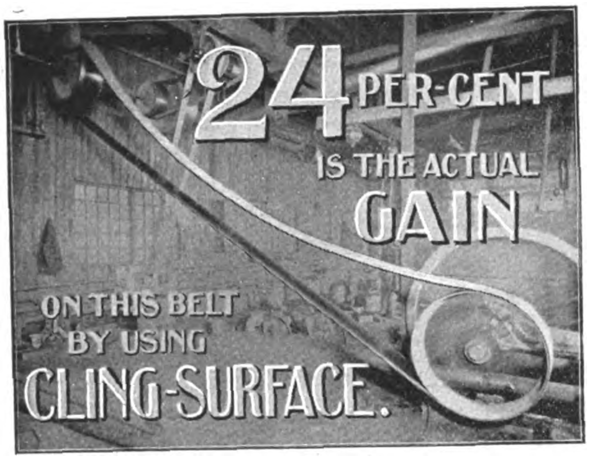
AMERICAN ELECTRICIAN CO., Havemeyer Building, NEW YORK.

OUR METHOD OF TREATING

OILY DYNAMO BELTS

WITH

CLING-SURFACE.



24 PER-CENT
IS THE ACTUAL
GAIN
ON THIS BELT
BY USING
CLING-SURFACE.

WILL STOP ALL SLIPPING, RELIEVE THE BEARINGS,

INCREASE THE POWER,

In some cases as much as Thirty Per Cent,

AND KEEP THE BELTS SOFT AND PLIABLE.

We Guarantee Entire Satisfaction ON ANY KIND OF BELTS.
If not Satisfactory we will bear all the expenses.

ORDER A SAMPLE CAN **NOW.**

3 COURT STREET, BUFFALO, N. Y.

American Electrician.

Vol. X. New York, October, 1898. No. 10.

THE TRANSMISSION PLANT OF THE FRIES MANUFACTURING & POWER COMPANY.

In the State of North Carolina there are a great many undeveloped water powers varying from 1000 to 10,000 h.p. in capacity, and among these has been selected for development one which is known as the "Shoals," and which is located on the Yadkin River, at a point about 14 miles by road from the twin cities, Winston and Salem.

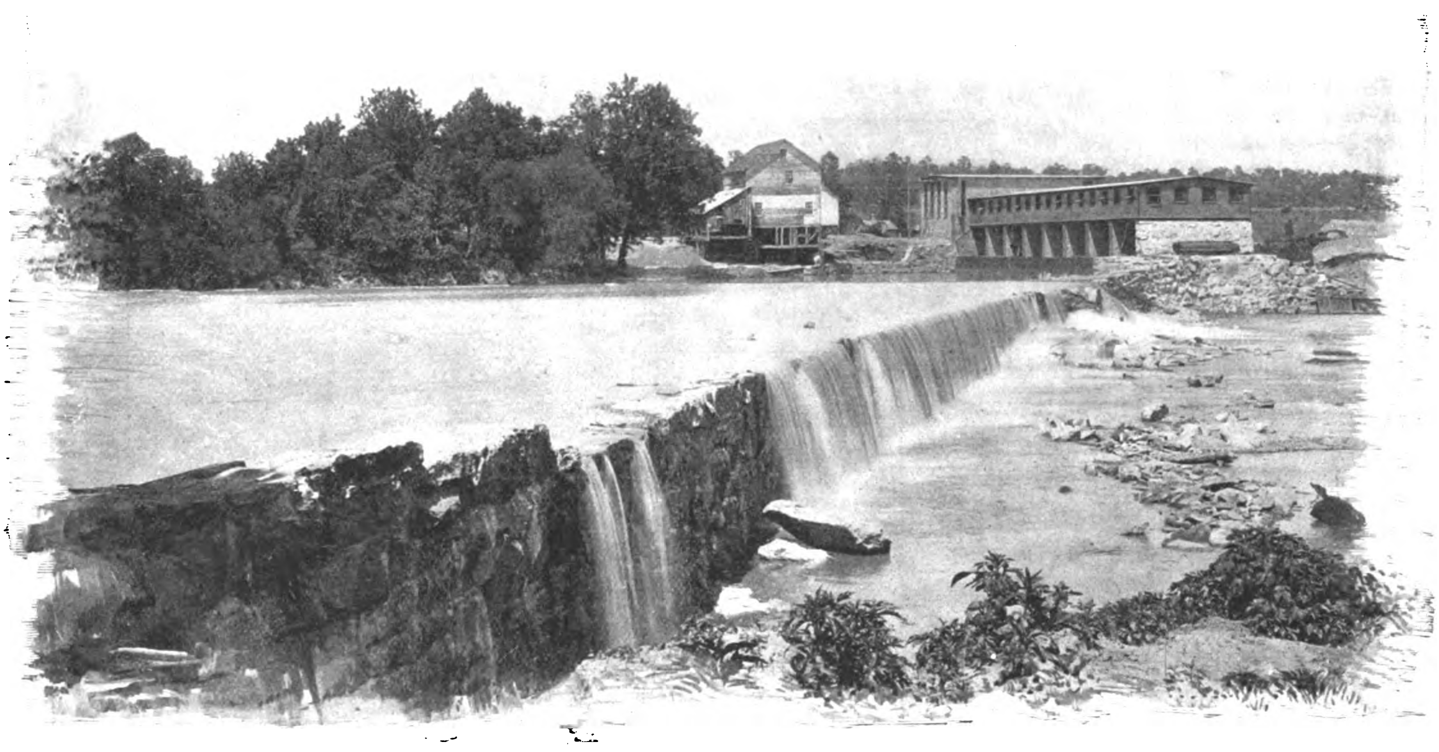

FIG. 1.—GENERAL VIEW OF POWER HOUSE AND DAM.

The fall at this point is about 8 ft., and took the form of rapids before its development. In previous years a portion of this power has been used to operate a saw and grain mill.

The development of this power was by no means a simple problem, for the river, rising as it does in the foothills of the Blue Ridge range, is subject to severe freshets in the rainy season. The country above the power house site is low lying and the employment of a high dam would create considerable land damage. Even so slight an increase of head as 2 or 3 ft. was not practical, and hence the dam could effect but little storage of hydraulic power, and the somewhat irregular flow of the river had to be in a measure depended upon. This is estimated to give with a 10-ft. head from 2000 to 2700-h.p., with a yearly average of about 2300-h.p.

To develop and transmit this power to Winston-Salem the Fries Manufacturing & Power Company was organized.

The plan decided upon by the company's engineer was to build a 10-ft. dam across the river at the "Shoals" and install in a suitable power house a sufficient number of turbines to generate 1000 h.p., the remainder of the available power to be taken care of by future addition.

It was decided to directly connect electric generators to the turbines and to transmit the energy in the form of three-phase currents at a pressure of 10,000 volts to a sub-station in Salem. From this station within a mile radius power is to be distributed at 1200 volts, and for greater distances the power-house pressure will be used. Of course, it is to be understood that at the places where the power is actually used, it is reduced to the proper voltage by suitable step-down transformers.

For the motor service induction types are used when the units do not exceed 50 h.p., and in larger sizes recourse is had to synchronous motors. The electric system adopted was the well-known S. K. C. system, the apparatus for which is built by the Stanley Electric Manufacturing Company of Pittsfield, Mass., and it is to be used throughout.

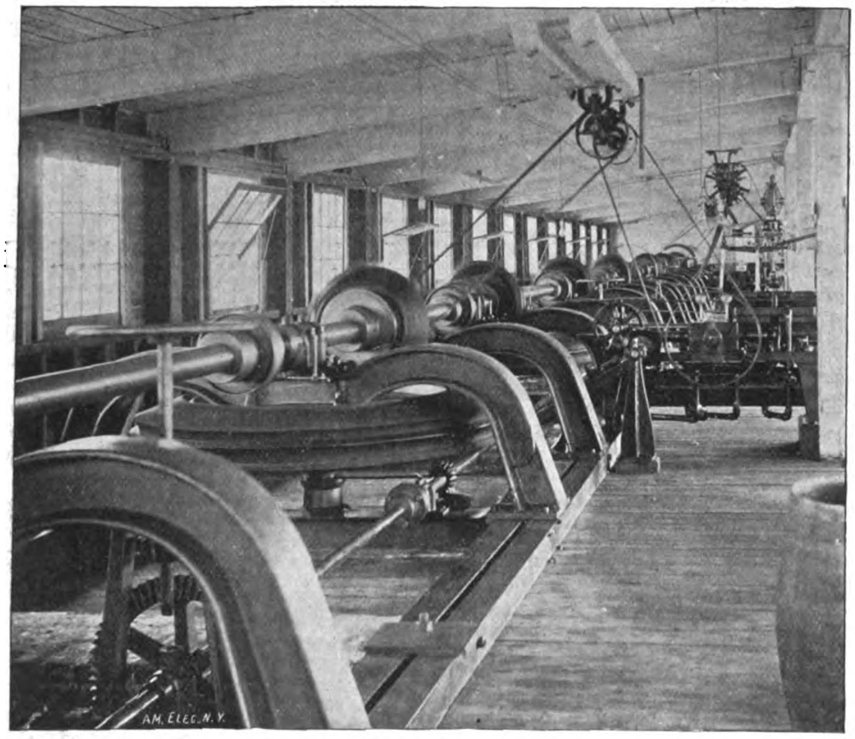

FIG. 2.—VIEW OF MAIN SHAFT AND GOVERNORS.

The hydraulic work was begun in May, 1897, and great precautions were taken to avoid damage from floods and freshets. The dam, of which the frontispiece is an excellent illustration, is built of rough stone, and is 500 ft. long and 10 ft. from the sill to the top of the spillway. At the ends the height is raised by steps to a maximum of 13 ft. The width of the dam is 6 ft. on the top, increasing to double that amount at its base. For a space of 6 ft. in the length of the dam the head is reduced to 9½ ft., where the fish ladder is placed.

The power house is built of brick and surmounts the wheel pits, which are of rough stone. It consists of a generator room and a wheel room, at right angles to each other. The wheel room extends for its entire length into the river, its foundation meeting the dam. It is 145 ft. x 36 ft., and is divided into eight wheel pits or open penstocks, the lower side of each being arched and opening into the tail race. The division walls of the wheel pits are of brick, and also serve as a foundation for the frames carrying the shaft and bevel gears. Each wheel pit is to be equipped with two turbines, with a 2 ft. x 12 ft. waste gate between them.

The present installation consists of one turbine in each pit. They are of the McCormick vertical gear type, manufactured by the S. Morgan Smith Company, of York, Pa., and deliver 165 h.p. each when running under a head of 9 ft. The wheels are submerged and are mounted on a 6-in. pine flooring, supported on I-beams 8 ft. below head water. The draft tubes pass through the floor and extend to the tail race 2 ft. below. Fig. 6 illustrates one of these turbines as it appeared before installation.

The eight wheels are geared onto a horizontal shaft, mounted in bearings supported by the division walls. The vertical turbine shafts carry a large bevel gear with hard wood teeth, meshing with an iron bevel pinion keyed to the horizontal dynamo shaft. Fig. 2 shows this arrangement to good advantage.

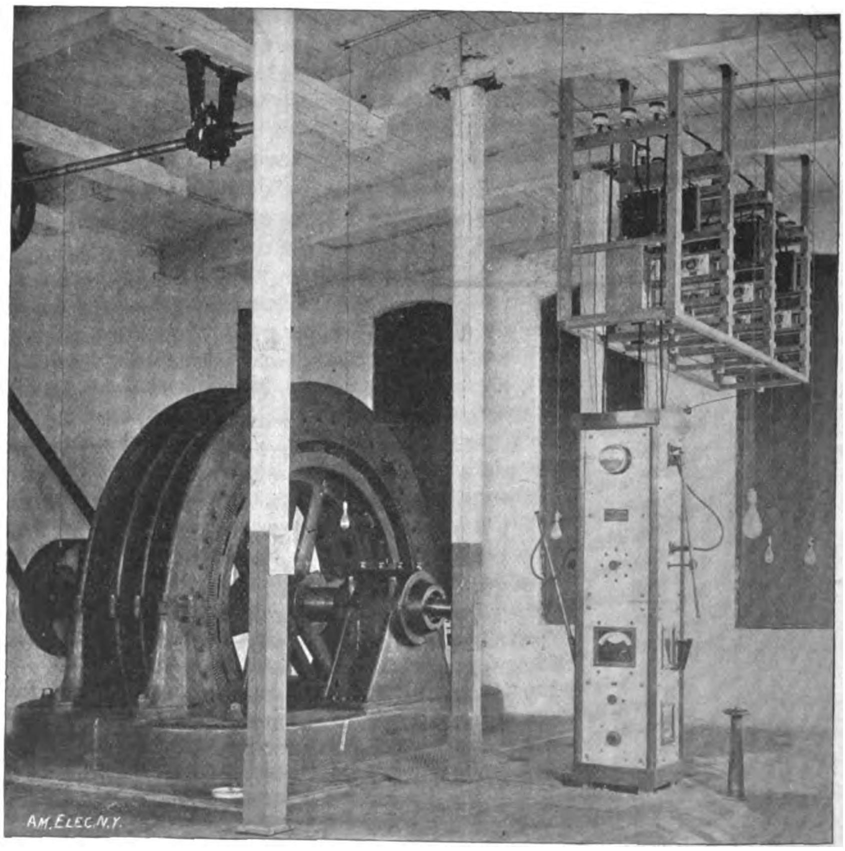

FIG. 3.—GENERATOR AND SWITCHBOARD.

The dynamo shaft is in two sections, each driven by four wheels, and by means of a coupling four or eight wheels may be used. The system is governed by two Lombard type B governors, one for each set of wheels. The governor controls only three in a set, the fourth being controlled by hand.

The generator room is but one story high and 39 by 60 ft. in floor dimensions. It is surmounted by a frame roof 18 ft. from the floor and supported by posts. There is ample room for two generators, with their necessary accessories, but at present there is but one machine with its exciter and switchboard installed. This machine is of the S. K. C. three-phase inductor type and has an output of 750 k.w. at 166 r.p.m. It is particularly interesting, as it is wound for 12,000 volts, and delivers three-phase currents at this pressure to the line without the use of step-up transformers. The efficiency of this machine at full load is claimed to be 93.5 per cent, and its exciting current is but a trifle over one-half of one per cent of its output, being about 86 amperes at 45 volts. The rise in temperature of the hottest part of this machine is but 28 degs. F.

This machine is mounted on a pit foundation, extending 25 to 30 ft. to bed rock, and the pit is thoroughly grouted and plastered within to keep out any high water.

The generator frame is 10 ft. 1 in. in diameter and is divided vertically in such a way that the two halves can be separated on the shaft, allowing room on the inside of the armature for repairs. These are of the simplest character, consisting merely of the renewal of a stationary coil or so, which are readily slipped into place.

The exciter is a 14-k.w. four-pole Crocker-Wheeler machine, driven at a speed of 1100 r.p.m. from the water wheel shaft. It can deliver its current at 70 volts, and is large enough to excite the fields of two such generators. It is interesting to note that the regulation of the water wheels is so close that no separate exciter turbine was needed.

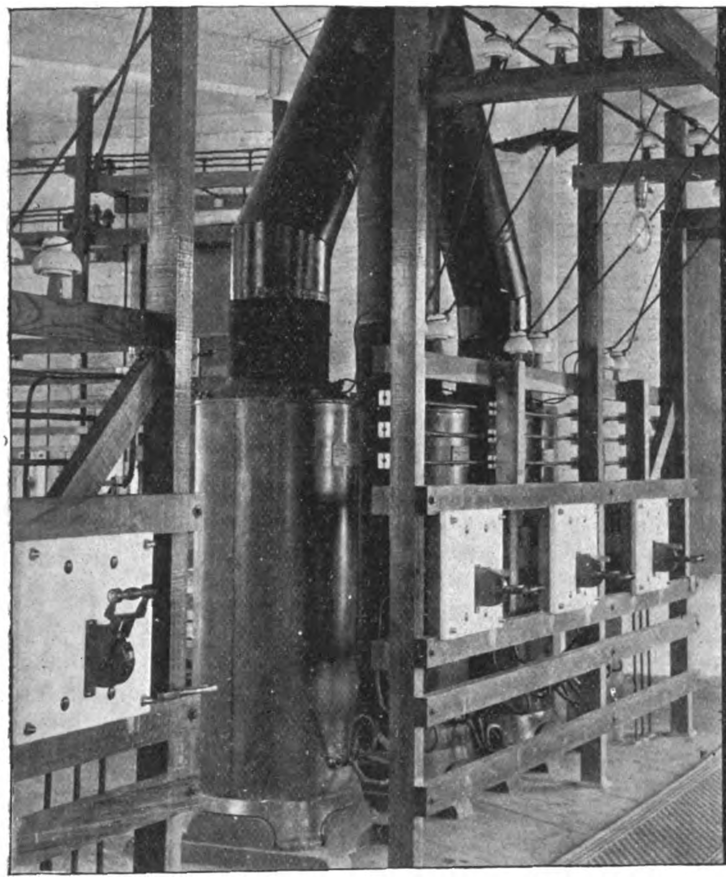

FIG. 4.—SWITCHES AND POWER TRANSFORMERS AT SUB-STATION.

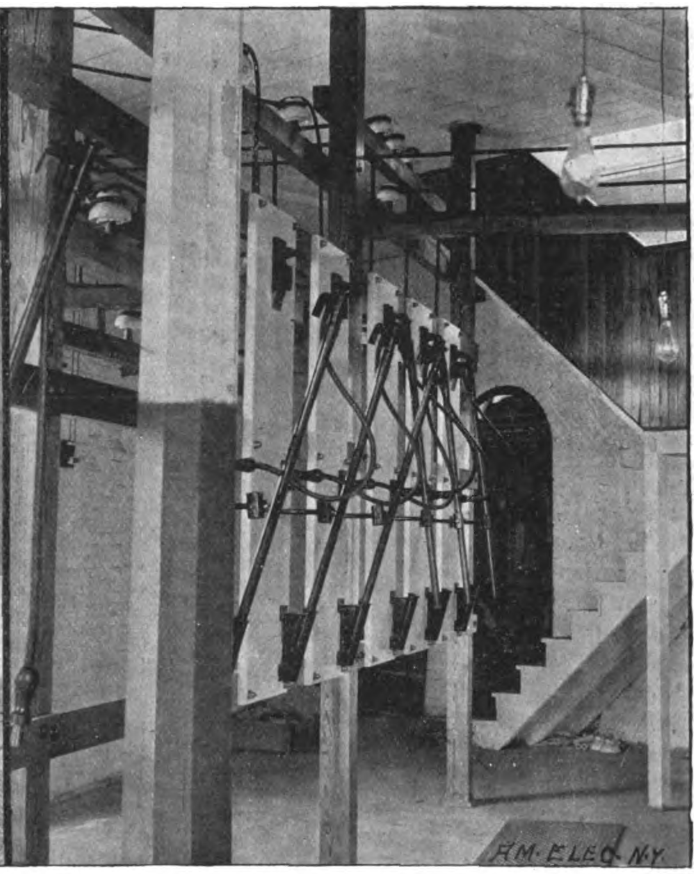

FIG. 5.—COLLECTING BOARD.

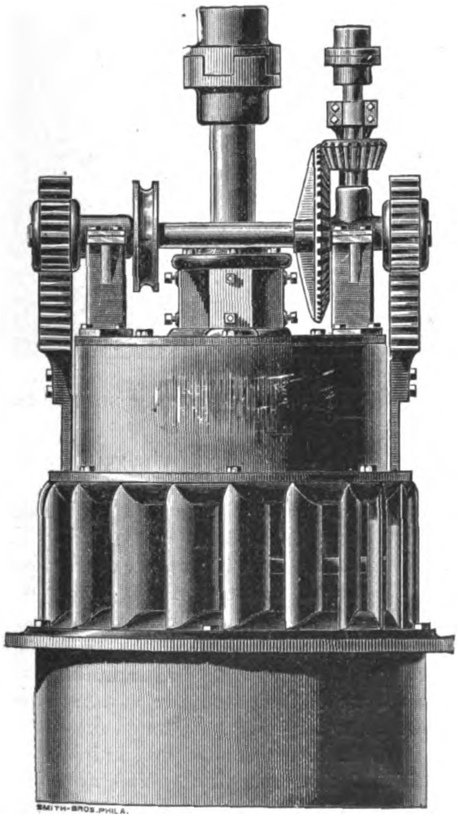

FIG. 6.—TYPE OF TURBINE USED.

The switchboard consists of four white marble slabs formed into a pillar 21 ins. square by 9½ ft. high. The mountings are of lacquered brass and are trimmed in oiled hard wood. This construction is very neat and compact, and as all live contacts are concealed within the pillar it is perfectly safe. Upon the board are mounted three high-tension single-pole single-throw switches. They are of the plug type, with long handles and a bayonet lock. Two 12,000-volt static ground detectors are also used and are connected in such a way that the needles deflect toward the grounded wire.

The generator voltage is read from a static voltmeter connected to the secondaries of a transformer stepping down to 2000 volts. The board is also provided with an alternate current ammeter, a voltmeter and a switch for the exciter circuit, and the exciter shunt rheostat. The field rheostat, the hand wheel of which may be seen to the right of the board, is suspended from the floor 18 ins. below, to provide ventilation and economize space.

Above the switchboard and extending to the wall is seen a lightning protection rack, which comprises three vertical sections, each of which carries a set of arresters and choke coils for each leg of the high-tension

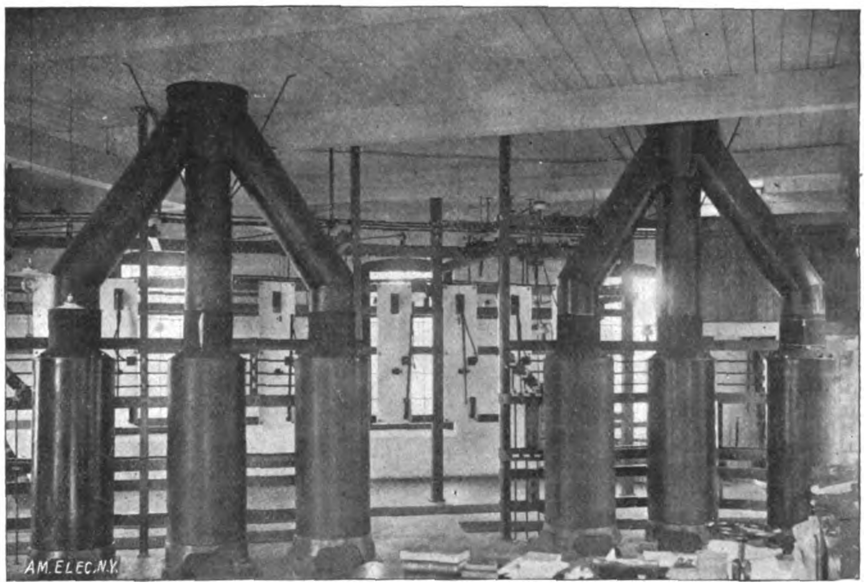

FIG. 7.—POWER TRANSFORMERS.

circuit. These protection sets, like those used at the other points of the line, have choke coils in series with each leg of the circuit, with S. K. C. arresters connected in such a way that there are always four arresters between the line and ground.

The station wiring is placed under the floor. The high-tension wires are insulated for 25,000 volts, and in addition are supported by triple petticoated porcelain insulators on horizontal cross arms. They reach the switchboard by passing through the floor at the base of the pillar. The three power wires pass out of the tops of the pillar and connect to the line.

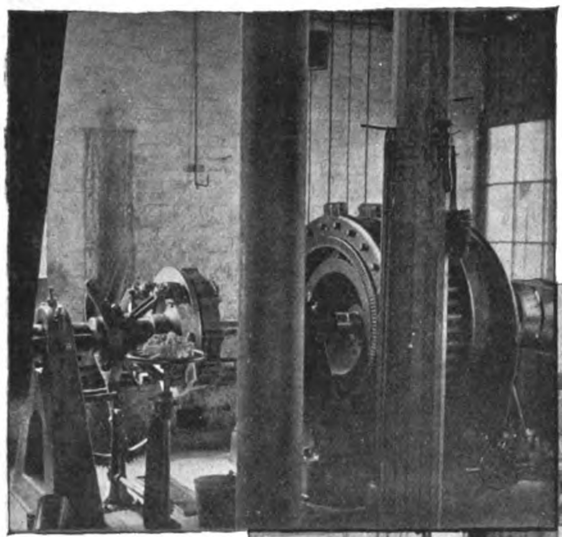

FIG. 8.—300-H. P. SYNCHRONOUS MOTOR IN ARISTA COTTON MILL.

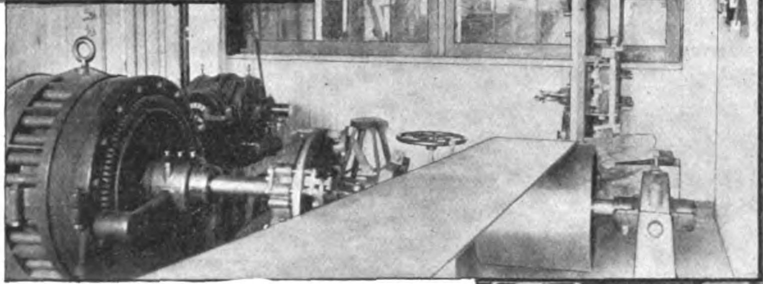

FIG. 9.—80-H.P. SYNCHRONOUS MOTOR IN WOOLEN MILL.

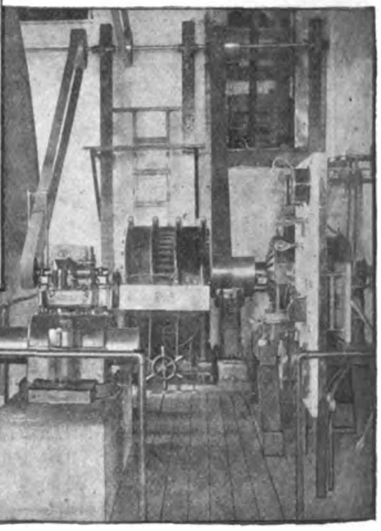

FIG. 10.—300-H.P. SYNCHRONOUS MOTOR AT SOUTH SIDE MILL.

The line is 70,000 ft. in length and extends from the power house to the sub-station in Salem. It consists of three No. 1 soft-drawn copper wires strung on 6-in. triple petticoat porcelain insulators supported on two cross arms. The three wires are 24 ins. apart and form an equilateral triangle, of which the lower cross arm is the base. There are two transpositions in the line, thus giving the triangle two-thirds of a rotation. The line follows the railroad almost all the way to Salem, and the wires are placed on the sides of the pole away from the track to facilitate the stringing of a duplicate set.

The poles are of white cedar and from 36 ft. to 48 ft. long. They are set from 5½ ft. to 6 ft. in the ground and spaced 100 ft. apart, excepting where the line crosses a highway, where they are set 50 ft. apart. Each pole carries three cross arms, the lower two being used for the power circuit. The top arm has six pins. Of these the outer pins carry a barbed wire ground circuit and the inner pins a telephone circuit, which can also be grounded in case of storm. The extra pins are used in transposing the telephone circuit, which is done every 500 ft. At every mile in the length of the line a branch from the telephone circuit is taken down the pole to within a short distance of the ground, so that frequently communications can be had with either end of the line. The barbed wire is grounded every 1000 ft. through a ½-in. galvanized iron pipe driven 10 ft. into the ground at the base of the pole. The poles are all numbered and the line construction is otherwise very complete.

The line enters the sub-station on the second floor and is duly provided with lightning protection, from whence it passes to the main bus bars on the first floor. From these bars three three-pole high-tension circuits are taken through nine single-pole high-tension plug switches. The first of these circuits connects to another set of bus bars, to which the power transformers shown in Fig. 7 are connected three-phase, two sets in parallel. The second high-tension circuit passes through a lightning protection rack and passes to what is known as the fertilizer line. This line is 3½ miles long, and consists of three No. 6 insulated wires, and terminates in a fertilizer works, at which the pressure is reduced by three 25-k.w. oil transformers, to 600 volts, and at that pressure supplies two induction motors, one of 50 h.p. and the other of 30 h.p.

The third high-tension circuit passes through lightning protection and connects with what is called the South Side line. The line is 2½ miles in length, and, like the fertilizing line, consists of three No. 6 insulated wires. It passes at what is known as the South Side mill to three 75-k.w. power transformers, which step down to 600 volts and supply current to a 300-h.p. synchronous motor, shown in Fig. 10, a 10-h.p. induction motor, and three 80-light transformers. The general construction of the second and third high-tension circuits is similar to that of the main line, with the exception of the telephone circuits. It may also be added that the poles are higher, to avoid the city wires.

The primary board in the sub-station is placed about 8 ft. in front of the west wall and parallel therewith. It consists of nine long-handled high-tension switches, having marble bases and mounted on a wooden framework. In the middle leg of the high-tension circuits is placed a Thomson ammeter, mounted on a marble slab.

The collecting board, shown in Fig. 5, is a wooden framework, on which are mounted six double-throw single-pole self-inclosing slide switches. These switches connect the secondaries of the transformers through twelve single-pole porcelain fuse blocks to the 1200-volt bus bars extending to the distributing board. The distributing board shown in Fig. 6 also has a wooden framework, upon which is mounted six 350-ampere single-pole throw switches on marble bases, two Thomson ammeters, two static ground detectors and one Bristol recording voltmeter. From this board two 1200-volt circuits are taken. One supplies current to a 300-h.p. synchronous motor and to two 80-h.p. motors of the same type in the Arista cotton, grain and woolen mills. These are shown in Figs. 8 and 9.

The second circuit supplies current to one 300-h.p. synchronous motor in the Wiston-Salem Electric Station, and to two induction motors of 50 h.p. and 30 h.p. in other shops.

The transformers are of the vertical self-ventilating type. They are ventilated as shown by large iron pipes extending through the roof to a hood about 3 ft. above. The working temperature is however very low and the commercial efficiency is not impaired.

The ground detectors in use throughout are of the static type. The ground wires for the several sets of lightning protectors are of No. 1 copper wire, securely soldered to large copper plates set from 6 ft. to 10 ft. below ground and imbedded in powdered charcoal. The plates are either in naturally wet places or are kept damp by periodically pouring water into a pipe connecting with them.

A duplicate or larger unit and line will shortly be added, as the capacity of the present generator is nearly reached.

Electric Lighting at the Grand Central Depot.

Within the past year the Grand Central Station, which is a Union depot for the New York Central & Hudson River Railroad, the New York, New Haven & Hartford Railroad, and the New York & Harlem Railroad, has been reconstructed with a view to improving its facilities and enlarging its office accommodations. This has necessitated the installation of an entirely new electric light plant, which in some respects differs from standard isolated plant practice, and is therefore interesting.

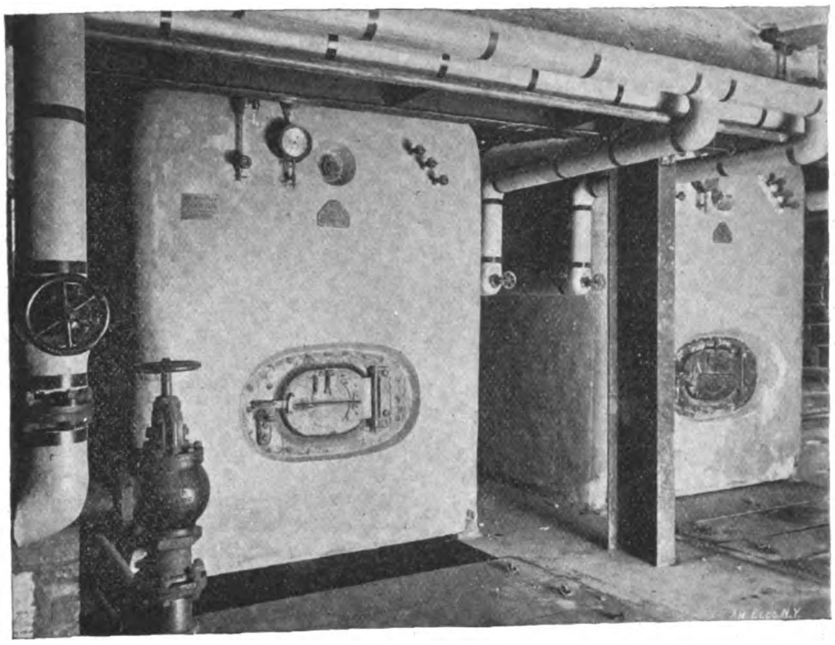

FIG. I.—BOILER ROOM.

One of the unique features of this plant is its boiler room. The space set apart for boilers is very limited and much cut up by foundation pillars and other members of construction. There was no room for boilers of the ordinary water tube type, or even for a customary brick setting used with common cylindrical boilers. The solution of the problem consisted in the installation of six boilers of the locomotive type, built at the Schenectady Locomotive Works. These boilers are worked at a pressure of 125 pounds, at which they can supply sufficient steam to actuate 200 h.p. each in steam engines. The boilers are arranged in a row, and their further ends are united by a long breeching which passes to a 120-ft. stack, 7 in. in diameter. The boilers are heavily sheathed in a magnesia covering, supplied by the H. W. Johns Company, of Brooklyn. The fireboxes are of the regular locomotive type. A spread firing carrying a moderately thick fire is used, and the plant is expected to consume about five tons of broken anthracite coal per day.

In Fig. I is illustrated two of the boiler fronts, and it may be said that this type of boiler is perhaps quite as economical as some of the horizontal cylindrical boilers for stationary work. The expedient has certainly realized the advantage of compact construction in a very high degree.

The boilers themselves are located directly between the abutments of the building, and the space for the firemen in front is under the sidewalk, which is convenient for the delivery of coal and for the handling of ashes, for which a hydraulic lift is provided.

The boilers are fed by two 10 x 5¼ x 10 duplex pumps of the Knowles type. They are supplied with Croton water from a surge tank or from a feed water heater. In addition the boilers are supplied with a Keiley regulator in the main breeching connection, and a butterfly damper in each boiler connection, which is controlled by the firemen.

These boilers deliver their steam to a long header which passes into the engine room. The piping system is not provided for in duplicate. The pipes are covered with the same magnesia covering that is used on the boilers, and are very carefully graded to traps, some of which are of the Keiley and some of the Creamer type. This effectually takes care of the condensation, which is discharged into the feed water heater or blow-off tank as necessity or occasion may require.

The drainage of the steam system is carried to a pump pit below the sewer line and a Braender automatic cellar drainer serves to lift the water into the sewer.

Passing from the boiler the steam enters a large Webster separator and from thence flows into a long header, which runs the entire length of the engine room. This header being of considerable length the expansion has to be allowed for, and this is done by making the taps which pass to the engines with a large loop, thereby much increasing their flexibility and minimizing the strain at the joint between the tap and the header. This arrangement is shown to good advantage in Fig. 2, a picture of one of the units. The steam pipes supplying engines and the elevator pumps are provided with separate separators.

The engines in this plant were made by the Ball & Wood Company. Two of them are single expansion engines of 80 and 120 h.p., respectively. The 80-h.p. engine has cylinder dimensions of 11 x 11, and a speed of 265 r.p.m. The 120-h.p. machine has a speed of 250 r.p.m. and cylinder dimensions of 13½ ins. x 12 ins. There are also two tandem compound Ball & Wood engines 13½ ins. x 22 ins. x 16 ins., capable of developing 240 h.p. at 230 r.p.m. One of these units is the subject of Fig. 2.

The engine foundations are of concrete, and four generating sets are mounted on a single large foundation. The flooring of the engine room is of small hexagonal tiling. The engines are lubricated from a large reservoir on each engine and the feed is by gravity.

Three different provisions are made for the engine exhaust, comprising the station heating system, the feed water heater, or the atmosphere, as required. No condenser is used.

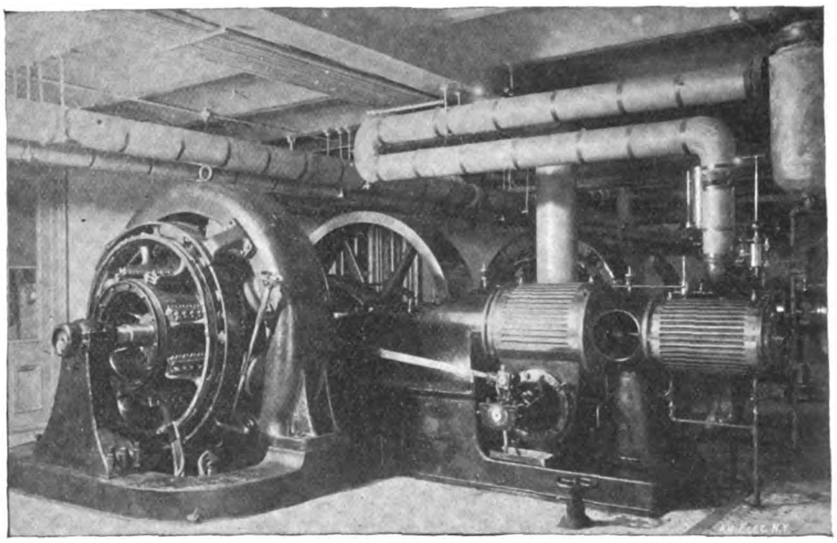

FIG. 2.—150-K.W. GENERATING SET.

The heater is of the Webster make and of 1500-h.p. capacity. The main exhaust is supplied with two grease extractors, but no attempt is made to use exhaust steam for feed water purposes.

There are five dynamos, all of which were made by the Crocker-Wheeler Company, of Ampere, N. J. The two large machines are of 150-k.w. capacity, and can deliver 1200 amperes at the station voltage, which is 125. The two smaller machines are of 75 and 50-k.w. capacity, respectively. All of the dynamos are directly connected to their engines and are therefore of the same speed as the latter. The dynamos, which are the latest Crocker-Wheeler production, have many unique features of design. The field frame is of cast iron, to which the pole-pieces are bolted.

On the inner edge of the field frame is cast a flange, which partly protects the field coils. The magnet is in halves, and is held together by bolts, which pass through flanges on the inner side of the frame, and as the outer surface is filled and rubbed down with great care, the frame looks as though it were all one piece. The pole-pieces are of peculiar shape, which may be best understood by consulting Fig. 6. It will be noticed that the fringing of the field is obtained by making the approach wedge-shaped, instead of gradually increasing the clearance. This is certainly an improvement, for it enables a more accurate adjustment of the stray field, which is a most important matter in commutation.

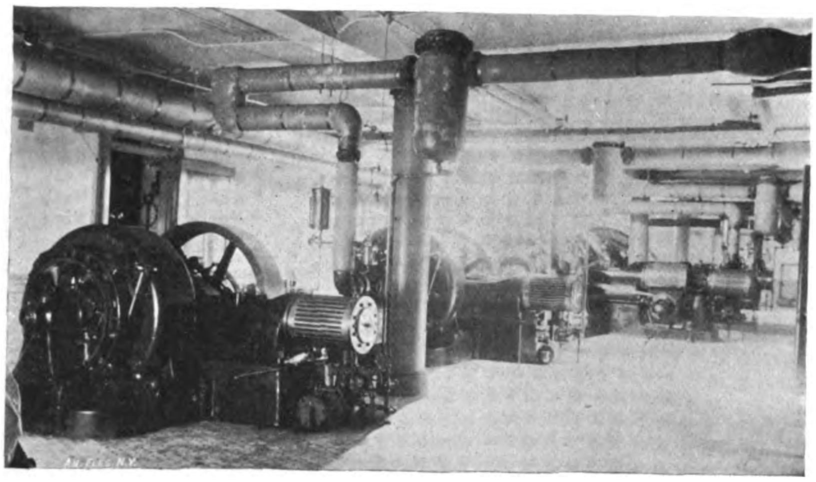

FIG. 3.—MAIN ENGINE ROOM.

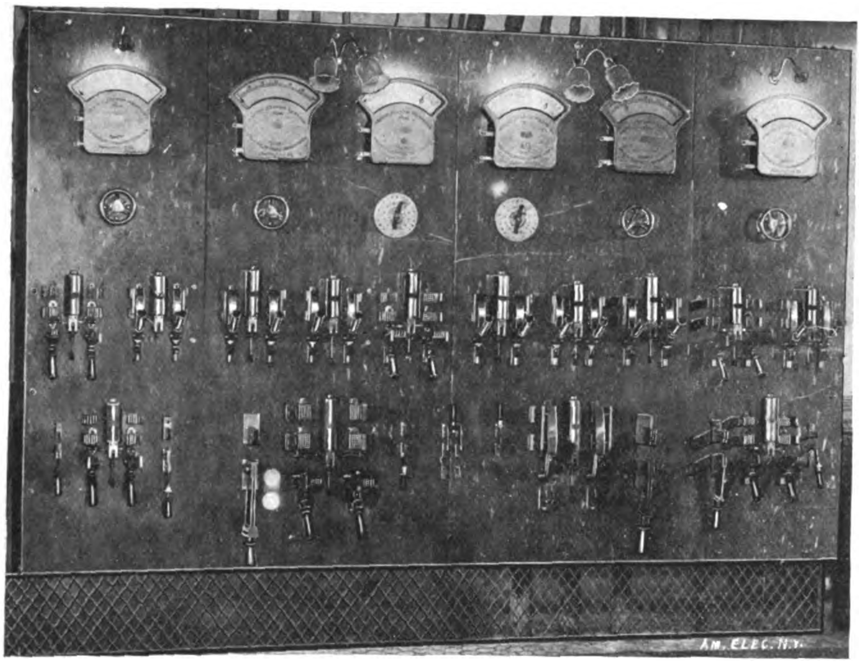

FIG. 4.—SWITCHBOARD.

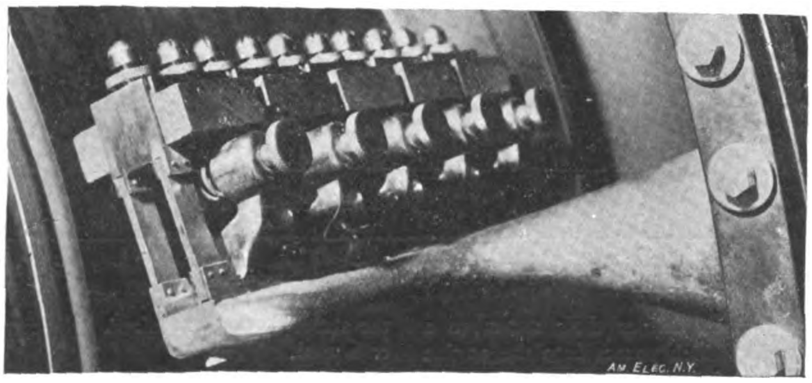

FIG. 5.—IMPROVED BRUSH HOLDER.

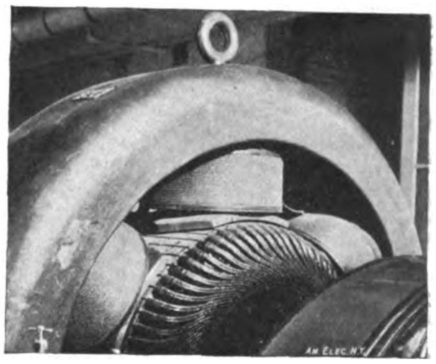

FIG. 6.—SHOWING PECULIAR SHAPE OF POLE PIECES.

The armature diameter of the 50-k.w. machines is 28 ins., the length is 11 ins. The 75-k.w. machine is but little larger, being 32½ x 12½ ins., and the armature dimensions of the 150-k.w. machine are 50 ins. x 16 ins.

The commutator of the smallest machine has 126 bars, that of the next size 111 bars, while the larger machines have commutators containing 192 bars each. The length of the bars on the commutators of these various machines are 6, 10¾, and 13½ ins. respectively.

The brush holders of these machines are worthy of special attention, and are illustrated in Fig. 5. The brush is securely clamped in a brass tube, which in turn is connected with a standard, on which it is mounted, by means of four flexible copper strips. A spiral spring connected between appropriate lugs provides a pressure to force the brush against the commutator, and by lifting on the screw which connects this joint, the brush may be lifted clear of the commutator and latched in that position. A slight turn of this screw suffices to replace it in its operative position once more. The merits of this holder are its simplicity, its convenience and the excellent contact provided from the surface of the brush to the stud. It is a recent creation of the Crocker-Wheeler Company, and is favorably commented upon wherever it has been used.

The output of these generators is controlled and distributed by means of a four-panel switchboard, shown in Fig. 4. The machines are connected by means of double pole switches to a set of bus bars, from which ten distributing circuits take their rise. Each machine is provided with a double pole circuit breaker of the Ward-Leonard type. The output of the machine is measured by means of two Weston voltmeters and four ammeters, two of 400 and two of 1200 amperes capacity. They are of the illuminated dial type. The voltmeters can be connected to the various machines or circuits by means of two Elliott compound voltmeter switches.

The station load is equivalent to 6400 16-c.p. lamps. The building is wired on the two-wire system, with a 7 per cent drop in the lines.

The motor service of the building is very small, consisting of two 1-h.p. motors, used to drive ventilating fans. Almost all of the power is used for lighting.

From the general view of the engine room, shown in Fig. 3, it will be noted that the machinery is not crowded, in which respect this plant is a notable exception to isolated plant practice; but it may be added that compact construction in isolated plant practice is in most cases a necessity rather than a feature of merit in the modern office buildings in crowded city districts.

◆

DEVICES FOR EXPLORING THE POTENTIAL AROUND COMMUTATORS.

BY GEORGE D. SHEPARDSON.

In studying the action of a dynamo or motor, it is sometimes desirable to investigate the relative intensity of the magnetism in different parts of the field, or, what is similar, the voltage between adjacent commutator bars when in different positions. Such investigations are useful in determining the effects of changes in the size or shape of the pole-pieces, the effects of the current in the armature upon the magnetic field, the difference between the armature reactions of a dynamo and of the same machine as a motor, the effects of varying the strength of the current through the field coils; with ring armatures the same method may be used to determine whether the magnetic field is the same on the opposite sides of the armature; also with multipolar machines which are not cross-connected between similar coils of the various circuits, one may determine whether the various parts of the magnetic circuit are equal.

For this purpose a number of methods have been developed, some of which are quite simple. The two methods requiring the least apparatus and also the least skill, are what are often called the single brush and the double brush methods. These require a voltmeter and one or two small brushes which may be moved so as to make contact with the commutator at various positions, while the machine is operating as a dynamo or motor. In the one-brush method one terminal of a voltmeter capable of measuring the total voltage of the machine is connected with one of the regular brushes; the other terminal of the voltmeter is connected with a small auxiliary brush which may be held successively at different positions between the main brushes, as indicated in Fig. 1, in which P and N are the main brushes and b is the auxiliary or exploring brush. By plotting the results, using the various positions of the auxiliary brush and the corresponding readings on the voltmeter, one may obtain a curve which will show to the eye the more or less gradual increase in the voltage from bar to bar.

By connecting the voltmeter between two exploring brushes which are separated the width of one commutator bar and which may be moved to various positions between the main brushes, as suggested in Fig. 2, one may measure the voltage in a single armature coil when in the various positions. Since the voltage in a coil is directly proportional to the rate at which the magnetic lines of force are being crossed or cut, the readings of the voltmeter at the various positions of the pair of brushes are direct indications of the strength of the magnetic field at those points, it being understood of course that the armature is rotating at constant speed.

A number of arrangements have been used for holding the exploring brushes at the different positions desired. An ingenious and simple device was described in the "American Electrician" of March, 1898, page 110, by Professor McKissick, from whose article Fig. 1 is reproduced, and in which may be found examples of curves plotted from the readings taken as indicated above. The device there described involves a considerable outlay for hard rubber, for which vulcanized fibre might be substituted with some less expense and without appreciably affecting accuracy; the fibre is less subject to rotting from the oil, which is liable to make trouble with hard rubber, and the objection of fibre absorbing moisture and swelling may be largely overcome by a coat of shellac.

A somewhat similar device was used in one of the railway shops in Minneapolis, consisting of a ring 9½ ins. in diameter cut from fibre ¼ in. thick. This ring was bored out to an internal diameter of 7 ins. to fit the average commutator, and was then laid out into sixty-four sections, the number of bars in the commutator, and a 3-32-in. hole was drilled through the ring flatwise at each division. One hole was drilled radially through the ring so as to allow a No. 11 wire to fit snugly and yet be free to move in and out. A wire spring pressed this wire against the commutator. A pin passing through any one of the sixty-four holes in the ring and also through a clamp attached to one of the brush-holders, allowed the ring to be rotated one step at a time, so that the short radial wire or exploring brush could be placed in any desired position.

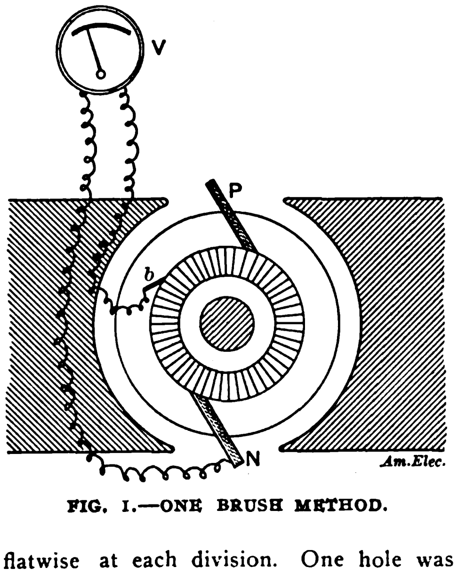

FIG. 1.—ONE BRUSH METHOD.

Another device differing from the above was also designed, consisting of a ring turned from hard fibre one-half inch thick and bored out to fit the average diameter of the commutators. The ring was then laid out into as many sections as there were commutator bars, and a 1-16-in. hole was drilled radially through the ring at each division. The ring was then split for easy placing on the commutator, a soft rubber band stretched around the outside serving to hold it together and also to press a short piece of pointed wire through one of the holes so as to touch the commutator. Suitable clamps held the ring from moving. One terminal of the voltmeter was then connected with one of the regular brushes of the motor, the other terminal being connected by a flexible wire to the short piece of wire which could be placed in any of the radial holes in the ring, so as to make contact with the commutator at any desired point.

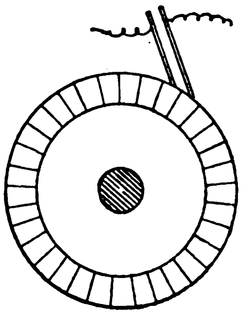

FIG. 2.—TWO BRUSH METHOD.

A still simpler, but less accurate scheme, suitable for machines having two or more brushes on a side, is to slip a narrow strip of stout paper under one brush and stretch it around the commutator to the corresponding brush on the opposite side. Then, while the machine is standing still, make a pencil mark on the paper directly opposite the mica insulation between the commutator bars. Now put the machine to work, and if the paper has been properly fastened, it will stay in place long enough for the experiment. The exploring brush may be simply a wire (No. 16 or larger) filed to a sharp point, which is held in the hand opposite one pencil mark at a time. This method requires two experimenters, one to hold the wire and the other to read the voltmeter. The two-brush method may be used with this "apparatus," it it may be so dignified, by fastening two wires together so that the points shall be apart the width of a commutator bar and mica; the two wires are then handled as one, the voltmeter being connected between the further ends of the two wires.

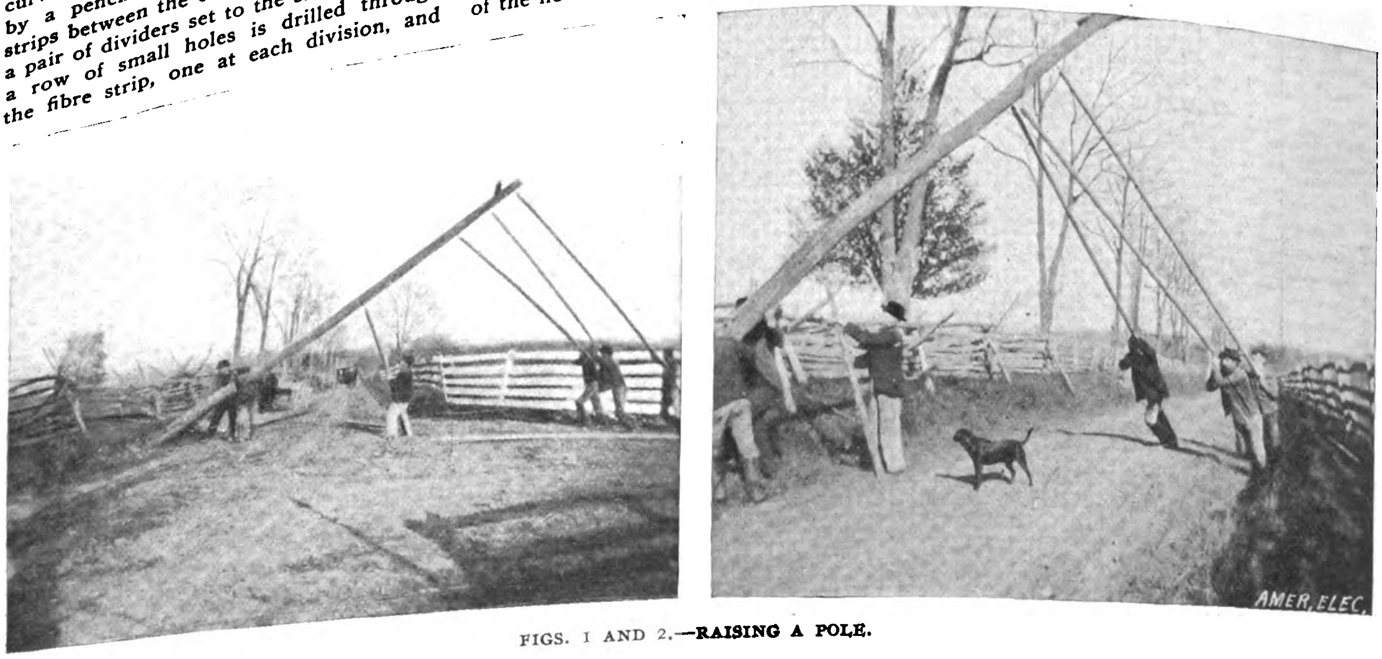
A more durable and more accurate device has been in use for some time in the electrical laboratory of the University of Minnesota, giving so much satisfaction for easy manipulation, accurate results and low first cost, that a description may be of interest to others. A strip of hard fibre 1-16 in. thick, ¼ or ⅜ in. wide, and long enough to reach a little more than half way around the commutator, is soaked in water until quite soft. A strip of oiled paper is then wrapped around the commutator to protect it from the moisture. The softened hard fibre is then wrapped around the commutator and tied closely, so that in drying it will take the curvature of the commutator. In a few hours the fibre will have become dry and hard so that it will retain its proper curvature. The fibre strip is now marked by a pencil or knife opposite the mica strips between the commutator bars, or by a pair of dividers set to the same distance; a row of small holes is drilled through the fibre strip, one at each division, and the holes are numbered with a pen or, preferably, with steel stamps. A larger hole is drilled at each end of the strip, into which a hard cord or wire is fastened. A thin coating of graphite or hard grease is then smeared over the inside of the ring so as to lubricate it sufficiently to prevent it from binding upon the commutator, and the outfit is ready for use.

This simple strip of fibre with a row of holes and a cord at one or both ends constitutes the exploring device. It may be placed in position while the machine is running, and may be removed without disturbance. When placing in position for use, the strip is sprung over the commutator and one of the cords is fastened to some convenient part of the machine below the commutator so that the cord holds the strip against the tendency toward being pulled around with the commutator. The length of the cord is adjusted so that one of the holes comes opposite the toe of one of the brushes, and the other cord is tied down so as to keep the fibre strip from moving sidewise. The potential around the commutator may now be explored by either the single or double-brush method, the end of the wire being held against the commutator through the holes. The whole operation of adjusting, taking readings and removing the apparatus requires little more than half an hour, even for a novice.

ERECTING A HIGH VOLTAGE TRANSMISSION LINE—III.

BY S. H. DAILEY.

The set of raising tools consists of 2 pike poles, 12 ft. long; 3 pike poles, 14 ft. long; 1 dead man, 6 ft. long; 1 dead man, 8 ft. long; 2 tamping tools; 1 short handle shovel; 1 crowbar, 8 ft. long; 1 cant hook; 1 monkey wrench, 12-in.; 1 hand axe. The pike pole, dead man and tamping tool are shown in Fig. 5.



FIGS. 1 AND 2.—RAISING A POLE.

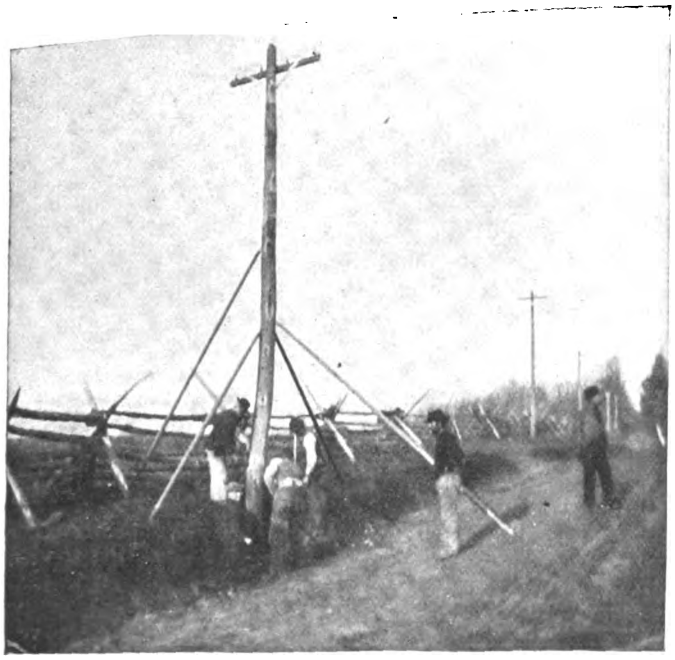


FIG. 3.—POLE RAISED.

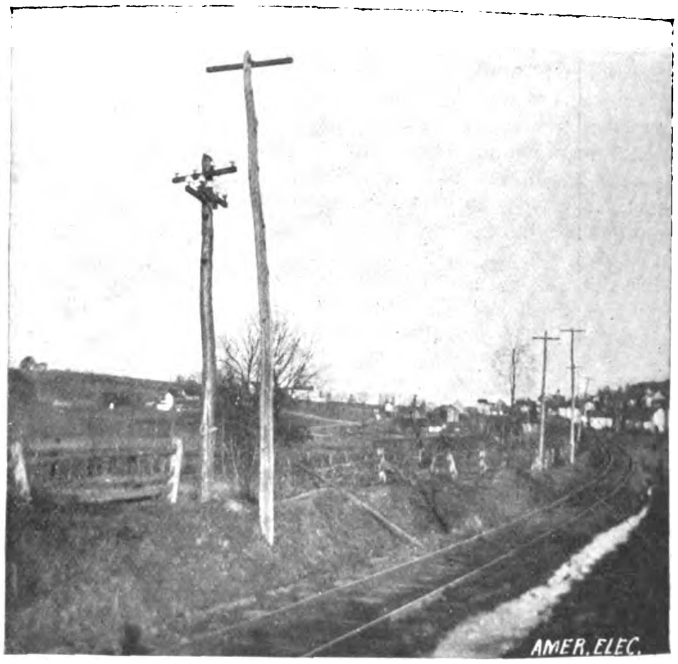

FIG. 4.—REVERSE TURN.

It is understood that the same gang that did the digging is to raise the poles, so select the shortest man to man the "dead man" and four of the heaviest to do the "piking," the remaining man to place himself at the butt of the pole to help steady it from swinging, and also direct the pikers as to whether or not the butt is entering as it should.

First, take the pole and place it so that the tip is up hill and the butt is over the hole, pushed up against the crowbar, which should have been set in the hole and against which the pole slides, to prevent it from plowing into the ground. If the pole should have been placed any great distance from the hole, it can be easily slid to it by rolling the butt on a shovel and all hands lifting at the top and pushing together.

Now take all hands but the one manning the dead man and lift the tip of the pole high enough to set the dead man under it, being careful to have the dead man slant toward the butt so as to prevent the weight of the pole from slipping it out. Continue lifting and working the dead man toward the butt till the pole is high enough to allow the two short pikes to get a hold.

Here a few words about piking will not go amiss, as there is a knack in it like all other work. The pike should be firmly set in the pole at such a point as will allow of getting a good push on the butt end, which should be placed against the shoulder. Keep the men as near directly under the pole as possible, spreading only enough to insure steadiness in keeping the pole from swinging. Fig. 3 shows a gang of men raising a 30-ft. pole. The piking should be steady and all the gang pushing together until the pikes are out of reach; then one should call out "high pike," then change the pikes to a lower hold, one at a time, alternating from side to side, so that the weight will not come all on the same side at once. In changing pikes to a lower hold be sure that the "dead man" is set firm and taking its share of the weight. As soon as the pole is high enough to allow using the other pike poles, let the other men take a hand at it and send the pole in the hole.

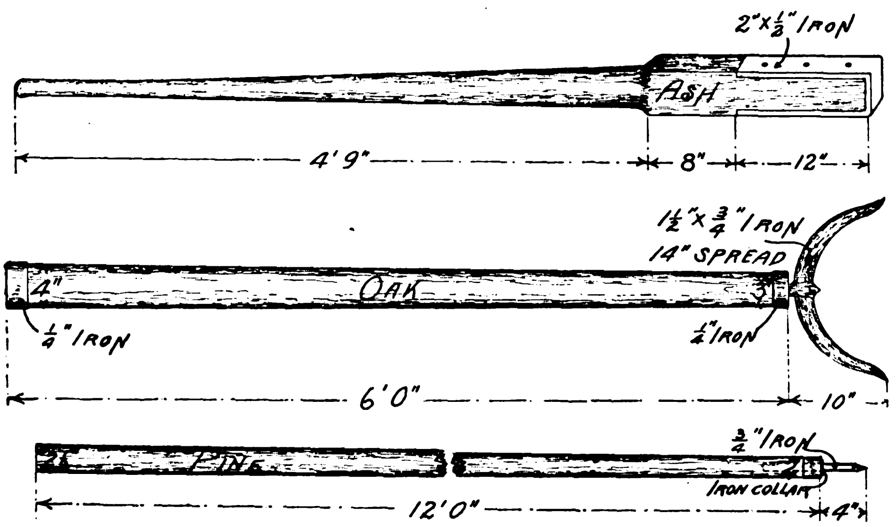

FIG. 5.—PIKE POLE, DEAD MAN, AND TAMPING TOOL.

Now place four pike poles around it with a man at each to steady it, and turn the pole around with the cant hook till the arm faces in the right direction; line it up so that the arm sets horizontally and the pole is vertically in line with those already set. Along comparatively level ground turn the arms so that two are facing each other, the next two back to back, and on a hill face all arms up hill; this will insure the best wear by distributing the pull from the weight of the wire evenly.

When the pole is lined satisfactorily, "ground" the pikes, Fig. 3, and tamp the ground well around the pole as the hole is being filled up. A few stones thrown in will help to make it more secure.

Poles which are out of line or on turns should be anchored at the heel with heavy stones on the opposite side from the direction of the strain, and keyed at the top or level of the ground on the other side.

The average time of raising a pole and tamping it should not be more than fifteen minutes, thus making twenty in a half day, or as many as there were holes dug for in the morning. If it becomes necessary to set a pole in a place where the hole is filled with water from a neighboring stream, put nothing but stones around it to a height level with the water, then fill the rest with ground. Press the ground well up around the pole to allow for settling, which after a few months will be down to an even surface with the surrounding ground.

The importance of properly guying all poles in a high voltage transmission line cannot have too much attention.

In the May issue of this paper, Fig. 3 shows the manner of attaching the guy, generally a ¼-in. or ⅜-in. stranded steel cable. The ends are held in place by clamps made for that purpose, consisting of two oblong pieces of galvanized iron with grooves cut in lengthwise to fit the cable, and held together by bolts, which when screwed up clamp the cable.

The guy stub should be of such a height as to keep the cable high enough not to interfere with road travel. For the anchor of the stub use a heavy stone, around which fasten the cable, and just above the surface of the ground fix a loop in this cable, as shown in the cut. On top of the anchor stone pile as many stones as you think sufficient to make the anchorage solid and cover all with dirt even with the surface. A convenient method of taking up the slack in guys is by placing a turnbuckle in the guy at the loop just above the ground, as this may be tightened up at any time necessary without unfastening the clamps. When it is found convenient to use a tree for a guy to be fastened to, be sure to place strips of wood between the guy wire and tree, which will prevent the wire from cutting into the tree.

In cases where the strain is not very severe on a pole, the cost of guying can be reduced by using two strands of solid No. 8 galvanized wire, twisted. To twist this, fasten the two ends to one pole and the other two to another pole, separated the required distance, leaving enough slack to be taken up with the twist; then twist them together by using a stout stick placed in the middle of the span between the wires.

Do not forget to erect the guy stub and place the anchor stones when the poles are being set, thus being able to do away with carrying and raising tools along when stringing wires. The guy wires from the pole to guy stub may be put on when erecting, but do not clamp them permanently, as they would have to be taken down again to get the line wire on the poles.

Ground wires to connect with the barb wire for lightning arresters should be placed on every twelfth pole, or one-half a mile apart. For this use solid No. 8 galvanized wire and fasten on the pole before raising up by staples, leaving 18 ins. over top of pole; on the bottom curl it up in a spiral of about 8 or 10 turns, also fastened with staples. The damper the hole the better will be the ground.

There will be cases where the lines must make a turn at an angle approaching 90 deg., or a right angle, and for this purpose a reverse turn must be made in order to keep the wires sufficiently far apart. To accomplish this, the cross arms are set at an angle equal to that of the turn and double arms used, one on each side of the pole, which, together with the usual braces are made secure from wabbling by being bolted together on the ends, having a block of wood between them through which the bolt passes.

The art of climbing can only be acquired by continual and persistent practice and for which there are no set rules, as every one has his own peculiar style; so the best way to learn it is to purchase a pair of climbers and start in. A few points, however, to a beginner, may be of some help: Do not strap the climbers on too tightly, and in beginning be sure to keep the knees well out from the pole to prevent the spike from "cutting out." Take small steps, keeping the body well away from the pole; and when it is desired to remain for a time in any place on the pole, stand on one spur only, with the other leg thrown around the pole.

Climbers can be purchased of any supply house, costing about $4.00, complete with straps.

◆

ELECTRICAL COMBINATION LOCKS.

The possibilities of electrical combination locks for cash drawers and similar receptacles does not seem to have been realized to its fullest extent. It requires but little ingenuity to arrange four or five push buttons in such a way that only one combination will close the circuit of an unlocking magnet, and any other will ring an alarm. The alarm could be placed at any convenient point, and at other points could be placed cut-out switches which, when manipulated, would render it impossible even for one who knew the combination to succeed in opening it. The device is easily developed and marketable.

WINDINGS OF MULTIPHASE ARMATURES.

BY J. P. STONE.

Thus far we have treated entirely of coil windings, but for low voltages a bar winding is often used, especially on large machines, as this permits of getting a greater amount of copper in a given space than a coil winding, so, when the number of turns necessary to produce a given potential will allow of it the bar winding is often found preferable.

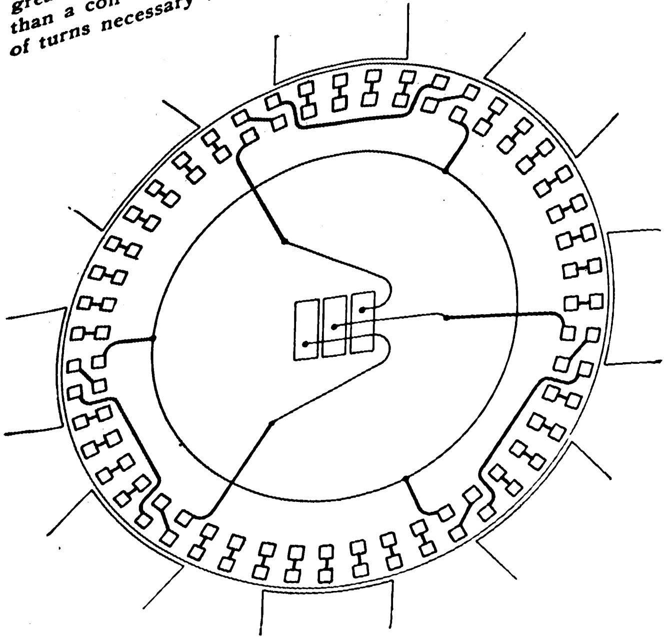

FIG. 12.—THREE-PHASE BAR WINDING; END VIEW OF CONNECTIONS.

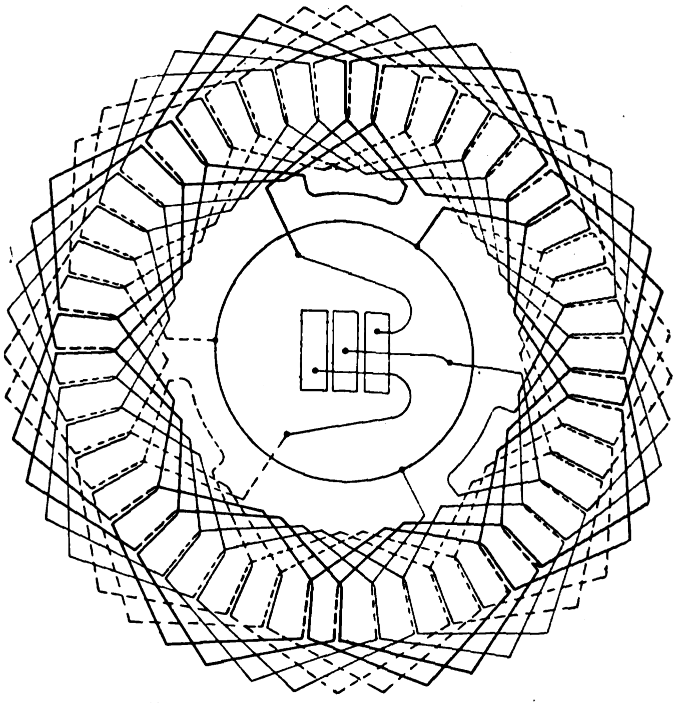

FIG. 14.—THREE-PHASE BAR WINDING, HAVING TWO SLOTS PER POLE PER PHASE.

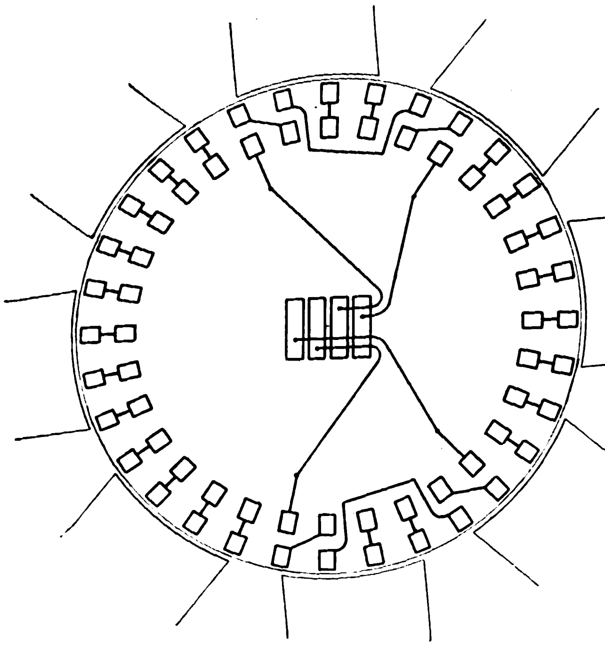

FIG. 15.—QUARTER-PHASE BAR WINDING, HAVING TWO SLOTS PER POLE PER PHASE.

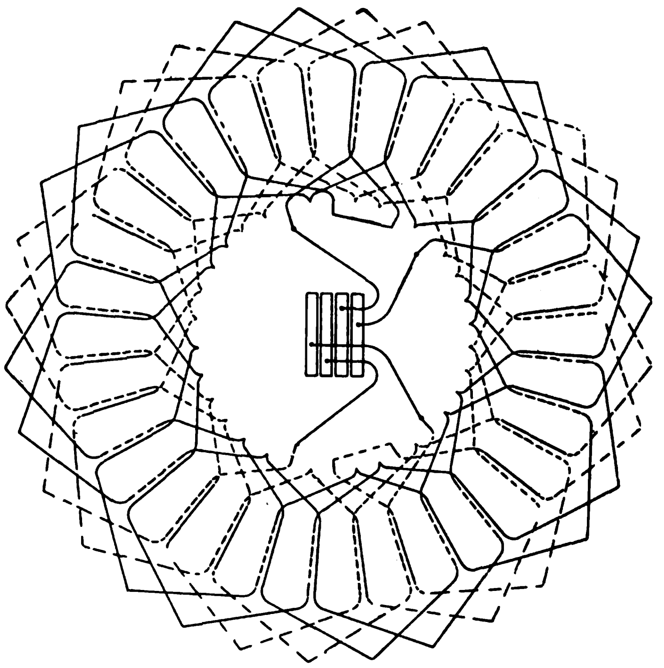

FIG. 13.—QUARTER-PHASE BAR WINDING; END VIEW OF CONNECTIONS.

A bar winding is best made in the form of a drum winding, and is made similar to the coil winding, two bars forming a turn similar to the coil winding. A bar winding can be made either as a lap winding, as shown in Fig. 12, or as a wave winding, as shown in Fig. 13, but as the wave winding has many advantages over the lap winding the latter will not be shown, as it is not extensively used in alternating-current work. In the wave winding the circuit progresses around the armature in a series of waves, as shown in Fig. 22.

A three-phase bar winding is shown in Figs. 12 and 14, having two slots per pole piece per phase and two bars per slot.

As will be seen from the diagram (Fig. 16), the ends of the bars which project beyond the slots on the ends of the armature are bent so as to form connections that would correspond to the ends of coils on a coil-wound armature. As the upper and lower bars which form sides of a coil each reach half way across, they are simply joined by a clip.

All the top bars in the slots on one end of the armature have their ends bent in one direction, and all the bottom bars in the same slots have their ends bent in the opposite direction; and as each bar, or conductor, spans half the distance between the slots, all that is necessary to complete the turns being to join the ends of two bars which are directly over each other by means of a clip, as shown in Figs. 17 and 12.

Fig. 17 shows a bar-wound armature with all the conductors in place.

On the other end, as shown in Fig. 15, special connecting pieces are required.

On the other end, as shown in Fig. 12, 14), the winding progresses twice around the armature in one direction, then reverses and goes twice around the armature in the opposite direction, thus going around before reversing as many times as there are slots per pole piece per phase, the two bars per slot being shown in the diagram side by side, whereas in the armature they are placed one above the other. The same winding is shown connected for quarter-phase in Figs. 13 and 15.

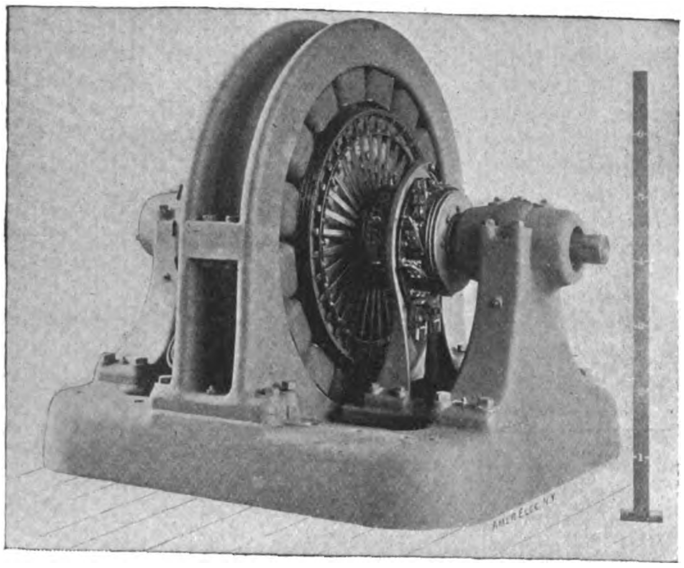

FIG. 16.—COLLECTOR SIDE OF ROTARY CONVERTER, SHOWING LEADS TO COLLECTING RINGS.

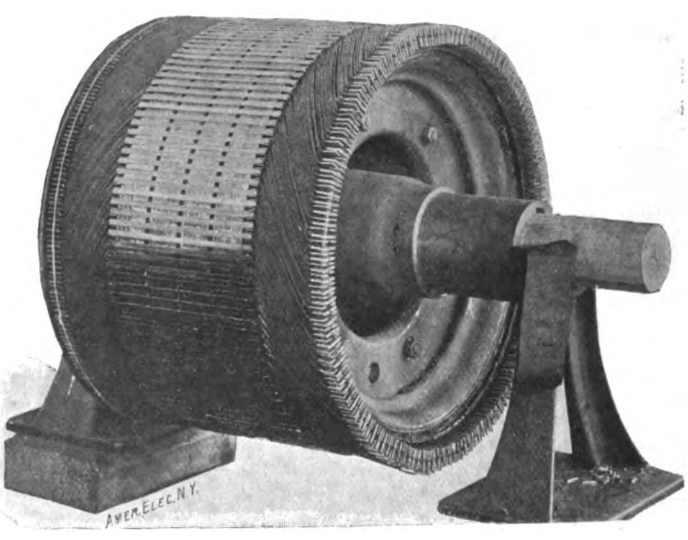

FIG. 17.—BAR WOUND DRUM ARMATURE, WITH ALL THE WINDINGS IN PLACE.

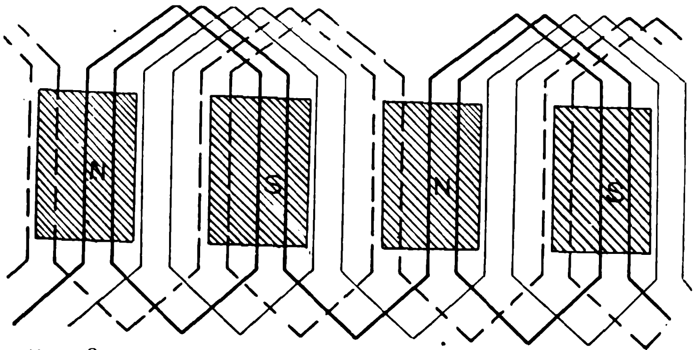

FIG. 18.—THREE-PHASE LAP WINDING WITH TWO SLOTS PER POLE PER PHASE.

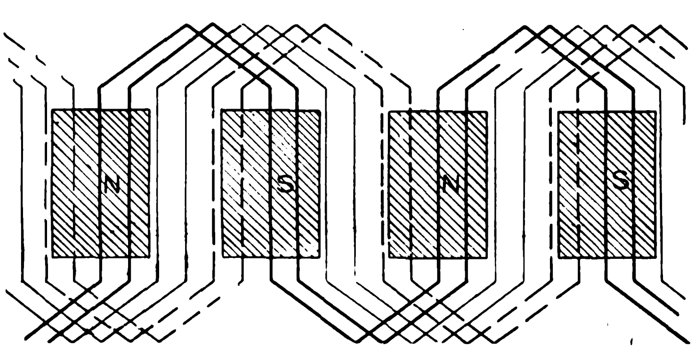

FIG. 19.—THREE-PHASE WAVE WINDING WITH TWO SLOTS PER POLE PER PHASE.

In the above diagrams full-pitch windings have been shown, that is. the spread of a coil (or the two bars corresponding to a coil) is the distance between the centers of two pole pieces. If it is less than this it is a fractional or minus pitch (as a —1, —2, —3 pitch winding), or if more is a plus pitch (as a +1, +2, or +3 pitch winding).

In a similar way a winding can be laid out for any number of slots per pole piece per phase.

A completed polyphase armature is shown in Fig. 21, having a drum winding.

The windings just described can be also laid out for an odd number of slots, and wound with either bars or coils, and are by some thought to possess advantages for certain classes of work when made this way.

The drum winding here described as used for alternating armatures is similar to the drum winding used in direct-current machines, which latter differ only in having a greater number of slots, and not being connected in separate phases, but in a continuous closed circuit, the clip joining the bars on the front end of the armature being extended down and soldered into commutator segments.

In rotary converters which combine alternating with direct current a regular continuous-current drum winding (which may be either bar or coil, as best suits the conditions of each particular case) is used, and taps are brought out at the proper points and connected to the collector rings,

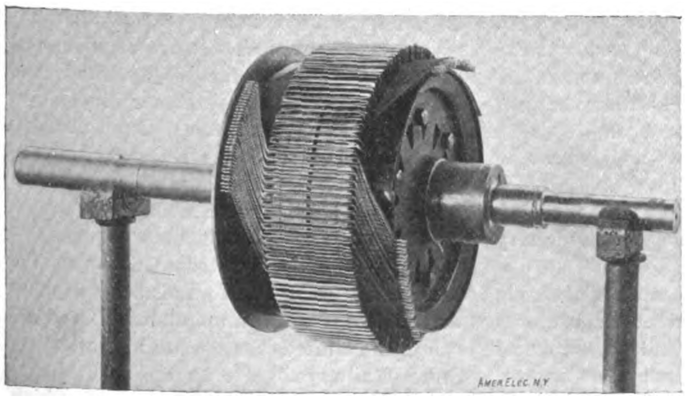

FIG. 20.—BAR WOUND DRUM ARMATURE, PARTLY WOUND.

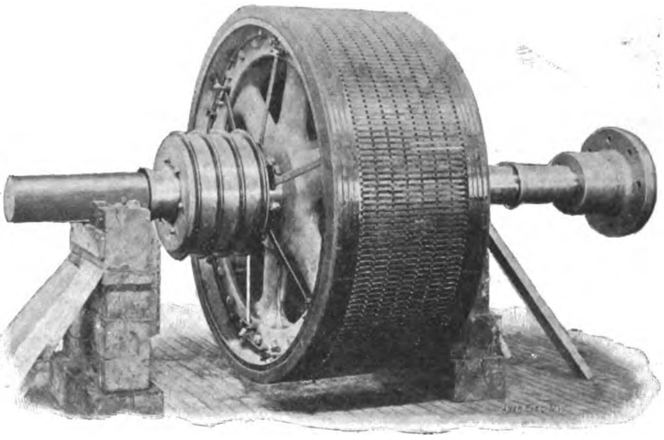

FIG. 21.—COMPLETED POLYPHASE ARMATURE.

as shown in Fig. 16, there being as many leads or taps to each ring as there are pairs of poles, these leads being connected to the winding at points equally distant from each other, all around the armature.

Thus, in general, many of the continuous-current armature windings may be employed for alternating-current work, but the special considerations leading to the use of alternating currents generally make it necessary to abandon the styles of winding best suited to continuous-current work and to use windings specially adapted to the conditions of alternating-current practice.

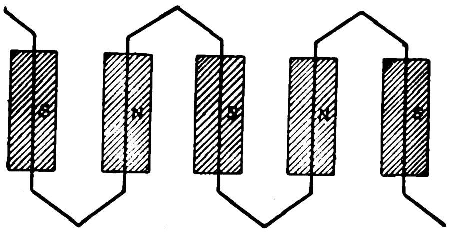

FIG. 22.—WAVE WINDING.

But all the closed-circuit continuous-current windings are of a necessity two-circuit or multiple-circuit windings; while alternating-current armatures may, and with the exception of rotary converters and delta-connected three-phase machines almost always do from practical considerations have a one (or single) circuit winding (one circuit per phase). From this it follows that any continuous-current winding may be used for alternating-current work, but the reverse is not true; that is, alternating-current windings cannot generally be used for continuous-current work. In other words, the windings of alternating-current armatures are open-circuit windings, with the exception of the ring Δ-connected polyphase windings, which are closed-circuit windings. These latter are, therefore, the only windings which are applicable to continuous-current work, and are used on rotary converters and similar machines which combine alternating and continuous currents.

THE CONVENTION OF THE AMERICAN STREET RAILWAY ASSOCIATION.

The seventeenth annual meeting of the Street Railway Association convened at the hall of the Massachusetts Charitable Mechanics' Association, and was in session from September 6 to September 9. The building was exceptionally well suited for this meeting and was provided with an excellent amphitheatre, which was just large enough to hold the exhibits, and contained admirable facilities for the evening entertainments. The exhibits were very complete, and the efforts of the supply men to display to the street railway officials details of their latest practice was highly commendable. The attendance was large and enthusiastic, and interest was shown both in the meetings and in the inspection of the exhibits.

TUESDAY, SEPTEMBER 6.

The meeting was called to order at 11 o'clock in Paul Revere Hall, by President A. E. Lang, who introduced Mayor Josiah Quincy of Boston. The Mayor delivered an address of welcome, in which he recognized and discussed the importance of the advance and development of electrical transportation.

After thanking the Mayor for his kindly interest thus cordially expressed, President Lang read his annual address, in which he traced the history of the Association from its birth, and referred briefly to the various meetings, reviving some pleasant remembrance in the case of each one. He thanked the technical press, the supply men and the Executive Committee for their efforts in behalf of the Association. He also suggested a few suitable subjects for future papers and discussions, and in closing called attention to the Street Railway Accountants' Association, which held its meeting simultaneously with the Street Railway Association every year, and which was even then in session in another part of the building. He recommended that these two associations endeavor to be in close touch, as their interests were largely identical. In closing, he thanked the secretary, the Excutive Committee and the members of the Association for their support, and expressed his appreciation of the honor of being called to the office to which he was unanimously elected a year ago.

Following the president's address a vote of thanks was tendered to the Mayor of Boston, after which the report of the Executive Committee was read by the secretary and approved.

A report on the relative merits of single and double trucks for street-car use was read by Mr. Richard McCulloch, electrical engineer for the Cass Avenue and Citizens' Street Railway Company, St. Louis, Mo. The conclusion of the writer seemed to be that he considered the cost per passenger, of wear and tear on the trucks and motors, and the power required, was about the same on a single or double truck car. Passengers, however, seemed to express a general preference for the double truck cars, due to the improvements in the lowering of the steps and their easier riding. In general, he considered that the double truck car was more suitable for long haul, high speed pleasure travel, and for lines competing with other systems, while the single truck car is better for dense traffic, many stops and slow speed.

In the discussion which followed, Mr. Beggs, of Milwaukee, spoke favorably of double truck cars, and stated that the performance of the double truck on the Milwaukee & Waukesha line had confirmed him in the opinion that the four-motor double truck equipment is very desirable.

It was suggested that all members of the Association who were present at its organization in Boston in 1882 should rise, and the following gentlemen rose: Messrs. W. W. Bean, of St. Joseph, Mich.; George B. Kerper, of Dayton, Ohio, and Julius E. Rugg, of Boston. The meeting then adjourned.

MR. CHARLES S. SERGEANT,
PRESIDENT OF THE AMERICAN STREET RAILWAY ASSOCIATION.

In the afternoon the Massachusetts Charitable Mechanics' Association provided an entertainment in the shape of a trip to Lexington and Concord. Various historical points along that route were visited, and many others of lesser interest pointed out. In the evening the Ladies' Committee of the Massachusetts Street Railway Association arranged a reception and dance, which was held in Paul Revere Hall.

WEDNESDAY, SEPTEMBER 7.

The meeting was called to order by the president at 10:30 A. M., and the first paper was read by W. S. Dimmock ,on "The Carrying of United States Mail Matter on Street Railways." He spoke of the benefits to the Post Office Department which pertained to electric car service, and called attention to the fact that the electric mail cars experienced fewer delays and interferences on the route. He considered that the compensation for this service was altogether too small, and that the electric railroads counted too much on the protection granted against interference of strikers, and consequently had taken the mails at almost any price. The present flat rates paid by the Government of three cents per mile for pouch service, and sixteen cents per mile for 16-ft. cars, he considered too low, and it was suggested that the members use what influence they could toward getting the Government to increase these rates.

In the discussion of this paper, Mr. C. S. Sergeant, of Boston, gave some interesting details of the mail system there in use. After further discussion it was moved and seconded that a committee of five be appointed by the chair, to act under the Executive Committee and communicate with the different members of the Association to collect facts and keep the Association advised of their proceedings, and to have authority to confer with the post office officials. The motion was carried.

The next paper was that of Mr. M. S. Hopkins, on "The Maintenance and Equipment of Electric Cars for Street Railways." The paper discussed the choice of car bodies, trucks and electric equipment. Referring to maintenance, he said that the character of the man who operated the cars, the manner of operation, the way in which repairs were made, and the material used are controllable elements, and, in many instances, the chief features affecting the cost of maintenance. He spoke of the care and equipment of car houses at considerable length, going into considerable detail. He advocated the use of oil as a lubricant on armature and axle brasses as being more satisfactory and economical, and stated that under ordinary conditions six months was the average life of a babbitt or brass bearing on a street railway motor. He strongly recommended the use of phosphor bronze for bearing brasses, and that street railway men cast their own bearing shells. Speaking of commutators, he recommended soft, close grained carbon brushes treated with good lubricating compound, pressed against the commutator with strong tension, stronger than is ordinarily used.

He advocated amber mica in commutator construction, stating that hard, clear mica would not wear away as fast as the copper, thereby producing imperfect contact. Referring to tests, he considered that the practical value of elaborate testing systems had not been fully demonstrated, and that tests should only be made when motors were not working properly. For testing systems he recommended a portable Wheatstone bridge testing-set, capable of showing a variation in resistance of 1-1000 of an ohm, and a first class magneto as all that was necessary.

A vote of thanks was tendered to Mr. Hopkins for his paper, after which Mr. W. Caryl Ely, first vice-president of the Street Railway Association of the State of New York, extended an invitation to the members of the National Association to attend the annual convention of the New York State Street Railway Association at Manhattan Beach, on Tuesday and Wednesday, September 13 and 14. Letters of invitation to the Association to hold meetings in various cities next year were presented by delegates, and a committee on nominations was appointed by the president. The meeting then adjourned.

In the afternoon the delegates quite generally attended an excursion to Nantasket Beach.

THURSDAY, SEPTEMBER 8.

The meeting was called to order by the president at 10:30 A. M. The first paper read was that by Mr. W. H. Holmes, who took for his subject, "To What Extent Should Railway Companies Engage in the Amusement Business?" The writer seemed to think that street railway companies should confine themselves to the provision of ample means of communication with public places of amusement, rather than creating them. The maintenance of such enterprises bv street railway companies has generally been found to be ill-advised and unprofitable, except in places where more than a five cent fare could be collected. The author's experience in this line in Kansas City was described, and as the result of the investment they abandoned this line of work, and provided transportation to parks maintained by independent corporations, the company paying these corporations a fixed sum for giving its patrons the privilege of the parks. The company has given financial aid to various festivities which have occurred in Kansas City, which sums the author considered was well spent.

Quite a general discussion followed this paper, the opinions being closely divided. At the conclusion of the discussion the report of the nominating committee was read, as follows:

For president, Charles S. Sergeant, second vice-president Boston Elevated Railway Company, Boston.

For first vice-president, Henry C. Moore, president Trenton Street Railway Company, Trenton, N. J.

For second vice-president, Ernest Woodruff, president Atlanta Consolidated Street Railway Company, Atlanta, Ga.

Third vice-president, Walton N. Holmes, general manager Kansas City Railway Company, Kansas City, Mo.

Secretary and treasurer, Thomas C. Penington, treasurer Chicago City Railway Company, Chicago, Ill.

Executive Committee:

Albion E. Lang, president Toledo Traction Companv, Toledo, Ohio.

George E. Yuille, second vice-president of the West Chicago Street Railway Company, Chicago, Ill.

Frank Jones, president Memphis Street Railway Company, Memphis, Tenn.

John I. Beggs, general manager Milwaukee Railway & Light Company, Milwaukee, Wis.

Ira McCormack, general superintendent Brooklyn Heights Railway Company, Brooklyn, N. Y.

A unanimous ballot was then cast for the gentlemen nominated, and Chicago, Ill., was chosen for the next place of meeting.

An invitation from the Boston Elevated Railway Company to the delegates invited them to visit any of the power houses, shops or car houses of the company, stating that particular attention would be shown to visitors.

The privileges of the floor were then granted to Mr. T. Y. Dzushi, Chief of Finance and Manager of Stores of the Imperial Government Railways of Japan, and to Mr. K. Sugahara, the chief engineer of several street railroads which are soon to be built in that country. The latter gentleman spoke on the street railway systems of Japan, and stated that they were in embryo state as yet. Electric traffic has been greatly interfered with by the use of the jinrikisha, and by other types of vehicles drawn by men, aggregating some 130,000. Several electric railways, however, have been proposed. At present there are only 60 miles of track in use, and most of this trackage is operated by horse-power.

A paper was then read by Mr. Fred D. Perkins on "The Inspection and Testing of Motors and Car Equipment by Street Railway Companies. This paper was on a similar line to that of Mr. Hopkins' of the day before, but was of a more specific nature, and discussed at length the best methods of caring for street railway equipments, repairing and testing them. Owing to lack of time there was no discussion on this paper. The meeting then adjourned.

In the afternoon the delegates attended an excursion to Plymouth and visited the historic points in that town and the National monument to the Pilgrim Fathers. In the evening a banquet was held at the Brunswick Hotel, and was attended by nearly 350 people, including many ladies.

FRIDAY, SEPTEMBER 9.

The meeting was called to order at 10:40 A. M. Mr. R. W. Conant read a paper on "The Cost of Electric Power for Street Railways at the Switchboard," which was briefly discussed.

The newly appointed president was introduced by the retiring president, and took the chair. Mr. Sergeant spoke, thanking the Association for his appointment, and promising to do everything in his power to further its interests, and to benefit street railways. The Association then adjourned.

In the afternoon a trip was taken to Norumbega Park in Auburndale, which was reached by a trolley line extending through the handsomest part of Boston's suburban district.

CONSOLIDATION OF THE WESTINGHOUSE AND WALKER COMPANIES.

On Friday evening, Sept. 16, the final papers were signed for the consolidation of the Westinghouse Electric & Manufacturing Company and the Walker Company. In connection with this transaction the following statement has been issued by George Westinghouse, Jr., president of the Westinghouse Company:

"The election this day of Roswell P. Flower and Anthony N. Brady as members of the board of directors of the Westinghouse Electric & Manufacturing Company to represent the interests of the former stockholders of the Walker Company, completes the union of the interests of the Walker Company, of Cleveland, with those of the Westinghouse Electric & Manufacturing Company. The purchase of the Westinghouse Company includes substantially all of the outstanding stock and all but $850,000 of the $2,500,000 of the twenty-year bonds of the Walker Company, the $850,000 remaining a first lien upon the property. The recent sale by the Westinghouse Company of $3,000,000 of debenture certificates has erroneously been connected with this transaction. The entire proceeds of the sale of these debenture certificates were used in retiring the floating and other debt of the company, as previously announced.

"The increase in the total yearly fixed charges of the Westinghouse Company, due to the purchase of the Walker Company, will be but a little more than the sum that the Walker Company has been expending annually in defending patent litigation instituted by the General Electric and the Westinghouse companies. The acquisition of the Walker Company will, by reason of the agreement of March 31, 1896, between the General Electric and Westinghouse companies, put an end to this patent litigation and very large annual expenditure on both sides. The business of the Walker Company, as a controlled company of the Westinghouse Company, will be entitled to the protection of the patents of the Westinghouse and General Electric companies, and will in all respects be subject to the agreement between these two companies in relation to patents.

"The Westinghouse Company regards the business and good will of the Walker Company as a valuable acquisition, especially as the Walker Company brings with it upward of $1,250,000 unfilled orders. The Walker Company has at Cleveland modern and extensive works, equipped with machinery capable of manufacturing the largest type of railway apparatus, and will, with the works of the Westinghouse Company at East Pittsburgh, constitute a manufacturing plant second to none in the country. The capacity and profits of the two companies will be increased by carefully harmonizing the manufacturing and selling operations, and the direct savings thereby effected should exceed the fixed charges incurred by the purchase of the Walker Company. The shipments of both companies, owing to the large orders on hand, have been increasing during the past few months, and exceeded $750,000 for August.

"The total fixed charges of the Westinghouse Company, including those due to the Walker purchase and the dividends on its preferred stock, will be $42,000 per month."

To George Westinghouse, Jr.—one of the most remarkable business men of this generation, combining, as he does, fine inventive and engineering ability with strong practical common sense in financial and commercial matters—is undoubtedly due the credit for bringing about this consolidation at a time when the advantages to be derived from the removal of the Walker Company as a serious competitor in the field could best be realized. Large and valuable contracts for electrically equipping important elevated and surface railway systems are soon to be placed, and it has been well understood for some time that the Walker Company was in a position certainly to dictate the prices at which these contracts will be let, and also to bring important influence to bear toward the actual securing of them. At one stroke Mr. Westinghouse has removed this competition from the field, and at the same time has greatly improved the chances of his own company for securing these contracts. The entrance of ex-Governor Flower, Anthony N. Brady, James W. Hinckley and Perry Belmont into the Westinghouse directorate is an important feature of Mr. Westinghouse's plan, as they will doubtless influence contracts in many directions aside from the large markets in many cities which they completely control.

Major J. W. Hinckley, president of the Walker Company, has had an important influence in shaping the latter's business policy, and has been a tireless worker in its behalf. Though a man of large and varied financial and business interests, this in the electrical field has been in many ways his favorite enterprise, and to its development he has given much of his time, and has secured for the Walker Company not a few important strategic and commercial advantages. Among the orders recently closed by the Walker Company may be mentioned one for 500 Walker motors, placed in Paris a few weeks ago, and an order for 600 Walker motors and 600 Walker controllers, placed by the Brooklyn Rapid Transit Company early in September.

It is understood that the Walker Company will retain its separate commercial existence for the present, at least, and perhaps permanently, and that so far from reducing the force at the Cleveland factory, it may even be increased, as it has been well known for some time that the factory facilities of the Westinghouse Company are inadequate for their constantly increasing business.

Sidney H. Short, vice-president of the Walker Company and the man to whom the credit is due for building up its large line of successful apparatus, is a prominent figure in the electric railway industry of to-day at home and abroad. The history of the Walker Company and a bare statement of the character and amount of original designing and construction work which has been done during the past four years, are interesting and well worth recollection.

The first product of the Walker Company was the Walker spring mounted street railway motor, brought out about four years ago. There were rapidly designed, built and placed upon the market a complete series of this type of motor, ranging in size from 20 h.p. capacity for 31-in. gage track to 200 h.p. for elevated and heavy railroad service. Thousands of these motors have been maufactured and shipped to all quarters of the globe, and it is claimed for them that not one has been returned to the shop for failure to do the work for which it was sold. Forty different sizes of generators, ranging from 25 k.w. to 3000 k.w. (the largest generator in the world, now under construction for the Boston Elevated Railway Company), have also been designed, built and put into service in this brief period. Nearly all of these machines have been of the direct connected type, and built for isolated and central lighting, power and railway stations.

On both generators and motors there has been introduced the new so-called "straight out winding," which is now a feature of modern electrical machinery, and which represents an enormous advance over previous methods of winding. The Walker dynamos and motors are noted for their high efficiency, simplicity of construction, and their sturdy ability to take heavy overloads without destructive sparking at the commutators. Many other detail improvements of great importance have also been introduced in the design and construction of these motors and generators, such as the sliding of the generating field frame lengthwise of the shaft of the machine so as to uncover the armature and fields for inspection, cleaning and repair without disturbing any of the parts of the machine; the making of motor coils entirely of flexible conductors, avoiding soldered joints, the placing of motor bearings entirely outside the motor casing, thereby excluding oil from the interior of the motor; the hinging of the lower half of the motor in such a way as to permit it to swing down without disturbing the armature or the suspension; and the spring suspension of the motor over the axle, as well as at the side furthest from the axle.

Among the later work carried out by the Walker Company is the development of a full line of alternating current apparatus of the "rotary field stationary armature" type, of which about 15,000 h.p. in generators, motors and rotary converters is now under construction; the development of a full line of switchboard apparatus, and the introduction of the solenoid blow-out controller.

It will easily be seen what an immense amount of technical work is represented by these achievements. At the end of the first year after the introduction of the manufacture of electric apparatus into the Walker Company's shops, the gross sales of manufactured product were more than doubled, and at the present time, four years after this introduction, the annual business of the company has increased tenfold. One-half the factory output is shipped to Europe, and the company has come to be recognized all over the world as one of the three largest American concerns engaged in the electrical manufacturing business.

It is needless to say that this enormous development of business has required large additions to the capital invested, and in 1896 a reorganization was made, by which the Walker Company succeeded to the business of the old Walker Manufacturing Company. Cleveland capital was at first sought for and obtained, but eventually Messrs. Flower, Brady and Hinckley, who are, as has been previously mentioned, large purchasers of electric railway apparatus, were invited to become stockholders in the Walker Company, and finally obtained by purchase a controlling interest.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Color Photographs by Electrolysis.—M. L. Delvalez has presented to the Académie des Sciences a method for making photographs in natural colors by the aid of electrorysis. His method is, in brief, as follows: If a plate of brass is put into a bath of a mixture of solutions of lead and copper acetates, through which a uniform current is flowing, the brass plate becomes a "parasite" electrode, current entering it on one side and coming out at the other, and a thin isochromatic sheet of lead peroxide is deposited upon it.

Becquerel has shown that if two plates of silver or copper, placed in an electrolyte, are unequally illuminated, that an e.m.f. is set up between them. Hence if different points of the same sheet of metal are differently illuminated currents will flow in the electrolyte surrounding it. These currents produce electrolysis and a deposit of lead dioxide is thrown down. Points equally illuminated will be equally covered in the same time, and will show the same color (the color being due to the thinness of the film of lead oxide).

On a brass plate under a negative with an exposure of twenty minutes to full sunlight a colored positive was obtained. The blacks of the negative gave the clear yellow of the brass plate, the shades gave various colors according to their density, dark green, fawn yellow, red of several degrees of purity, etc. The plate should be washed in much water and immediately dried. It changes, but slowly. If the positive is viewed through red glass in a proper light the actual colors of nature are said to be apparent in the picture. This may be true, but it seems at least doubtful. The author is seeking a white metal for the plate and a proper electrolyte, and suggests iron and tartar emetic solution.

Telegraphy with Ultra-Violet Light.—Prof. Karl Zickler contributes to "Elektrotechnische Zeitschrift" a long article describing a novel method of wireless telegraphy, which was designed to obviate the difficulty caused by the radiation of the ordinary Hertz-wave signals equally in all directions from the transmitting apparatus. This feature of Hertz-wave signaling makes it of little value for the purposes to which it is best adapted. Prof. Zickler uses ultra-violet light as the medium for his signals. An arc lamp of convenient size is arranged with a parabolic mirror or quartz lens to gather its radiations into a parallel beam. This is received at the receiving station by the apparatus illustrated in the accompanying diagram. A glass vessel having a window of quartz, p, contains the electrodes, e_1 and e_2, one of which is in the form of a plane inclined at 45 degs., and the other is a small ball. The air in this vessel is exhausted to a moderate degree. An induction coil is arranged as shown in the diagram, its secondary e.m.f. being adjusted to a point just insufficient to spark across the gap between the electrodes.

The arc lamp gives off radiations rich in ultra-violet rays. To these glass is practically opaque, while quartz is transparent. These rays have the power to promote electric discharges. Hence if the light of the lamp is allowed to enter the receiving apparatus sparks will pass and the signals may be received as electrical radiations by a coherer or read off by means of a telephone in the secondary circuit of the coil. A plate of glass mounted in front of the arc lamp is used as a shutter to cut off the ultra-violet radiations and produce the signals. This apparatus can be easily adapted to the ordinary searchlight. The glass shutter makes no apparent change in the visible light, so that the messages sent along the beam are secret. With an arc of 25 amperes Prof. Zickler thinks that signals may be sent to a distance of several miles.

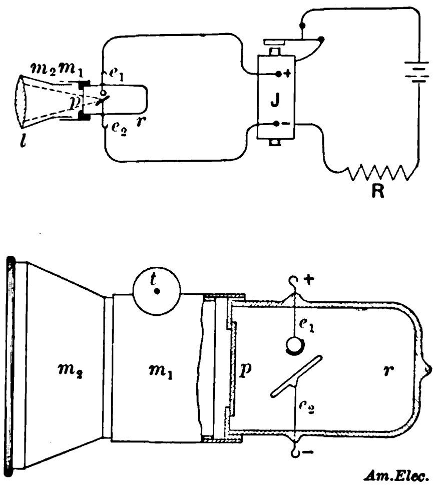

DIAGRAM OF ZICKLER RECEIVER AND CONNECTIONS.

It seems possible that this method is capable of much refinement. If an appropriate screen is provided, which will allow the ultra-violet rays to pass and block off the luminous rays, the message and the location of the stations as well would be secret and the apparatus well adapted to military telegraphy. The receiver is far less complicated and delicate than the coherer apparatus, while the induction coil required is so small as to be easily portable and reliable in its action.

Electrical Resistance and Temper of Steel.—M. H. Le Chatelier has presented to the Académie des Sciences a series of valuable observations on the effect of temper and constitution upon the electrical conductivity of steel. The most important experiments were directed to ascertain the influence of the temperature of tempering upon the conductivity, samples of steel containing 0.84 and 1.13 per cent of carbon being chosen. The subjoined table shows the ratio of the resistance after tempering to that before tempering, the temperatures being given in the top line:

Temperatures: (Centigrade)...	710°	740°	810°	850°	950°	1000°
0.84% carbon..	1	1.3	2.1	2.2	..	2.2
1.13% carbon..	1	1.3	1.6	2.1	3	..

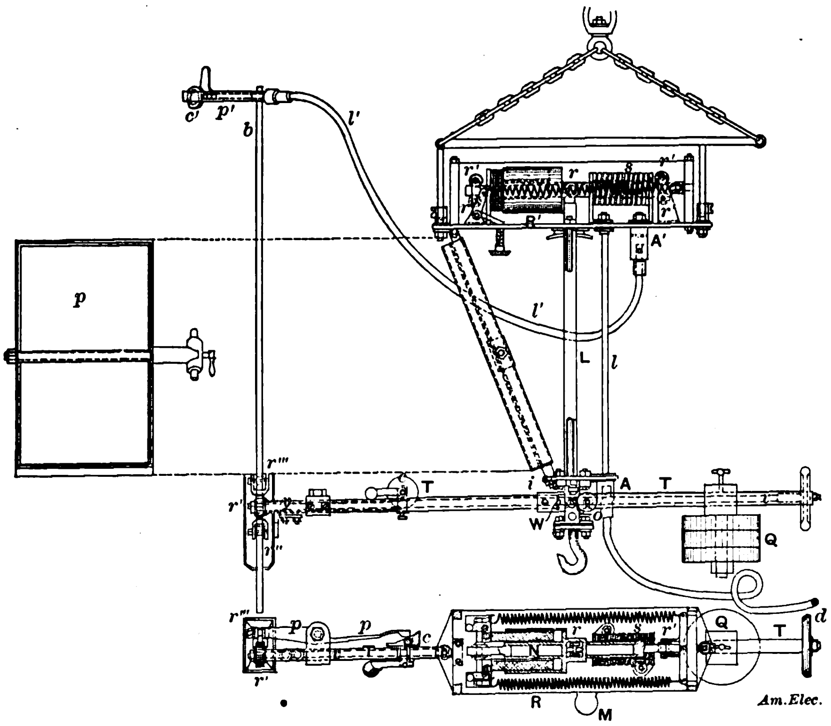
These results go to show that tempering does not modify the resistance if performed at temperatures below the point of recalescence (710 degs. C.), the same condition holding good for the change in mechanical properties. The resistance then increases with the temperature of tempering up to a maximum depending upon the carbon content of the steel, the higher carbon steels going up to higher resistances. The presence of chromium in the steel causes the increase of resistance to become more marked, while tungsten seems to exert a contrary influence.

Electric Soldering and Welding.—M. Simon Hetter presented to a recent meeting of the Association des Ingénieurs Electriciens, of the Montfiore Institute at Liege, Belgium, a most interesting paper on the various electric soldering and welding processes in use in Russia. These comprise a number of methods not generally known in this country and contain many valuable and practical suggestions.

The Bernados process uses the arc established between the metal to be built up or repaired and a carbon rod held in the hand of the workman. To repair a blow-hole, for instance, the surface of the work is first heated with the arc, then a number of bits of metal are placed upon it and dusted with sand or some other material to act as a flux. The arc is then struck between these pieces and the carbon and when they are melted the current is turned off and they are forged into place before they harden. The proper current strength is determined by experience. If the arc makes no sound it is not strong enough. If it hisses sharply the current is too strong. The proper current is indicated by a slight humming of the arc. To prevent too much contamination of the metal by carbon the arc should be as long as possible. Care should be taken not to heat the metal too much, as few metals can stand the arc temperature long without destruction. After the patch is in place it should be reheated for some time by a charcoal fire, otherwise the unequal contraction of the neighboring parts may produce a rupture. In working on cast iron the arc is shortened when the metal is melted (the added metal being the purest obtainable iron) so that it will absorb as much carbon as possible and make an easily worked cast iron when cool.

In the Slavianoff process a metallic rod is used in place of the carbon electrode of the Bernados process. This rod may be of the same metal as the piece worked upon or of any other metal, according to the necessities of the case. By choosing a metal that melts at a comparatively low temperature the melting of the electrode reduces the temperature of the arc, so that there is less danger of burning the work.

The electrode is generally suspended on a feeding mechanism over the work, and is fed to it mechanically. If a blow-hole or a crack is to be repaired it should be enlarged so that the arc can reach every part of its interior. A mould can be built up around the work of coke or carbon blocks and sand, if this is necessary, as it may be if the pieces to be repaired are broken entirely apart. The author gives illustrations of the method of forming new teeth on a large gear wheel by the use of carbon moulds of appropriate shape. In general this method consists of the melting down of the material of the electrode and of pieces of metal placed in the mould. The illustration shows the arrangement of the feeding mechanism for the metallic rod. The whole is suspended from a crane, Q being a counterbalance weight and P a frame of colored glass to protect the eyes of the workmen. The metallic electrode is shown at b b. In the upper part of the apparatus is a regulator for feeding in the rod as it melts away. To start the arc the rod b is placed in contact with the work and the current turned on, when the arc is automatically struck and the rod fed down as it melts. Direct current is used, the polarity being such as to suit the work and depending upon whether it is desired to melt the rod rapidly or heat the work. The current strength depends upon the size of the surface worked upon, being generally about 8 amperes per square millimeter or 5000 amperes per square in. at a minimum pressure of 50 volts. The rod melts quite rapidly, a cast iron rod melting at the rate of 1 lb. in one and one-half minutes under a current of 400 amperes.



SLAVIANOFF ELECTRIC WELDING AND SOLDERING APPARATUS.

The remainder of this important article is comprised of practical directions for operation and formulæ. It is, unfortunately, too long to bear condensation into the space available here.

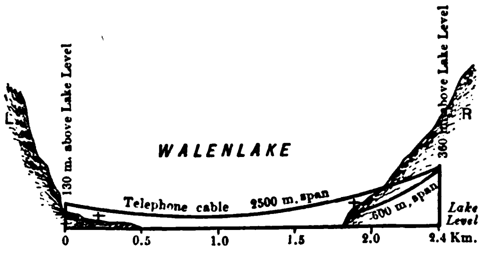
The Resistance of the Human Body—A paper has been presented to the Académie des Sciences by M. Dubois concerning the variable period of current flow when a difference of potential is applied to the human body. His method was to measure the charge gathered in a condenser connected in circuit with the resistance to be studied and a battery, contact being made for a very short interval by a steel rod rebounding from a steel anvil. He concludes that the reactance of the body, during the period before the current reaches the state of definite and steady flow, is less than its resistance; in fact, the capacity of the body seems to partly neutralize its ohmic resistance. During the period of variable flow the resistance of the body remains constant, its value depending on the surface of the electrodes in contact and the length of the part of the body between them. M. Dubois thinks that the body acts as a condenser with a liquid dielectric and places its capacity at about 0.165 microfarad.

Contact Resistance of Similar Metals.—M. Edouard Branly describes in "Comptes Rendus" (abstracted in the "Electrician") some experiments on the contact resistance of similar metals. A column resembling a Volta's pile was made by threading forty-five discs about 1½ ins. in diameter and ¼ in. thick on an ebonite rod and putting the whole under slight pressure. In the case of iron, aluminum and bismuth the resistance was low if the discs were placed gently on one another, but if they were dropped on one another with a slight shock the resistance was enormously increased. With discs of zinc, copper or brass the resistance was practically zero however the column was assembled. The following figures show some of the data of these phenomena. With a pile of aluminum discs gently laid together and subjected to a pressure of about 5 lbs., the resistance was 1.5 ohm. By dropping the discs on one another and submitting the column to the same pressure the resistance was increased to 40 ohms, diminishing to 21 ohms after twenty-four hours. On taking the column apart and rebuilding it gently without cleaning the discs, the resistance was 2.2 ohms, and when again remade by dropping the discs together it was 215 ohms. Connecting the column between the spark terminals of a radiator reduced the resistance to 0.5 ohm. The same effect was noticed with iron and bismuth. M. Branly makes no attempt to explain these curious phenomena.

Aluminum Electrodes—Mr. E. Wilson gives, in the Proceedings of the Royal Society, an account of his experimental work upon the behavior of aluminum electrodes in a saturated solution of alum. Aluminum and carbon electrodes were used and an exploring electrode, consisting of a bit of platinum wire sealed in the end of a glass tube, was inserted midway between the plates. The current was adjusted to 3.5 amperes, using the aluminum as the cathode. On reversing the e.m.f. the current also reversed for a few seconds, but soon fell to zero. The effective e.m.f. opposed by the aluminum amounted to about 22 volts. To determine the nature of the resistance of the surface of the aluminum the plate and its film of oxide were immersed in clean mercury, the results going to show that while the film is a fairly high insulator it is not stable. At times the resistance fell to zero, when a sharp crackling noise, like sparking in air, would be heard in the cell, the resistance at once mounting up to as much as 10,000 ohms. Even under a pressure of 30 volts the film was able to restore its insulating properties at ordinary temperatures, but at 70 degs.C. about 3 volts was the limit. A film formed by wetting the aluminum in a solution of alum and then exposing it to the air gave the same results as the film formed in the electrolytic cell. Experiments with alternating currents showed that the best rectification effects are obtained if large currents at low e.m.fs. are used. The full effect is not developed if the frequency is higher than about sixteen cycles per second.

Working Aluminum.—The following hints for the working of aluminum are taken from the "Practical Engineer." It is best melted in a sand crucible, without any flux, at a temperature very little above its melting point (a dull red heat). In casting allowance should be made for the great shrinkage in cooling, and large risers and plenty of vents should be provided. The molds should be cooled from the bottom upward to allow the gases to escape. Aluminum can be forged hot or cold, but best at a temperature that causes a hard wood stick to smoke when pressed against the metal. In turning the cut should be very light, the speed high, and both tool and work plentifully lubricated with kerosene. In filing use a single cut file, as the metal soon clogs a cross-cut file. Frosting, which must be done before the surface will take paint or enamel, is accomplished by dipping the metal in a solution containing 10 per cent of caustic soda and 2½ per cent of common salt. When the work turns black take it out, brush in water, and immerse in strong nitric acid until the surface becomes white again, then wash and dry in sawdust. For polishing use a mixture of olive oil and rum followed by rouge and turpentine. To engrave the surface should be coated with oil and rum, otherwise the tool slips continually.

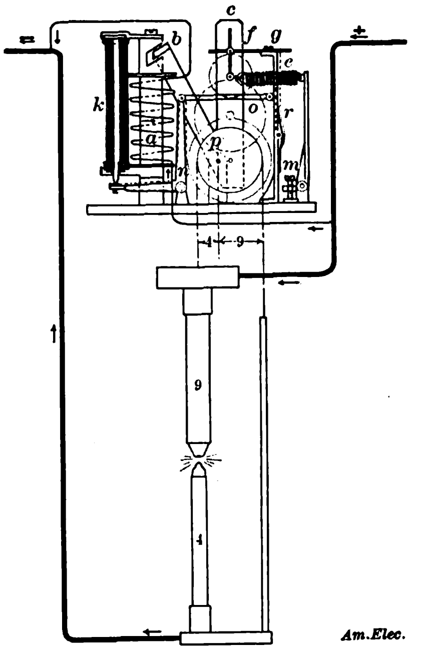
A Long Span.—The longest span of wire in Europe, says "Engineering," crosses the Walenlake in Switzerland. The span crosses the lake between the villages of Quinten and Murg, its length being 2500 meters or 1.56 mile. On the Quinten side the point of suspension is on a rocky spur 1180 ft. above the level of the lake, another single span 0.375 mile long being led back to the station in the town. On the Murg side the point of suspension is 426 ft. above the lake level. Between the two points the cable hangs in a curve having a dip of 590 ft., its lowest point being about 160 ft. above the water level. The first wires used on this span, both single steel wires, broke either from winds or ice forming on them, and they were replaced by a cable of three galvanized steel wires, each about No. 8 gage. This cable has also recently broken, the wind causing a sort of whipping action or wave motion in it, which is attributed in part to the unequal heights of the two end supports. It is proposed to reerect it with terminal stations of equal height.



TELEPHONE CABLE ACROSS THE WALENLAKE.

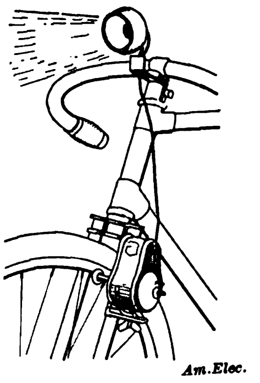
Artificial Rubber.—A new process for the manufacture of artificial india-rubber comes from Germany, says the "Mechanical World." It consists in the oxidation of linseed oil with the addition of prepared jute refuse or other similar hitherto worthless textile fibre, a substance being produced having many of the qualities of genuine rubber. It is capable of being utilized in many ways and of being manufactured into various articles hitherto made of rubber. It is not stated what oxidizing agent is used, but it seems that this would be a good opportunity for the use of ozone. Whether or not the new substance can be vulcanized is not stated, but it seems possible that it may lend itself to this process. There is certainly no reason to suppose that the synthesis of rubber is impossible, now that the chemical journals have just announced the synthesis of albumen.

Heat Compensator for Arc Lamps.—In shunt arc lamps the heating of the coil increases its resistance and hence causes the lamp to maintain a longer arc unless some device is used for the correction of feed mechanism. An English lamp, described in the (London) "Electrical Review," uses an ingenious compensator. The system of tubes, in the accompanying figure, is composed alternately of iron and brass, so connected as to add their expansion under increased temperature. As the lamp mechanism warms up in use these tubes expand and by a simple lever mechanism adjust the position of the striking tongue of the feed release train, as plainly shown in the figure. A great advantage of a regulator of this type is the saving of energy due to its use, as the increased resistance of the arc caused by the heating of shunt coils simply causes waste without any compensating gain. Of course in compound wound lamps the tendency to lengthen the arc as the mechanism heats is less noticeable.



HEAT COMPENSATOR FOR SHUNT ARC LAMP.

The Dynamo Bicycle Lamp.—The (London) "Electrical Review" prints the accompanying illustration of a dynamo bicycle lamp, the dynamo being driven from the front wheel of the bicycle. It is a little strange that this device still holds a place in the journals. Assuming such a mechanism added to a bicycle, the energy required to keep the lamp going would soon wear out the hardiest rider, while the light would promptly go down whenever he slowed his speed. To be of the least use a bicycle lamp should be of from 2 or 3 c.p. Taking 2 c.p. and allowing 10 watts for the current consumption, and supposing the dynamo or magneto to have the high efficiency of 50 per cent—high for so small a machine—the rider would be required to furnish 20 watts of power, or, allowing for friction and losses, 25 watts. This is almost exactly the power required to propel a 150-lb. man on a 20-lb. bicycle at the rate of 9 miles per hour on a level. Riding at that speed the turning on of his light would mean to the rider doubling his effort. It is safe, therefore, to predict that the dynamo bicycle lamp will continue to be popular only in illustrations.



A DYNAMO BICYCLE LAMP.

The Bow Trolley.—An article by Herr Stobrawa in "Elektrotechnische Zeitschrift" (reprinted in "L'Electricien") discusses the advantages of the Siemens & Halske bow trolley as compared with the usual wheel variety. The bow trolley, which is without a single example in this country, consists (see Fig. 2) of a light metal frame, the upper part of which is bowed upward, the whole being pressed up against the trolley wire in the usual way. The contact is not a rolling one, but a sliding contact, the upper part of the bow sliding along always at right angles to the trolley wire. This form of trolley has many advantages to commend it. While at first sight less mechanical in its arrangement than the familiar wheel, it shows excellent results in comparison, and it is unfortunate that it has not had a test under American conditions.

By making the bow of relatively softer metal the wear upon the trolley wire is rendered nil, the whole wear being confined to the bow, which is replaced when worn out. The first serious disadvantage encountered was the noise due to the sliding of the bow on the wire, but this has been ameliorated by the use of bows having a cross section shown in Fig. 1. The frame of the bow is aluminum, the hollow parts being filled with stiff grease. In Basle (Switzerland) the life of such a bow was found to be about 13,000 car miles, and the replacement cost about 0.017 cent per mile run. The greasing of the trolley wire not only gets rid of the noise, but assists in its preservation and prevents the formation of ice on it in winter. The great and prominent advantage of the bow trolley is, however, that it stays in contact with the wire.

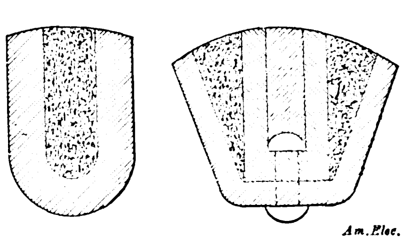


FIG. 1.—CROSS SECTION OF BOW TROLLEY.

Referring to Fig. 2, which shows an end view of a car thus equipped, it is seen that by making the framework of the bow of flexible and elastic tubing the bow, even if the alignment of the overhead conductor is so bad as to throw it into the position shown by the dotted line, will by its own friction work back under the wire. No cords are used with these trolleys. When the car is reversed the bow catches under the wire by its own friction and is thrown over to the proper running position. It is stated that the wear on the trolley wire at Dresden, where these trolleys are used, has diminished its section only 4 per cent in four years. The diameter of the trolley wire is not stated.

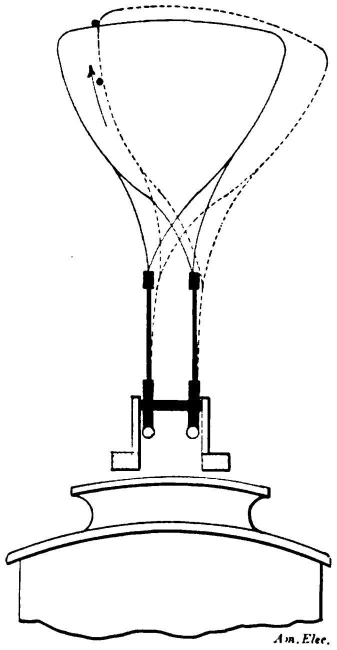

FIG. 2.—FRONT VIEW OF BOW TROLLEY.

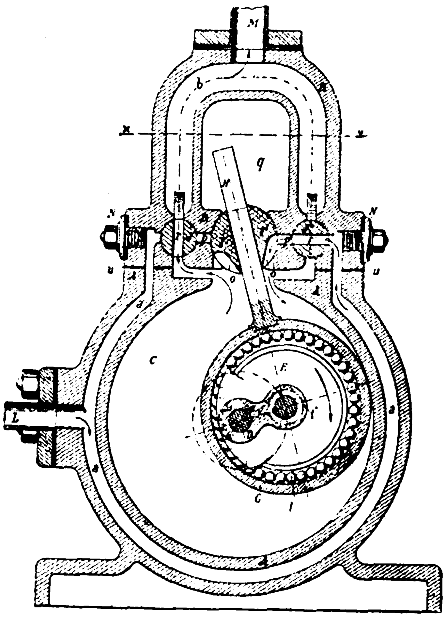
Regenerating Fluorescent Screens.—At the recent meeting of the Association Française pour l'Avancement des Sciences M. P. Villard presented a communication upon the regenerative action of light on fluorescent screens of platinocyanide of barium. It is well known that when these screens are exposed for a long time to the action of X-rays the salt darkens in color and the fluorescence of the screen diminishes. According to M. Villard an exposure of the screen to direct sunlight for fifteen or twenty minutes completely restores its properties. The infra-red rays in sunlight seem to be the most active in the work of regeneration. A practical suggestion is that such screens should be kept exposed to daylight, their properties being thus indefinitely preserved.

Electrolytic Damage to Ships.—The "Electrician" abstracts from the "Engineer" an account of a curious lawsuit brought by the captain of the port of Leghorn (Italy) against the owners of certain wooden yachts. It appears that these yachts, which were copper sheathed, were moored with steel cables to a buoy in the harbor to which some new warships and other steel vessels were also made fast. Under these circumstances electrical action ensued, the bottoms of the vessels being the plates of a gigantic battery, and the fact of damage to the steel vessels from the ensuing electrolysis was clearly proved. The court directed that the port captain's order for the removal of the coppered yachts to another part of the harbor be sustained.

A New Rotary Steam Engine.—An exceedingly ingenious and interesting rotary engine is described at some length by M. Emile Demenge in the "Revue Générale des Sciences." The illustration here given showing a cross-section through the shaft is almost self-explanatory. An eccentric cam, E, is surrounded by a ring piston resting on two runs of balls, as shown. Attached to this piston is a steel partition plate, H, which slides through and oscillates the valve, II. Steam is admitted at L, and, after encircling the working cylinder, is admitted through the valve, II, to one side of the piston and the partition plate. The exhaust goes out through the valve, J, which is constantly open. By turning this valve and its counterpart on the other side of the machine through 90°, the direction of rotation is reversed. Nothing is said as to the efficiency of this engine, but a machine of this type 12 ins. x 14 ins. x 24 ins. in size and weighing 308 lbs. is said to have shown an output of 6 h.p. at 300 r.p.m. with steam at 145 lbs. It might be developed into a valuable type of engine for direct-connected dynamo driving on a small scale, though the steam turbine will probably soon have this field all to itself.



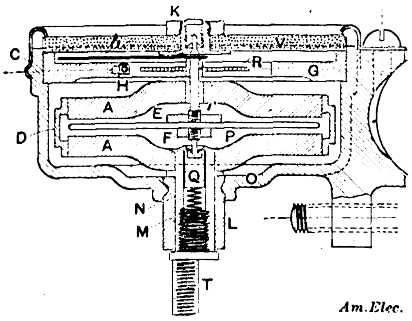
ROTARY STEAM ENGINE.

Station Lights.—The (London) "Electrical Engineer" makes the sensible suggestion that the lights in an electricity supply station should be wired from an independent source whenever practicable. In this way an accident resulting from the shutting down of the station would not leave it in darkness. In the Shoreditch station the lights are connected to the storage battery independently of the main switchboard, but this method of connection is only useful where there is an accumulator. In case of the bursting of a steam pipe, for instance, the plant would be left in darkness under ordinary conditions at the very time when light is most urgently needed. This detail is one of great importance, as many stations are entirely dependent upon their own operation for light. Would it not be a good idea to pipe city stations for gas and introduce fixtures for emergency use? The suggestion seems a step backward, but it is nevertheless a practical one.

Influence of Electricity Upon Clouded Liquids.—Herr Spring, in "Chemische Zeitung," gives some interesting and important observations upon the action of electricity in clearing muddy fluids. Pure water, in which is suspended particles of non-electrolytic material in fine subdivision, becomes clear when a current of electricity passes through it or when a salt or an acid is added to it, or when it is warmed. The current may be very small if the e.m.f. is sufficiently high. Herr Spring explains this phenomenon by the assumption that the suspended particles, in a non-conducting fluid, are in an electrical condition, perhaps a condition intermediate between the neutral state and that of ions, and that this prevents their aggregation and sedimentation. When a current flows, or if the fluid is made a better conductor through the addition of an electrolyte, or if convection currents are set up in it by heat, the particles are discharged and are free to aggregate in masses and sink. According to the author this peculiar electrical condition of suspension is possibly due to the overcoming of the original adhesion of the substance reduced to the finely divided condition of suspension.

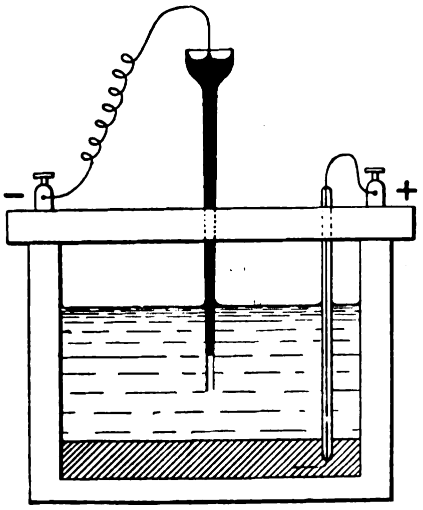
This phenomenon is certainly worthy of the most careful study on account of its important practical bearing. If the sedimentation of muddy waters can be brought about by electrical action it may be possible to substitute some variety of electrical treatment for filtering plants in many places, notably along our inland rivers, where clay in suspension, rather than any bacterial impurity, is removed from town water supplies by filtering.

A Magnetic Speed Indicator.—A new form of speed indicator, adapted to use wherever it is desirable to read off the instantaneous revolution speed of a shaft, is described in "La Revue Technique." The permanent magnets, A A, are rotated by the shaft T, which is attached either directly or through gearing to the shaft whose speed is to be measured. F F is an aluminum disc turning on a pivot resting on a jewel, Q, in the head of the shaft, T. The motion of this disc is restrained by a spring. On the pivot is a needle, a, playing over a graduated scale. When the magnets are turned the rotating field of force between them tends, by virtue of the formation of eddy currents in the aluminum disc, to cause it to rotate in the same direction. This tendency being opposed by the spring causes the disc and its needle to take a position of equilibrium depending on the speed of the magnets and of the shaft T. The principle of the apparatus is an exceedingly ingenious application of well known laws, and seems worth development into other forms of apparatus.



MAGNETIC SPEED INDICATOR.

Simple Capillary Electrometer.—The "Electrician" contains an abstract of an article by Sig. G. Vanni in "Nuovo Cimento," on a form of capillary electrometer adapted for school use and for lantern projection. The figure is almost self-explanatory. The glass-sided cell contains a layer of mercury on the bottom covered by a 30 per cent mixture of sulphuric acid and water. A capillary tube with a funnel top is inserted through the cover into the acid and water and mercury poured into it. This descends to a position determined by hydrostatic pressure, the bottom of the column forming a good contact with the acidulated water. Potential differences of less than 0.001 volt may be readily shown with this instrument.



A SIMPLE CAPILLARY ELECTROMETER.

ELECTRICAL MISCONCEPTIONS.

The student of electricity frequently encounters odd misconceptions, and these are persistently the same with different individuals. For instance, the term "line loss" has puzzled many an electrician. He cannot at first conceive of a loss in the line unless there is an actual loss of electricity. He is told that amperes means the volume of electricity flowing in the wire, and he consequently expects that at the end of the transmission line he will find less amperes delivered than at the engine room. Add to this the actual fact that such a phenomenon obtains in telephony and telegraphy, and unless he is carefully instructed, he is very likely to remain for a long time under the impression that the line loss, as commonly expressed, means a loss of amperes, and not of volts. His ideas on the subject are apt to lead him into very amusing errors. For instance, we hear of a salesman, who writes home asking his company how much it would cost to wire a building for 5 per cent loss, and also, how much it will cost to wire it for no loss.

The sinusoidal curve, commonly employed to illustrate alternate-current phenomena, is frequently a great source of worry to the student. In his search for something tangible he imagines the electricity taking a similar tortuous path in the wire. He may, perhaps, study the subject a little deeper and realize that the current is merely of rapidly varying strength, and perhaps has this illustrated to him by the mechanical analogy of water oscillating back and forth in a tube. Unless he is carefully instructed at this point he will shortly be under the misconception that the ordinates of the alternate-current curve represent linear distances on the wire, and that the current is at various densities at various parts of the wire, accurately spaced off according to the sine law. The superposition of two or three current curves, together with curves of impressed and induced e.m.f. upon the same platen, gives him an idea of multiplicity of currents and pressures within the wire, all of which does not tend to reassure him that he is mastering the subject.

An armature-winding diagram is another source of trouble to the student. The closed circuit type is particularly distressing. He starts to trace out the current, and proceeds from commutator bar to commutator bar around the armature, and arrives at the place whence he started, forgetting that the circuit is from brush to brush.

He then gets the idea that the revolution of a closed circuit armature generates a current which doubles around and around on itself through the winding, and that this current is tapped off to the commutator at points of greatest potential difference.

Another source of trouble to the student is the arc dynamo. Here is a machine in which the more resistance you put across the terminals the higher the potential becomes. It is a series dynamo. He has been taught that to insert resistance reduces the current; according to that, the current in the series fields should be reduced, and hence the e.m.f., which is proportional to the field strength, is also reduced.

If he studies the dynamo further, he gets into still more interesting tangles. He has been taught that the torque of an armature, which is the measure of the h.p., is proportional to the strength of the field and to the current in the armature wires in the arc dynamo. The current is constant, and therefore constant in the field magnets, which are in series with the main circuit. The armature current is also constant, and hence he draws this surprising conclusion, that, as the strength of the field and the armature current are always the same whatever the load, the torque of the dynamo is always the same, and, if the speed is constant the h.p. is always the same, no matter what the load may be.

Perhaps his attention is now called to the regulator and the function that it performs, and he may for a time charge the regulator with the explanation of a great many of his troubles, until he finds that manufacturers produce arc dynamos some of which are almost, and others quite, inherently self-regulating. Then he is back where he was before.

Again, we find our student puzzled in the study of the transformer. He learns that the primary and secondary current are 180 degs. apart, practically opposed in phase. He learns that the secondary current neutralizes the magnetic effect of the primary, and when the transformer is fully loaded, the primary acts almost as a non-inductive resistance. In line with this reasoning, he finds that in transformer design the two currents are inversely as the transformation ratio, and that the ampere turns of each are identical. He then argues if the ampere turns of the primary are opposed to those of the secondary at all times during full load and equal thereto, they neutralize each other and there is no flux of force in the transformer core at all. Why should the transformer be complicated with such a construction? There have been cases where the student has solved the difficulty by the conclusion that the core was only needed to start the action, and after the load is on the core is unnecessary.

He studies electric motors and learns that the weaker the field of a motor the faster it will run. This bothers him for a moment, but the various arguments are advanced, and possibly a dash of practice or two are thrown in, and he is convinced that it is the fact. He then studies the principle of the Thomson recording wattmeter, which is a motor with its armature on constant potential, the speed varying in proportion to the load that it measures, and to his confusion he finds that the stronger the field current the faster the motor goes.

If he attacks the subject of electric heaters, he very quickly deduces the fact that electricity is transformed into heat conveniently and economically by allowing it to flow through a resistance, to strangle it down, as it were, and force it to give out its heat. The more resistance, the greater should be the heat, so says his formula, $C^2 R$, and such has been his understanding all along. He is, therefore, most wonderfully surprised, and inclined to doubt the sanity of the instructor he has always looked up to, when he finds that in order to get more heat out of a constant potential circuit the resistance of the heating device is reduced.

It is puzzles like these that make the study of electricity hard. The young electrician asks for information on a few of these points, and finds that his misconceptions are so ludicrous that he gets roundly laughed at. To avoid ridicule, he forbears to ask again, and unless he dissolves his difficulties by strength of intellect, they remain a continuous puzzle and protest against the accuracy of the science.

Dangerous Voltages.

If the reports of recent electrocutions are to be believed, it is possible to make a sufficiently good contact with a man's body so that 2000 volts will pass through it at a current of 10 amperes, and therefore the resistance of the body is in such a case about 200 ohms. Almost every electrician has at one time or another measured the resistance of his body, either by clasping two handles firmly or by pressing his fingers on the tops of binding posts, and varying results have been reached, some as high as 40,000 ohms. Indeed, the fact that the resistance of the body varies so widely is well known to electrical engineers, and even to those who are merely interested in the science. In view of this there does not seem to be any reason for the wonder which is sometimes expressed, when a man receives a shock from terminals, the pressure between which is in the thousands of volts, and survives. The conditions of contact determine the matter entirely.

It must be evident to anyone that it is the amount of current that is forced through a man's body that kills him, and if his resistance can be satisfactorily reduced, 500 volts will be as fatal as 5000. As a matter of fact, however, accidental shocks are generally made through very poor contacts. The current usually has to pass through the most highly resistive part of the body, the callous of the hands, and, moreover, the contraction of the muscles, which instantly follows the reception of a powerful shock, frequently disconnects the victim from the wires altogether, although in some unfortunate cases it has been known to tighten his grip upon them, according to the position his hands may have been in at that time. These conditions account for the reason that sometimes death is incurred through a 500-volt shock, while another person accidentally subjects his body to a potential of 2000 volts and recovers.

The voltage is a very unsafe criterion on which to base the fatality of a shock. The volume of the current is what kills, and is a much more accurate measure of the fatality. Unfortunately for accuracy, however, what the current was in the case of a shock is seldom if ever known. The voltage is almost always known, at least approximately, and consequently it has been used as the basis of comparison; but when it is realized that in order to obtain an estimate of the ordeal through which the victim has passed, this voltage must be divided by a resistance varying from 200 to 50,000 ohms, it is easy to see that the conditions might have been almost anything.

The Use of Electro-Magnets for Mechanical Control at a Distance.

In passing through a switchyard, where a large railway traffic is transacted, the electrical engineer is at once imprssed with the multiplicity of rods, bell crank levers, interlocking bolts and complicated mechanism between the rails, and the mass of wires, chains and pulleys which operate them. This mechanism has to be boxed in, wherever possible, requires continuous oiling and attention, is more difficult of operation the longer the distance it is required to span, is easily obstructed and liable to be hopelessly wrecked if a car should be derailed upon it. This has been appreciated by engineers, and in many places pneumatic systems have been installed, whereby pipes take the place of chains and wires, and cylinders and pistons at the point where the work is to be done supply the necessary pushing and pulling forces.

Pipes leak; cylinders and pistons are accurate mechanical devices and require cleaning and attention; and the system requires a source of pneumatic power to operate it. It seems strange that electricity has not been used for this service. A well-designed ironclad solenoid, taking only about 100 watts, can exert a pull of 100 lbs. through a distance of several inches, and can be conveniently supplied from a 110-volt lighting circuit. There is no question but that the necessary pulling power to manipulate the switches and signals can be electrically supplied in apparatus more compact and convenient than any other. But this is not the only advantage that electrical switching apparatus presents. The connecting and controlling wires may be laid in lead covered cables in ducts under the trackway or in the ground. Distance does not enter into the consideration; the magnets will operate as well at the distance of a mile as at a distance of 20 ft., and a mile radius far exceeds the range of any interlocking switch system. The cost of a lead-covered cable buried in the earth is very likely to be less than that of a wire supported at intervals on pulleys and boxed in, and will not require one-tenth the attention of the mechanical devices. With the electrical system the track can be cleared of all moving parts, an advantage which cannot be overestimated. The destruction attendant upon the derailing of an engine has been mentioned, but, aside from that, mechanical devices require to be kept clear from obsruction. A piece of coal falling from an engine tender can easily block a switch, and in winter time the track has to be kept clear of snow throughout all the intricate construction of the levers and rods. It can be seen at once that to obviate the necessity of this care is no mean advantage, and it certainly pertains to electrical methods.

In addition to all that has been mentioned, we have an immense advantage in interlocking. The very simplest devices will render it impossible to supply a magnet with current until another has been manipulated and a tell-tale lamp system can be inaugurated which will give the operator at all times exact information concerning the condition of the track. With the present mechanical systems a miniature track may be operated by the same levers which operate the actual switch, but it is easily possible for the miniature to operate and the switch itself be blocked. With the electrical system, the tell-tales can be arranged to positively show whether the switch is open or closed.

The control station becomes at once very much smaller. A flagman's house will answer where a large structure was required before.

In these days of electric lighting it is possible to obtain sources of current to manipulate such a system which shall be practically unfailing. At central depots the electric light plant at the station can be called upon, also the mains of the local electric lighting company, and perhaps wires from a third isolated plant in the neighborhood can be brought into play. The amount of current required is so little that the duty impressed on any of these installations is negligible. A small storage battery might be added, and in this way it would be easy to obtain at least two supplies of power, either of which would be very unlikely to break down. The certainty of operation would thereby be brought to a point far in excess of either the pneumatic or mechanical system. There is a field for business here which is very nearly a virgin one. New interlocking switch stations are continually being installed throughout the country. The pneumatic system is displacing the mechanical one, and it remains for an electro-magnetic system to displace them both.

The Regulation of Dynamos.

When the rheostat on a shunt dynamo is adjusted to effect a change of voltage the operator cannot fail to note that the response is very sluggish, so much so indeed that it is very easy to manipulate the rheostat handle so rapidly that the voltmeter cannot follow it. Although most designers are certainly aware of this, it is surprising to note that at stated periods a device appears which has for its object the regulation of voltage and for its principle of voltage-controlled device which in turn controls the field rheostat. If the action of a field magnet is so sluggish that it will not quickly follow changes in rheostat resistance made by hand, how can it be expected to follow the infinitely more rapid variations which sudden changes of load will create in a sensitive automatic device? In making an automatic regulator to keep the voltage steady under sudden changes of load the variation of the field strength must not enter as a factor. There have been cases where regulators have been produced, using two field magnets in the linkage of regulating factors between change of voltage and readjustment thereof. This was done by the device of separately exciting the exciter field and controlling the current in that circuit. The idea of this seems to be that the controlling device would be smaller, its parts would have less inertia and it would therefore be more sensitive. The designer seemed to be totally oblivious to the fact that however sensitive the regulator was made, the interposition of a field magnet in the regulating system destroyed its utility and the insertion of two such sluggish members, the one dependent on the other, is practically fatal. Extreme accuracy of potential regulation is not obtainable in this way, and unfortunately there is little else of a practical nature that can be offered in its stead. Absolute regulation, while always desirable, can be dispensed with in commercial work. An expedient which may answer in some cases is to vary the speed, to which function the voltage almost instantly responds, as every gas engine manufacturer can testify. Of the many ways of doing this the method of shifting a belt on two conical drums by a magnetically controlled shifter may be suggested. In such a case the generating armature must be of small flywheel capacity. There is, however, a more practical application which may be used on engine-driven dynamos, namely, that of controlling the speed of the engine electrically. The cut off of the engine can be varied by potential magnets instead of centrifugal or inertia governors. This device is by no means a new one. It has been tried in numbers of instances and always with marked success. The difficulty which seems to have stood in the way of its commercial exploitation is the fact that engines and dynamos are separately manufactured, and the steam engineer has no faith in anything but a centrifugal or inertia governor. If some maker was to incorporate enough electrical engineering talent into his draughting department and produce an engine that would regulate for constant current or constant potential, as required or ordered, he would certainly create a stir among plant designers who have had troubles of their own, especially in the case of alternate current machinery.

Electrical Heaters.

The theoretical efficiency of an electrical heating device is 100 per cent, but it is well known that this does not in any way affect the fact that electric heating is the most expensive of all methods of supplying calorific energy. The only excuse for the existence of electric heaters is the great convenience in application which they afford, and to date the fullest advantage has not been taken of this feature. For instance it is a simple matter to improve the efficiency of heaters for liquids by placing the heat emitting resistance within the liquid to be heated, thereby absorbing all of the heat generated, and economy of heat in such devices is much to be desired when the source of heat is so expensive. It would seem that alternate currents can easily be adapted so as to control the entire field of electric cooking and similar applications of electric heating, because of the facility with which the voltage can be transformed. By reducing the voltage and correspondingly increasing the current volume it is possible to heat a plate of metal to any degree desired, and that plate may be the bottom of a cooking utensil. One of the chief difficulties of electric heaters, especially those intended to give very intense temperatures, such as soldering irons and the like, is the insulation of the heated conductor. With low voltage currents the conductors are few in number and the insulation required is very slight, and the task becomes an easy one, and very frequently the heated conductor can itself be the actual working surface of application without involving the wasteful process of radiation or conduction.

Electrical heaters designed to take the place of stoves are practical only on the electric street car, where current is generated in large quantities and the cost to the company is merely that of production. It is certain that existing types of car heaters can be improved upon and their location better chosen. It is proverbial that heat applied to the feet of a chilled person will be more effective than anywhere else. It therefore follows that the position for railway heaters is directly in front of the seat and flush with the floor line. Beside this economy of position the heater coils can be separated, so that part of them form the motor regulating resistance, which in cases of crowded traffic frequently becomes hot enough to boil water and even red hot. In summer time a double throw switch will serve to switch in the ordinary resistance under the car and cut out the heater. The actual saving by this device is by no means inconsiderable.

SIMPLE VOLT-, AMPERE-, AND WATTMETERS.

BY CHARLES T. CHILD.

Many experimentalists and workers in practical electricity are embarrassed by the high cost of commercial forms of ampere-, watt- and voltmeters, and are unable to provide themselves with these almost indispensable instruments. It is the purpose of this article to describe several forms of such instruments that can be easily made by the amateur or student with the tools generally found in a small shop and at small cost.

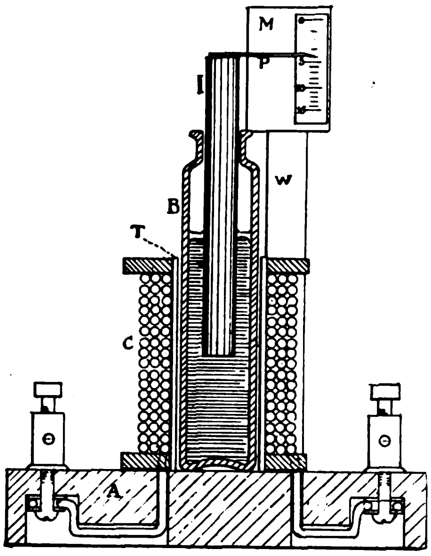

FIG. 1.—SOLENOID AMMETER.

The fundamental principles underlying the construction of such meters are extremely simple. Almost any arrangement of parts that is subject to alteration by the passage of an electric current can be made to serve as a meter, provided it is properly calibrated; that is, if it is known exactly what changes a definite current causes. For example, a simple compass, with a current-carrying wire stretched parallel to the needle in its normal north and south position, will serve the purpose of an ammeter if it is first determined what deflection will be caused by each of several given currents in the wire. By varying the current and noting the position of the needle a scale may be made reading directly in amperes, and the instrument thus becomes a rough form of current meter. An ordinary high-resistance galvanometer may be used, in the same way, as a voltmeter, but these instruments, from their crudity and sensitiveness to disturbing conditions are not reliable or convenient, and in practical work have been superseded by instruments specially designed for the measurement of current or electrical pressure. The difference between a voltmeter and an ammeter is simply a matter of the way the instrument is connected to the current-carrying system that it measures. An ammeter is an instrument of low resistance, through which passes the whole of the current to be measured; a voltmeter is in all respects similar, except that it is of high resistance and is connected in multiple with the circuit, or across the points whose difference of potential it is designed to measure. Under these circumstances a small current, small on account of the high resistance it encounters, flows through the instrument, and as this current is proportional to the potential difference which causes it the instrument measuring the current gives an indication of the pressure at its terminals. It is evident that the higher the resistance of the voltmeter the less the current withdrawn from the system by it and the less the disturbance of the potential conditions due to its use.

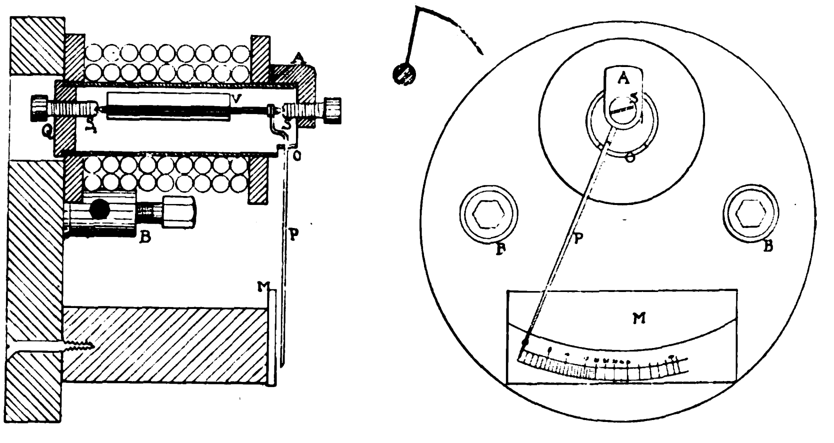
Nearly all forms of meters depend upon the magnetic effects of the current for their action. These may be divided into solenoid instruments, magnetic vane or needle instruments, and moving coil instruments. Another class of instruments of great importance uses the heating effect of the current, which produces expansion in a strip of metal or a wire, as the source of their indications.

One of the simplest forms of ammeters is shown in Fig. 1. This instrument is intended to stand on a table or bench, and is of the semi-portable variety; that is, it may be moved about if care is taken not to spill its liquid contents. It consists of a bar of soft iron, I, floating in mercury contained in a glass bottle, B, and surrounded by a coil, C. The bottle is of the sort known as a "sample phial" and much used for exhibiting samples of oil, etc. It should have a neck about ⅜ in. inside diameter, and the body of the bottle should not be more than twice the diameter of the neck. The iron bar, I, should be turned down until it fits loosely in the neck of the bottle. The coil is about two-thirds the height of the bottle and contains a number of turns and a size of wire proportional to the currents to be measured by the instrument. For currents up to about 15 amperes No. 10 wire and about fifty turns are recommended. The mercury should be poured into the bottle until the bottom of the iron rod floats at about half the height of the coil, and on the top of the mercury should be poured a few drops of kerosene to prevent oxidation of the mercury surface and the formation of a film which would impede the motions of the rod. When current passes the rod is drawn down into the solenoid against the buoyant action of the mercury.

Soldered to the top of the iron rod is a pointer, P, moving in front of a scale. This scale is drawn on paper and pasted to a piece of looking-glass, M, which is supported by a wooden standard, W. No iron should be used in the construction of this ammeter except the rod, I. The purpose of the looking-glass is to avoid errors of "parallax," or those caused by reading the position of the pointer from an angle. By placing the eye so that the pointer just covers its image in the mirror the observer is certain of being in the proper position for correct reading.

To make the scale the position of the pointer with no current passing in the instrument is noted. The instrument is then connected in series with another ammeter and a current sent through both of them. By varying this current and noting the positions of the pointer for definite indications of the standard instrument the scale is dotted down, and can be afterward carefully ruled in permanent shape. The care that is taken with this operation, the calibration of the instrument, will determine its future value. At best, however, this instrument is only a rough makeshift, though it will be found very satisfactory when only rough measurements are desired. It is not suitable for alternating currents and should not be used with them.

By replacing the coarse wire coil shown with a coil of very fine wire of high resistance the instrument becomes a voltmeter, but it is not recommended to use this type of instrument for that purpose.



FIGS. 2 AND 3.—SECTION AND ELEVATION, MAGNETIC VANE AMMETER.

A more satisfactory instrument is shown in Figs. 2 and 3. Here the fact that the lines of magnetic force crowd close together along the inner sides of a solenoid is used as the principle of action. The coil of large wire is wound on a brass tube with wooden or fiber heads, one end of the tube being closed with a brass plug, Q. A piece of brass, A, is soldered to the other end of the tube, and through this and the plug are screws, S and S_1, coned out for the reception of the pointed ends of the pivot, as shown. The screws must be of brass or other non-magnetic material. They are not arranged in the center of the tube, but are a little above it, say 5-32 in., if the tube is an inch in diameter. On the pivot, which is of hard steel, is mounted a little vane or wing of thin sheet iron (the sort used by photographers for the basis of "tin-types" is best) bent to the shape shown in the small detail drawing. This should have about the relative size shown in the illustration. The needle, P, is of aluminum wire, for the sake of lightness, and the whole is so balanced, by soldering on bits of copper wire if necessary, that it hangs normally as shown in Fig. 3. The vane being eccentric to the tube carrying the coil tends to approach its inner surface when current passes. It must be so attached to the pivot that this tendency causes the needle to sweep over the scale, M. As in the instrument just described this scale is of paper mounted on a scrap of looking-glass. The whole is attached to a circular wooden base and forms a convenient wall or switchboard instrument. A cover to exclude dust and keep off stray air-currents would be a valuable addition.

This ammeter may be made very sensitive and accurate if care is taken in its construction. The lighter the needle the more sensitive the instrument, other things being equal. To decrease its sensitiveness the lower part of the needle system should be loaded so as to bring the center of gravity of the whole lower and thus cause a greater tendency for the needle to return to its zero position. Like the first instrument described this may be converted into a voltmeter by the use of a fine wire high-resistance coils of many turns in place of the coarse coil shown. For such an instrument, used as an ammeter, and measuring currents up to 100 amperes, about eighteen or twenty turns of wire ¼-in. in diameter will be found sufficient.

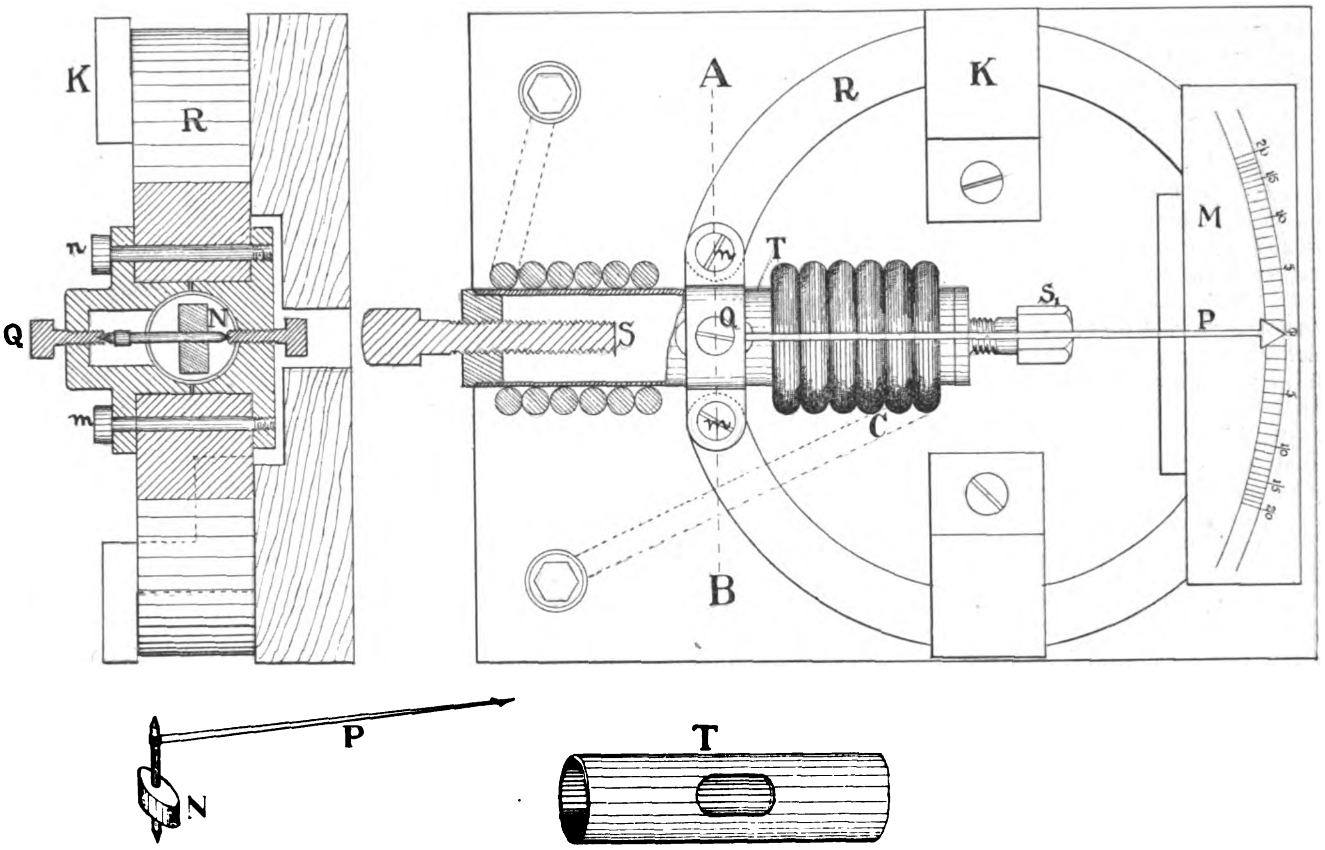
There are many cases where it is desirable to know the direction of the current as well as its volume. Neither of the instruments described indicate this. The next ammeter to be described not only indicates the direction and amount of the current, but also possesses two valuable qualities not shared by the cruder forms described—portability and freedom from vibration of the needle. In other words, it is a "dead-beat" instrument, the needle going promptly to its place on the scale and stopping without vibration. It is a very satisfactory and useful instrument and will be described at some length on account of its various good qualities.

The ring, R (Figs. 4 and 5), is made of good quality tool steel, 1 in. x ½ in., and bent around a diameter of 4½ ins. The ends do not meet, but are rounded off as shown by dotted lines in Fig. 5, leaving an opening about 1 in. between them. After this ring has been forged into shape and finished by the rounding of the two ends and the boring of the two holes for the screws, m and n, it is hardened by heating it red hot and suddenly cooling it in water, or better, a solution of sal ammoniac. It is then magnetized by wrapping it with about fifty or one hundred turns of wire and passing a strong current, or by rubbing it on the poles of a dynamo, and after magnetization it is boiled for an hour in water. Then it should be magnetized again, and again boiled, this being repeated several times, the magnetizing always being done in the same way and never reversed. By this method of magnetizing and boiling the ring is brought to a permanent state and does not lose its magnetism, as would be the case if no such precaution was taken.

The tube, T, shown also in one of the small detail drawings, is of brass, 1 in. outside diameter and about 1-16 in. thick and 4¼ ins. long. In the middle of it is cut an opening ½ in. wide by ¾ in. long, as shown in the small drawing. This is for the withdrawal of the iron needle described below. Referring to Fig. 4, which shows a cross section of the instrument on the line A B (Fig. 5), it is seen that the tube is supported between small castings of brass which are clamped between the poles of the permanent ring magnet by the screws m and n. To the lower of these castings the tube is soldered at its middle, the opening already described being on the upper side, as shown at Q, Fig. 5. The upper casting clamps the tube solidly in place when the two screws, m and n, are drawn up tight.

Through these two castings are tapped brass screws coned out for the reception of the pivot carrying the needle, N. This pivot is of hard steel wire, the ends being coned in a small lathe or ground off to shape on an emery wheel. On it is mounted the soft iron needle, N, shown in perspective in one of the small drawings. This should be of the softest and purest iron obtainable, ⅝ in. long over all, about ⅛ in. wide in the middle, and about the same thickness, measured along the pivot. It must be filed carefully into perfectly symmetrical shape. Attached to the pivot is the aluminum pointer, P, which sweeps over a scale and mirror as described above. It will be noticed that the zero point of this scale is at the middle, the needle being deflected in either direction, according to the direction of the current.

In the ends of the brass tube, T, are soldered two plugs carrying the soft iron screws, S and S_1. These are intended for the regulation of the scale of the instrument, and once adjusted are to be left alone. By screwing them in nearer the



FIGS. 4 AND 5.—PERMANENT MAGNET PORTABLE AMMETER.

needle, N, the instrument becomes more sensitive, that is, it gives a larger deflection for the same current. Hence, when the instrument is assembled, the maximum current it is intended to register should be sent through it and screws adjusted until the needle is at its extreme deflection.

To soften the iron screws, S and S_1, put them in a small sand crucible and cover them with powdered lime. Then heat the crucible to a cherry red heat in a charcoal or anthracite fire, leaving it to cool very slowly as the fire dies down. The lime prevents the formation of a scale of oxide on the screws, which may be cleaned after they are cool by dipping them for a moment in weak muriatic acid and washing in water containing a little ammonia.

The coil is wound as shown on the brass tube, its ends being attached to appropriate binding posts. The figure shows a coil of only twelve turns, intended for the measurement of fairly large currents, but for small currents the wire may be smaller and the turns more in proportion. For currents up to 15 amperes use No. 10 wire and put on sixty turns, thirty on each end of the tube.

The ring magnet, R, is fastened down to the wooden base by clamps, K. As shown in the illustration the instrument is a table form, adapted for use in a horizontal position only. If the needle system shown in the small drawing is balanced perfectly for all positions (which would require a small counterweight to compensate for the pointer, P_1), the instrument may be used in any position.

For use as a voltmeter the coarse coils shown should be replaced by coils of fine wire wound on insulating spools and slipped over the ends of the spool. Indeed, a combination instrument may be made by slipping these spools on over the ammeter winding as shown. For the best results these spools should contain the largest possible amount of the finest possible wire, and should be connected, in addition, through a resistance in the base of the instrument, care being taken to so wind the latter that it does not produce any magnetic effects. The total resistance of the coil and the additional resistance for measurements up to 150 volts should not be less than 9000 or 10,000 ohms. For higher voltages additional resistance or a shunt must be used. Unless the resistance is very high so much current will flow through the coils that they will heat or even burn out if the instrument is left in circuit, hence the necessity for care in providing enough resistance. It is also to be noted that a voltmeter is exposed to the full pressure of the current that it is measuring, and that its insulation cannot be too careful. In an ammeter the fall of potential is utterly negligible and insulation is not a feature of particular importance, but with a voltmeter this is different, a short circuit leading instantly to disastrous results.

The above instrument, which is similar to those made by Carpentier and Ayrton & Perry, is a thoroughly satisfactory shop meter, if carefully and accurately made. Unfortunately, like the other instruments described above, it is useless for alternating currents.

(*To be continued.*)

HOW TO MAKE A DRY CELL.

Dry batteries, so called, are only dry in the sense that there is no fluid spilled or slopped over when they are shaken or overturned. In every voltaic cell the current is derived from the chemical action which goes on within its substance, and no chemical action can take place between solids alone, but in all cases there must be present a liquid or a gas. Some few cells employ gaseous electrolytes, and some, fused salts, but the vast majority use aqueous solutions of their respective chemicals, and it is in this class that the ordinary dry cells are to be found. Even the old dry piles of Zamboni and others, which consisted of discs of paper coated with metals (gold and silver paper) laid up "dry," in reality contained a very small amount of moisture in the paper, and if the paper is really perfectly dry, the piles will not work. If the ordinary dry cell then requires moisture to make it work, and is in fact only a non-spilling wet cell, it is a natural inference that the wetter the cell, consistent with it not spilling or slopping over, the better. This inference is absolutely correct. The more fluid a dry cell contains the better, for many wet cells would be improved for having a larger amount of electrolyte than they do have.

It might seem in view of what has been said, that any wet cell, if well sealed up, would do for a dry cell, but such is not the case, for several reasons. Many cells will not stand sealing up tight, because they give off gases, and these must have free vent, and again it is not always practicable to seal up a cell so that it will not leak at all when inverted. Again, it is not worth while to seal up a cell, except one of the kind that will last for considerable time before it gives out or even needs replenishing. Another desideratum of a dry cell is that it should not be easily broken, as there are many places where cells are liable to fracture as well as upsetting, etc. For these reasons, it is customary to dispense with the glass jar, and to make the zinc serve the double purpose of containing jar and electrode, and further, to use an absorbent substance that will take up and hold the fluid electrolyte like a sponge, so that the seal is rather to prevent evaporation and creeping of salts, than spilling or slopping. The types of cells giving the best results on open circuit work, as wet cells, naturally do the best when put up in the dry form; consequently, as might be expected, the vast majority of dry cells on the market are some form or variety of the sal-ammoniac type. Several of the manufacturers of dry cells claim to have valuable secrets relating to their manufacture, but however true this may be in regard to the details, the main requirements are well understood.

In making a dry cell, the first thing requiring attention is the jar. This, as before remarked, is usually made of zinc. The cell is usually cylindrical, although sometimes square or oblong in section, but in any case a piece of moderately heavy sheet zinc is bent into the required form, the edges soldered together and a bottom soldered in. Any one who tries to solder zinc for the first time may be very much surprised and disgusted to find that it does not take kindly to soldering like tin plate, but balks and makes lots of trouble. However, by observing the proper precautions, zinc may be soldered with comparative facility. Thoroughly clean all the parts where it is intended that the solder should stick, by scraping; use clean chloride of zinc for a flux, and apply the solder as near the point where it is needed as possible, not trying to make it flow over the surface of the zinc as can be so readily done with tin plate, for the more the solder alloys with the zinc, the more intractable it becomes. Learn to make a joint quickly on the first application of the soldering bit, as the more you fuss and tinker with it the rougher, more unsightly and more uncertain it becomes. Another pleasant little habit of zinc is to strip the tinning off the soldering bit. You may have tinned your bit with the utmost care, but after using it a short time find it completely stripped. Some persons prefer an iron bit to the usual copper one, claiming that it holds the tinning better, although somewhat more difficult to tin in the first place.

Having made the jar, the next thing to attend to is the contents. One of the most important constituents of the contents is the absorbent. Several materials have been used for this purpose, among which are plaster of paris, gelatinous silica, gelatine, so called, which is really the starchy mass obtained from boiling Irish moss; gelatinous magnesium oxychloride and a material made from the granular portion of the rind of the cocoanut, called cofferdam. There are other materials, but these are the more important ones. As the process of filling the cell differs somewhat for each kind of filling, it is better to describe each one separately. The zinc usually has a brass binding post soldered to its rim on one side (there being no objection to this structure in a dry cell, because the electrolyte cannot possibly come in contact with the junction), and the other electrode, which is usually of carbon, has a binding post of the same kind, fastened in one of several different ways.

The seal is made of pitch or some similar material, which will form an air and water tight stopper, and also resist the tendency of the salts to creep, as does the paraffin coating on the upper part of the jar of an ordinary sal-ammoniac cell. It is simply melted, poured in on top of the charge and allowed to cool in most dry cells, but some manufacturers make a sort of safety valve or pressure regulator, by inserting a small piece of rattan so that it passes completely through the seal, its ends projecting slightly above and below the pitch. The natural porosity of the rattan is sufficient to relieve any pressure generated by the escape of gases, but it will not of course provide for the swelling of the more solid portion of the contents which sometimes takes place when the cell is subjected to too high a temperature, and cells are frequently destroyed by bursting when placed in boiler rooms and other situations where the temperature rises to an inordinate degree.

One of the important qualities of a dry cell is long life on open circuit, which means that the local action should be negligible, and it is in the prevention of local action that some manufacturers claim to have valuable secrets. Bi-sulphate of mercury is sometimes used to keep the zinc amalgamated, as in wet cells. This, of course, does some good, but it is not all. Anything that will tend to keep the chemical composition of the electrolyte uniform in all parts of the cell will help to prevent local action.

We will now consider some of the particular forms of dry cells. The Cox cell is formed by boiling Irish moss in sal-ammoniac solution until it is thoroughly gelatinized, and pouring it into the zinc jar, where the carbon electrode has been already placed. Bin-oxide of manganese in conjunction with the carbon as a depolarizer is, of course, used as in the wet form. The inventor also mixes a little bi-sulphate of mercury with the electrolyte. Some of the other sal-ammoniac cells as described do not use it, but there is no reason why they should not, and the reader should understand that he may use it or not in the other cells described. When the moss solution is cold it sets to a firm jelly, and is then ready to be sealed. Obach's cell is made by mixing plaster of paris with the sal-ammoniac solution and pouring it into the jar to harden. Mehner's cell is made by mixing the sal-ammoniac solution with chloride of calcium and calcined magnesia, forming a paste of about the consistency of cream, which is poured into the jar, and in two or three days forms a stiff jelly, owing to the formation of oxy-chloride of magnesium. In Gassner's cell the following composition is used: Oxide of zinc, 1 part; sal-ammoniac, 1 part; plaster of paris, 3 parts; chloride of zinc, 1 part, and water, 2 parts, all by weight. The oxide of zinc is intended to make the plaster more porous, giving this cell an advantage over the simple plaster cell before described.

Gelatinous silica is precipitated when any strong acid is added to a solution of silicate of soda, and several inventors have used silicate of soda to gelatinize the electrolyte in storage cells. This, of course, introduces sulphate of soda into the electrolyte, but this does no harm, and is even regarded as beneficial by some. The charge and discharge rate of the cell is much reduced, and it will not do to allow much gas to be generated in the jelly, neither can the cell be sealed up perfectly tight, but a vent must be left for the escape of gas. The spattering or spraying during charge, however, is cured, even if no cover is used.

Gelatinous silica may be used in any electrolyte in which the sodium salt, formed at the same time with the silica, is not detrimental. It is very difficult to wash the silica, and it does not pay to do it for such a purpose as this, so if it is intended to use the silica with sal-ammoniac it is better to precipitate it with hydrochloric acid, instead of sulphuric, as in that case the precipitated silica will contain chloride of sodium, instead of sulphate.

The Germain cell, which at one time attracted considerable attention, used the material known as cofferdam, previously mentioned in this article. The containing vessel of this cell is made of wood boiled in paraffin, the carbon plate is imbedded in lumps of peroxide of manganese and carbon, and the rest of the space is filled with cofferdam saturated with sal-ammoniac, the zinc, which is well amalgamated, is laid on top, and the cover (or rather the side) is screwed on, slightly compressing the contents.

It will be observed that some of the directions for the manufacture of dry cells are very particular about the amalgamation of the zinc, even when the electrolyte is sal-ammoniac, but, as a matter of fact, most of the dry cells on the market are made with unamalgamated zincs, which is a pretty good proof that the amalgamation is superfluous. There have been many other dry cells proposed, some quite elaborate in composition and others less so, but the different forms of the sal-ammoniac cell are at the present time used to the exclusion of everything else.

One practical difference between wet and dry cells is the different manner of using them. In the wet cell, we endeavor to use some of the parts, such as the containing jar, indefinitely, and the porous jar, if there is one, at least a very long time. We also endeavor to use up the zinc as completely as possible, expecting to renew the electrolyte several times before the zinc is all gone. With dry cells, however, it is the common practice to throw them away as soon as they fail from any cause to do their work. The zinc being also the containing jar, it manifestly cannot be all used up, but on the other hand must be discarded as soon as it is perforated, if indeed something else does not give out before this event, as is intended.

Dry cells are intended more particularly for a class of consumers who do not care to be bothered with the manipulation of wet cells. When they come from the factory they are ready for use without any preparation whatever, and when they are exhausted they may be thrown away without compunction, for they are made for such a low price that it does not pay to spend much time or trouble on them, even when they happen to be in such a condition that they may be restored, which is not usually the case.

The zinc electrode-jar must be insulated in some way, especially when several of the cells are used in series, as in this case any external conductor touching two of the cells would short circuit at least one of them. For this reason they are usually varnished, and often in addition placed in strawboard boxes.

Judging from the variations in the different cells on the market, and which work satisfactorily, it would appear that the exact proportions of the ingredients are not very important. In the nature of things the electrolyte is the first thing to give out, and there is no danger of getting too much of it, and the solution should be saturated. The carbon and manganese should not take up too much space, and as in the wet sal-ammoniac cells the manganese is usually thrown away before it is exhausted, from the fact that the inner part of each lump is unavailable, it is evident that a small amount of manganese will answer the purpose, if arranged so as to be available, for which purpose it is better to have it rather finely broken, than in large lumps, and in as intimate contact as possible with the carbon. There being no danger in a dry cell that the manganese will become displaced after having been once fixed, there is no objection to its being in a state of powder.

CUTTING BY STEAM.

BY JAMES F. HOBART, M. E.

The engineer has for a long time been aware that metallic surfaces suffer when exposed under certain conditions to the impingement of steam currents of considerable velocity. It is commonly stated that such action is caused by the "cutting action of steam." In studying this phenomena, it appears at first sight as if there really was a cutting action to or possessed by a jet of steam.

A closer study of the matter demonstrates that steam itself possesses no cutting force or erosive action, at least no more than that possessed by a jet of air at equal pressure. It cannot be said that pure air can ever cut a hole in a piece of iron or brass, no matter how long exposed, or how favorable the action. But charge the air with sand and the erosive effect will immediately appear.

Under the foregoing conditions the harmless air jet becomes a destructive sand blast, and cuts away the hardest steel with ease and rapidity. In like manner pure steam is, or has, all the characteristics of a perfect gas, and will blow through or against a piece of metal indefinitely as long as steam only is thus forced upon the surfaces.

However, an air jet will sometimes cut, and we know that steam frequently plays havoc with valves and other surfaces with which it comes in contact. Then, the cutting is not done by the steam itself, but by the substances it carries along with it. There may always be dust in the air blast, and water in the steam, and it is to the sand blast action of the dust and water that most of the destructive cutting is due in air and steam machinery.

To put the matter in another shape, I may state that in years of experience with steam machinery, in designing, constructing and operating, I have never yet seen a case of cutting by steam alone. All the cutting found in valves and in boiler shells and rivets, is done by something other than steam—in most cases altogether by water. The proof of the statement develops by an examination of any case of cutting which comes to light. A careful examination will show that the small particles of water carried along by steam under pressure have in all cases caused the destruction of the metals against which they have been blown by the steam.

An example of this may be found in Fig. 1, which is part of a pump generator valve used for keeping a Worthington fire pump in service condition. The cutting action is shown at a and also at b. Upon taking the valve out it was found that the cutting had taken place only at the bottom side of the valve, where water of condensation passed through it. The upper portion of the valve was free from any cutting action.

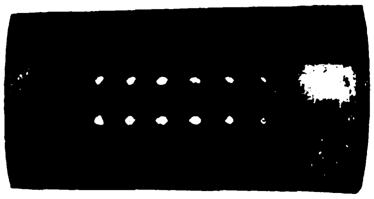


FIG. 1.—CUT PUMP VALVE.

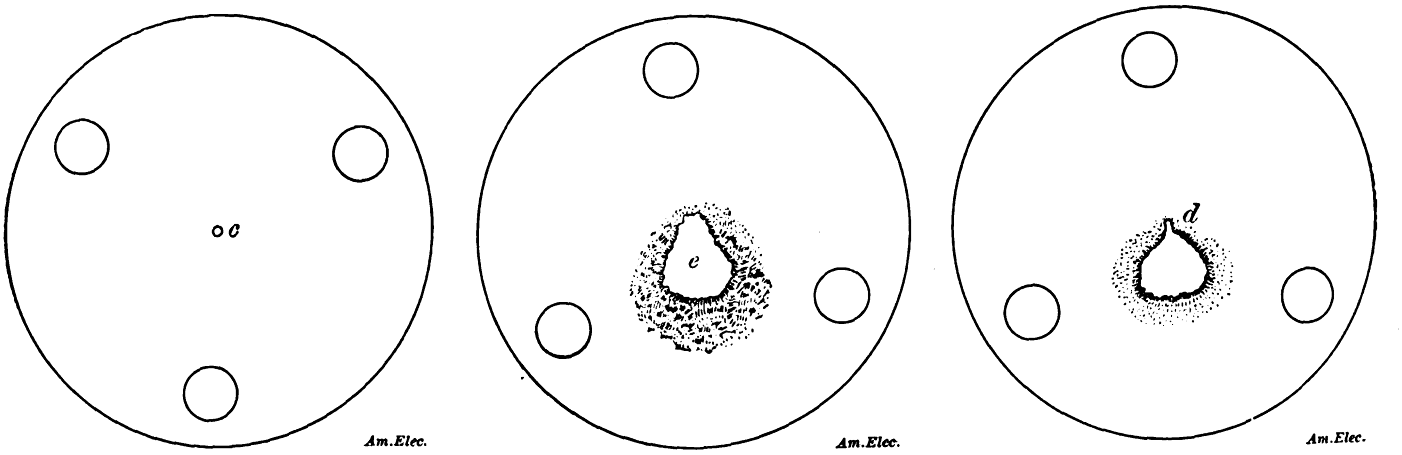
The valve is conical, and has a rotary oscillating motion when in operation. When nearly closed a very small portion of the opposing holes on the steam passage overlap, and these holes have been elongated on one side, as shown. The only traces of cutting at the top of the valve are in slight elongation of a few of the holes, and this was doubtless due to water in the steam pipe, which at times must necessarily flush the entire valve, as there is a good deal of water in pump pipes at times, when the pumps are run as slowly as possible.

One of the worst cases of valve cutting I have ever seen is represented by Fig. 2. These illustrations were made from a 1-in. valve taken from a steam plant in the West Indies. I cannot give the length of time the valve was in service, or the treatment it met with, therefore the testimony of the engravings must be all that will be known of this matter. The valve had the appearance of being new, and bore only the wrench marks made at the time the stem was removed from the body of the valve. No other wrench marks whatever were to be found upon that part of the valve in my possession.



FIGS. 3, 4 AND 5.—DIFFERENT SPECIMENS OF CUTTING IN A STEAM DIAPHRAGM.

From the appearance of this valve, the disc had been screwed down upon some foreign substance, probably a little dirt, and left there until steam had driven water enough through to spoil the valve. Then, even if the valve had been closed, the rest of the cutting is easily accounted for, and is only a matter of time. No repairs were made, and the cutting continued until the condition shown by the engravings had been reached.

The removable packing was soon cut through, then the brass was cut away until the collar on the stem was exposed to sight, as shown in Fig. 2.

This valve shows that in order to cut by steam it is only necessary that water be present in or with the steam, and that a certain direction be given to the jet. Then a steady continuation of the jet for a long time, and the conditions are complete.

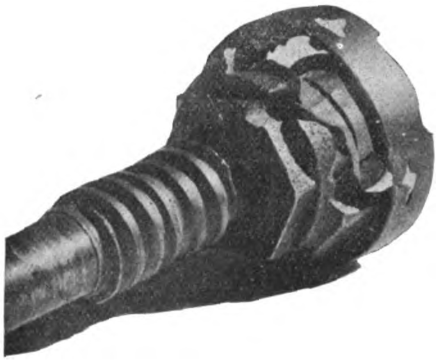


FIG. 2.—CUTTING ON GLOBE VALVE.

An example of cutting which occurred under my personal observation is a good illustration of the fact that water of condensation, and not steam, is to blame. The disc, Fig. 3, was made of plain sheet-iron a little over 1-32 in. thick, and had a 1-16-in. hole, c, drilled through it in the center. The disc was then bolted into an ordinary flange union in a ¾-in. steam pipe and served to reduce the amount of steam supplied to a heating coil for melting paraffine wax. After four or five weeks' use the disc would have to be renewed, and invariably would be found to be cut into the shape of a miniature horse collar, as illustrated by Fig. 4. The enlargement of the hole, d, was invariably at the bottom of the original opening, showing plainly that it was water, rather than steam, that had done the cutting. One diaphragm bore the peculiar cut shown by Fig. 6, where the original hole was left almost intact, and the cut opening entirely below and only connected by a narrow passageway, as shown at d.

In contradiction to the "water" theory of steam cutting, an engineer brought up the matter illustrated by Fig. 6, where a leak at the top of a boiler had resulted in cutting a groove alongside a rivet at a, under the head thereof, and into the head, b, of the adjacent rivet, as shown by the cross-sectional sketch mentioned.

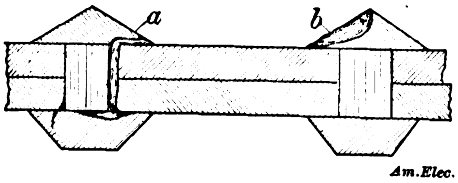
Here was apparently a case where pure steam had done considerable cutting, but upon a close study of the matter it only adds more proof to the "water" theory. It will be seen that the section of opening beside the leaky rivet is very small, as also is the escape of steam under the rivet horizontally. The adjacent rivet has suffered badly, probably ten times as much metal having been cut away therefrom as from the rivet where the leak actually occurred.

In this case, it is evident that the escaping steam has had very little water in it, for the channel is a very small one, and although the leak had existed for several months it had increased very slowly. This, in agreement with the water cutting theory, was because only at the time of getting up and letting down steam in the boiler would there be "watery vapor" blown through the leak, instead of gaseous steam.

On the other hand, the rivet at a distance was constantly being bombarded by particles of water condensed from steam the instant its pressure was released by emerging from the orifice under the first rivet. In addition to this, there is always present more or less dust from the furnace fire, and some of the particles thereof doubtless had a sand-blast action upon the second rivet. The combination of the two causes was enough to perceptibly wear away the second rivet, while the first showed no appreciable signs of increased cutting.

Blow-off and drip valves are more frequently found to be cut than are steam valves, and throttle valves, where the steam pipes are long, are frequently badly damaged. Safety valves are also cut when there is considerable condensation to be driven through them. I have found that safety valves closely connected to the boiler, so they would at all times be hot, were much less inclined to became leaky than were valves connected at a distance from the boiler, so that their temperature could change considerably between the periods of work and idleness.

The ordinary water line glass also exhibits another example of water cutting and freedom from damage by leaking steam. The slightest leak at the bottom end of the glass will result in the glass being cut or reduced in diameter around its entire circumference. Although this cannot properly be called a case of cutting, it shows that water, not steam, does the mischief, for while the water end of the glass tube will be reduced to almost paper thinness, the upper, or steam end will remain untouched and of its original thickness.



Am.Elec.

FIG. 6.—CUTTING AT LEAK IN RIVET.

The well known "snaky" tracks across the seats of valves are made by water being driven over the metal by high pressure, and the crooked paths so often made by cutting particles are caused in the attempt of the abrading particles to follow the line of least resistance.

Cases can be cited where a change in the material of which the surfaces were constructed has completely stopped the cutting action. In the case of the pump valve mentioned above the iron valve was replaced by bronze, with the effect of reducing the number of strokes of the pump per minute from twenty-five to four, and after a year of wear no perceptible increase in speed has been noted.

Another case was that of a throttle valve, in which there was originally a packing which could be renewed at will in the ordinary manner. This packing would cut out in a week so badly that it was impossible to stop the engine without shutting off steam at the boiler. The packing was replaced by a solid bronze disc, and no further trouble has been encountered.

BOILER SCALE AND FUEL CONSUMPTION.

It is stated on good authority that in general 2 per cent of fuel is wasted for every 1-64 of an inch of scale on the heating surfaces of the boiler, and that ratio increases as larger thicknesses are deposited. If engineers would bear well in mind that such minute deposits cause such perceptible wastes of fuel many of them would succeed in accomplishing the coal economy they are striving after. Not a few firemen, if asked why boiler scale was an objection, would reply that the plates which it covered were liable to be overheated and would consider that if they freed the boiler from scale sufficiently often to prevent this catastrophe that they were doing all that was necessary.

INTERIOR WIRING.

BY CHARLES E. KNOX.

FEEDERS AND MAINS.

The feeders and mains constitute the "trunk lines" of the distributing system through which the current is fed to the "branch circuits."

In these articles, where the term feeder is employed, it is intended to refer to a conductor which begins at the switchboard and terminates at a center of distribution; this center of distribution may serve to supply either mains alone (in which case it would be a main center of distribution) or branch circuits, or it might supply both. Any prolongation of a feeder other than a branch circuit is called a main. Formerly the nomenclature included feeders, sub-feeders, mains, sub-mains, etc., but confusion resulted from the use of so many terms, and they have gradually dropped from use and the trunk lines are generally classed as either feeders or mains, their definition being usually as given above.

Before proceeding to adopt any system or method of feeding, it is well to consider in each case certain questions which would influence the feeding system. As these questions present important problems we will now proceed to note them, and then consider them in detail:

1. Control of groups of light (other than hall or night lights) from the main switchboard.
2. Control of hall lights from main switchboard.
3. Maximum number of lights that should be supplied by one feeder.
4. The best maximum limit for the size of the feeder conductors.
5. Portion of total loss to be allowed in the feeders and mains.

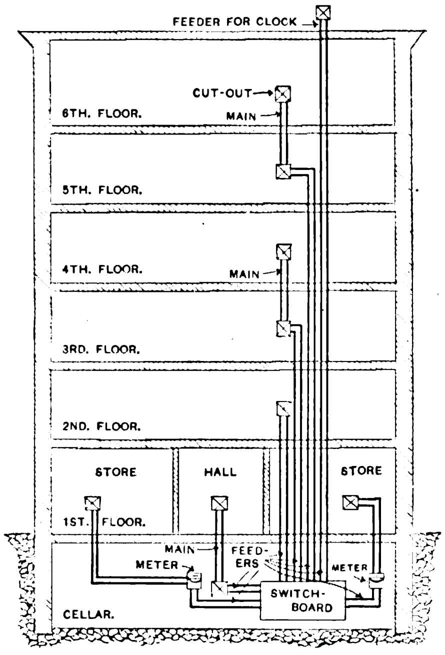
1. Control of groups of light (other than night or hall lights) from the main switchboard.

It frequently happens that it is desirable or even necessary to control the lights on each floor (or a portion thereof) from the main switchboard. Where such is the case, the feeder system must conform with this requirement and a separate feeder run to each floor (or group of lights).

In a large business building, for example, which is entirely or partly occupied by one concern having one or two different departments on each floor it is wise to make this provision, for the reason that one department may work longer or at different hours from the other departments, and therefore would require light at times differing from the other departments. Where this is the case it would result in a saving of current to be able to shut off the current from other floors just as soon as vacated, leaving current only on those floors where required.

An instance of such a case as this is a large insurance company in New York City, which occupies an entire building of eleven floors. As far as possible, each department is located on a separate floor. When one department does work after the others have gone, the feeder supplying current to that floor may be left connected to the switchboard, and the others may be disconnected. If the feeders were not so arranged, it would be necessary for the electrician to send to all the floors or departments connected to the same feeder which supplied the department working overtime, to turn off all the lights which the employees may have neglected to turn off when they left their work. In the case of a newspaper building, there may be certain floors where the light may be required all night, the occupants on the other floors going away at the usual time. Of course, it is expected that the occupants of the offices will turn off their light as they leave their offices, but this is not always done, and a saving of current could be effected by being able to shut off the current at the switchboard.

Where a business building is rented (as is frequently the case nowadays) with the agreement that electric light will be furnished at all times of the night and day, of course this arrangement of feeders is unnecessary. In this event, the feeder system may be laid out regardless of the control, so far as the room lights are concerned. In any case, however, it is well to have each of the lower floors, up to and including the ground floor, on a separate switch, as these floors require light at a greater number of hours and at more unusual times than the other floors.



Am.Elec.

FIG. 1.—ARRANGEMENT OF FEEDERS WHERE TENANT PAYS FOR LIGHT.

Wherever there is special lighting, such as the lighting of a clock dial, outside dome lights, or other decorative lighting, the lights should be provided with a separate distinct feeder controlled from the switchboard, because these lights are turned on and off at a set time from the switchboard.

In the case of a hotel, where the light may be required in any room at any time of day or night, of course this arrangement of feeders, so far as control is concerned, is of no importance, as it rarely happens that any of the switches controlling feeders supplying the bedroom floors are opened. They are closed the day the hotel opens, and are only opened in case of accident or other unusual circumstance.

Sometimes portions of buildings are rented on a contract basis, so that the tenant pays for the light he uses. In such cases, where there is a considerable number of lights, it is best to provide a separate feeder for each of these portions, so that a meter may be placed on the feeder and the current consumed measured at the switchboard. This frequently happens in a business building having stores or a restaurant on the ground floor.

Fig. 1 is an example showing a six-story building having two stores on the ground floor, each of which is rented on the basis that the current be measured and paid for, in addition to the rent, the upper floors being supplied with current at any time of the day or night, thus making separate feeders unnecessary; also having a clock on the roof provided with a separate feeder, so that the clock dial may be illuminated at dark and turned off, say at one o'clock. Here no provision is made for the separate control of hall lights, which is the next point to be considered.

(*To be Continued.*)

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

PROTECTIVE DEVICES.

The matter of protecting telephone apparatus from the damaging effects of currents other than those which properly belong on telephone lines, is not such a simple matter as might be at first supposed. The "lightning arresters" found on nearly all telephone instruments are for the purpose of protecting the instruments only from what may be called extremely high tension currents, such as those produced by lightning. The usual form of this arrester is shown in Fig. 1, in which A and B represent the two line plates carrying two binding posts and forming the terminals of the instrument. The plate C is connected with the ground. These three plates are not in contact, the idea being that a charge of lightning will jump across the air gap to the ground plate before it will pass through the high resistance and impedance of the instrument coils within. They do some good, but are by no means infallible, as lightning has too many freaks to be kept out by any such simple device. The holes e, f and g are for the reception of a metallic plug, which, if placed in e, short circuits the instrument, and if in f or g, connects either one side or the other of the line to ground. The placing of the plug in the hole e affords a very efficient means of protecting an instrument during a storm, but it is subject to the very grave disadvantage that people will forget to remove it after the storm. If but one subscriber is served by a line, no one is hurt but himself, but if it is a party line, constructed on the bridging principle, the insertion of such a plug causes a dead short circuit which disables the whole line. Cases are very numerous where a repair man has had to drive perhaps twenty miles in order to tell a subscriber to remove his plug, for, obviously, the subscriber cannot be called up by telephone.

The next most simple means consists in placing in the telephone circuit a fuse-wire of very small current carrying capacity. These wires are usually mounted upon mica strips which may be inserted between clips forming terminals of the line and instrument wires. Although largely used, these have not proved at all reliable, but they often save an instrument when the one shown in Fig. 1 fails. Considerable difficulty is apparently experienced by the manufacturers of very small fuses in gaging them to blow at a given ampereage. I have frequently found ⅛-ampere fuses to carry two amperes without showing any signs of blowing. Again, inasmuch as these fuses are necessarily very fine, being not much larger than a hair, it is a very easy matter to break them, thus causing an open circuit the location of which may not be at once apparent. In the case of a high tension current these fuses usually blow, but frequently start an arc across the terminals, which does the damage to the instrument as effectively as if the line wire was continuous. Strange to say, an instrument is sometimes found burned out with its fuse still intact, although this is uncommon.

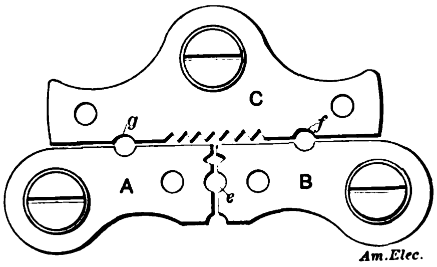


FIG. 1.—USUAL FORM OF TELEPHONE LIGHTNING ARRESTER.

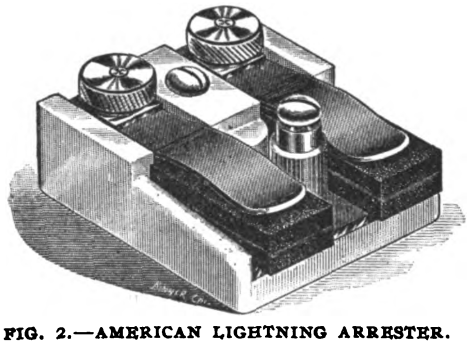

FIG. 2.—AMERICAN LIGHTNING ARRESTER.

Still another form of protector consists of two carbon blocks held apart by a thin disc of mica, one block forming the terminal of the line, the other being grounded. These blocks are usually arranged to slip in pairs between rather strong springs, so that they may be easily removed when desired. One form of these, shown in Fig. 2, represents the double carbon lightning arrester of the American Electric Telephone Company. The two binding posts at the top of the figure are attached to the two branches of the line, which are not cut, but run continuously to the telephone instrument, or whatever it is that is to be protected. The third binding post is in connection with the ground plate upon which the two lower blocks rest. The idea in this is that a current coming in over the line will jump across the very small space between the carbons and pass to the ground without harming the instruments.

The arrester shown in Fig. 3 is that used by the Western Telephone Construction Company, and is a combination of the carbon and the fusible arresters. In this the two line wires of a metallic circuit enter the two binding posts at the right of the cut, from which each circuit passes through the fuse-wires mounted on the mica strips, and then to the vertical springs bearing against the right-hand carbon block. These springs are respectively in connection by metallic strips underneath the porcelain block, with the two binding posts at the extreme left of the figure. The single binding post is in connection with the two vertical plates holding the carbons and is grounded. In this the fuse is supposed to blow for any current considered too great for the carrying capacity of the instrument, while, if the current is of a high enough tension to form an arc, it will jump to the ground between the lightning arrester plates. Some people advise connecting the fuse on the instrument side of the carbon arrester instead of on the line side, but this is not best; for, if there is a cable in the line and the cross occurs at some point beyond it, the current which would flow through the telephone instrument would, owing to the high ohmic resistance of the latter, not be strong enough to affect the cable; but, if the current jumps to ground through the carbon arrester a practical short circuit is formed which might allow a very heavy current to flow through the cable to the ground and thereby damage the conductor. For this reason it is better to have the fuse on the line side of the circuit.

The devices so far described have been designed to cut off all currents from the apparatus to be protected, above a certain maximum value. It frequently happens, however, that a very small current, due perhaps to a cross on the line, will not be sufficient to blow the fuse and will yet, by reason of a long continued flow, store up enough heat in a switchboard or ringer coil to char the insulation or burn it out entirely. These currents are the telephone exchange manager's worst enemies, and are very appropriately termed "sneak currents," because they usually pass all the protective devices placed in the circuit to arrest them, without producing any effect whatever; but, on reaching a close coil of wire, they, by slow degrees, develop enough heat to burn out the coil, or, as has frequently happened, to burn up the whole exchange.

A device to afford protection against such currents as these, types of which have come into almost universal use by Bell companies, is termed a heat coil and was, so far as I am aware, first introduced by Mr. Hammond V. Hayes of the Bell Company in Boston, Mass. This device is illustrated both in its assembled state and in its various details in Figs. 4, 5, 6, 7 and 8. In Fig. 7 is shown the details of the heat coil proper. A bobbin is formed of the two discs d and d¹, in the thin flat space x, between which is wound about 10 ft. of No. 32 B. and S. German silver wire. On the side d¹ is carried a metallic shoulder e and a flange 4, forming a deep groove f between them. A hole 8 is formed through the bobbin, through which projects a hard rubber pin s. The pin s is fixed in place by a small amount of easily fusible solder, which normally holds it in the position shown in the extreme left-hand portion of Fig. 8. One terminal of the German silver wire is attached to the flange e, while the other terminal is attached to an inclosing ring d² of brass. The flange 4 and the ring d² are thus insulated from each other, except for a path through the German silver wire w.

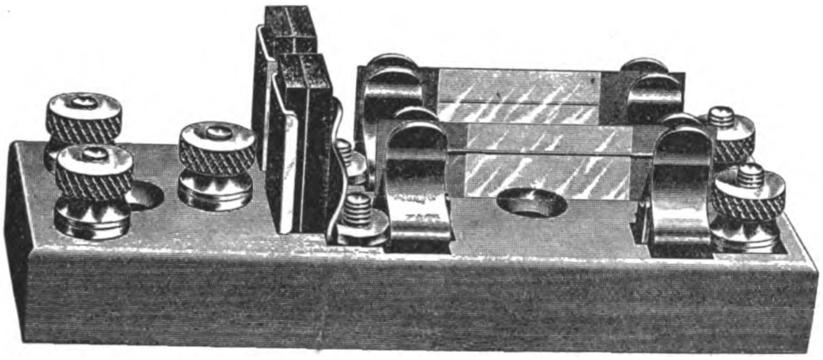

FIG. 3.—WESTERN TELEPHONE CONSTRUCTION ARRESTER.

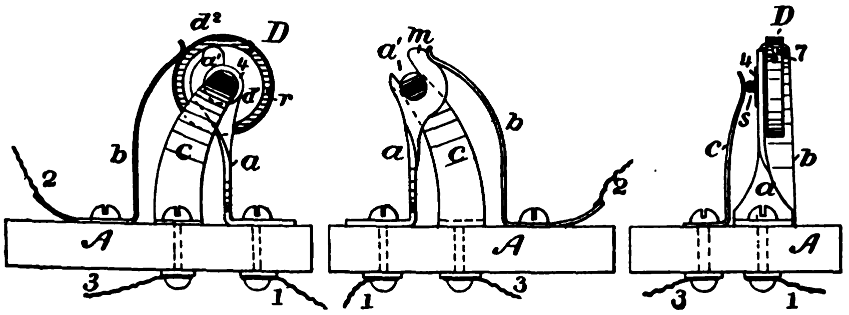

FIG. 4, 5 AND 6.—HAYES THERMAL ARRESTER.

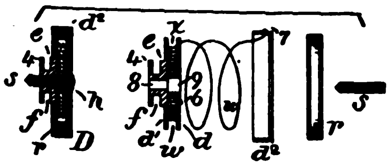

FIG. 7.—DETAILS OF HAYES ARRESTER.

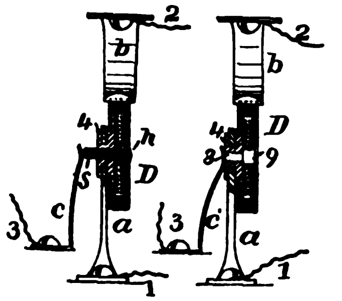

FIG. 8.—DETAILS OF HAYES ARRESTER.

Three springs, a, b and c, are mounted as shown, upon a base plate A. The spring a, which forms the terminal of the line 3, is slotted at a¹ in such manner as to receive the neck or groove f of the heat coil, as shown in Figs. 5 and 8. When in place, the spring b, which forms the terminal of the instrument to be protected, rests against the ring d², so that the circuit is complete from the line wire b through the spring a, flange 4, German silver wire w, ring d² and wire b to the instrument. When a current stronger than a certain predetermined value passes through the coil, a sufficient amount of heat is generated to melt the solder. This allows the spring c, which is connected by the wire 3 to the ground, to push the pin s entirely through the coil, so that contact is made between spring c and flange 4, as shown in the right-hand cut of Fig. 8. This at once grounds the line without leaving any air-gap whatever in the circuit, as in the previous arresters. It has been found advisable, however, to use these heat coils in connection with carbon arresters, and also with comparatively heavy fuses, as will be described later.

AN OPPORTUNITY FOR INVENTORS.

In every inclosed arc that burns there is a resistance in series which consumes from 75 to 150 watts, and in some cases even more. Arc lamp makers have striven to avoid the use of this resistance, but have finally yielded to the inevitable. It is necessary for purposes of regulation. In the 50,000 inclosed arc lamps now burning there is wasted over 5000 k.w. There is a market for some useful translating device that will absorb from 2½ to 5 amperes at 30 volts.

LESSONS IN PRACTICAL ELECTRICITY

HOW TO DESIGN A DYNAMO.

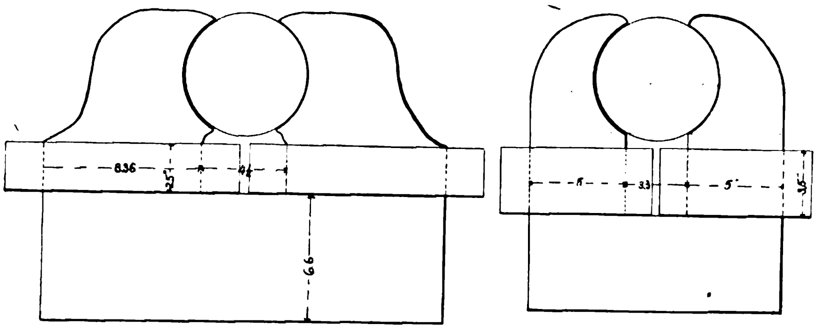
In the last article we determined that we needed approximately 3792 ampere turns in the field coils, and that the diameter of the magnet waists is 8.36 ins., if they are to be circular. We shall find it advisable to have the distance between the magnet waists quite small, not to exceed 4½ ins. This will allow us ½ in. in the clear between the spools and an available winding depth of 2 ins. Of this we must sacrifice at least .25 in. for insulation, leaving a winding depth of 1.75 ins. If we add twice the total depth available to the core diameter, we will obtain 12.36 ins. as a maximum diameter of a turn, and if we add twice the thickness of insulation to the core diameter we will obtain 8.86 ins. as a minimum diameter of turn. The average of these two gives us 10.61 ins., the mean diameter of turn. Multiplying this by 3.1416, we will find the average length of turn to be 33.4 ins.

It is now in order to explain a curious property of coils connected across a constant potential circuit. It is evident that if the coils are all of the same length their resistance is identical, provided the copper is of uniform quality. If we have, for example, ten coils, a certain current will flow and, if we multiply that current by ten, we shall have the total number of ampere turns that are available. If, without reducing the potential or the gage of the wire, we merely reduce the number of turns to five, we shall cut the resistance in two, thereby increasing the current to twice its former amount, and as we have divided the number of turns in two, the ampere turns remain the same. This can be proved to hold true universally, provided that the coil is not heated so as to vary its temperature and consequently the specific resistance of the wire of which it is made, and provided that the average length of turn is not altered. We may then lay down this rule for shunt coils: That their magnetizing power is dependent only on the average length of turn, the potential to which they are subjected, the gage of the wire and its specific resistance. It is entirely independent of the number of turns if temperature considerations are neglected. The latter feature must be determined by the amount of current that it is found wise to use in the coil, and sufficient turns must be wound on to reduce the current to an amount that the efficiency conditions will permit.

Acting on this rule, we may, for the purpose of determining the gage of the wire, suppose that we have but a single turn on the field spools, and that flowing in that turn is a current of 3792 amperes. This will give the necessary ampere turns. It receives its current from a potential of 110 volts, and its resistance must therefore be the volts divided by the amperes, or .029

.029 ohms. Knowing its length, we at once determine its resistance per foot to be .0104 ohms, and from a wire table we find that No. 20 Brown & Sharpe most nearly approaches this size. In a machine of this size the exciting current should not exceed 3 per cent of the total output of the dynamo. The total output is 55 amperes, and we must therefore keep the exciting current within 1.6 amperes. We must, therefore, provide enough turns on the field magnet so that their combined resistance, when placed across 110 volts, will produce this current. This we find to be 110 ÷ 1.6 = 68.7 ohms, which is equal to 2370 turns in all. We divide this number of turns by two to obtain the amount on a spool, as we shall have two spools. By previous calculation we found that we have an available winding space of 1.75 ins., and this will hold thirty-eight layers of double cotton No. 20 wire. To find the turns per layer we divide one-half of the total number of turns by the possible number of layers, and we obtain thirty-one turns. This will occupy a distance of 1.4 ins., to which we must add .6 in. more for spool heads and insulation. To this we must add an additional width for the series coil. This will consist of only a few turns of wire large enough to carry the main current, which is 55 amperes. This wire should be, however, quite large, not on account of its current-carrying capacity, but because we do not want to introduce an excessive drop in the dynamo circuit. No. 0 Brown & Sharpe gage is a suitable size, and as that is .36 in. in diameter insulated, it is wise to add to the length of the core ½ in. more to allow for a series coil of several turns, one turn per layer. This makes the total length of the spool 2½ ins. From the data we have already calculated we may now summarize the following:

1. Distance between magnet limbs, 4½ ins.
2. Length of magnet limbs, 2½ ins.
3. Diameter of magnet limbs, 8.36 ins.



FIGS. 1 AND 2.—APPROXIMATE FORMS OF FIELD MAGNET.

If we assume the yoke piece is to be rectangular in section and equal in width to the magnet core, its area must be the same as that of the magnet waists, which necessitates a thickness of 6.6 ins. It remains to make a drawing of this field magnet and examine it to see where it can be improved. Such a drawing is that shown in Fig. 1.

It will be observed at once that the magnet is very squatty and massive, and at first sight it seems too large for the armature it is to magnetize. We have, however, chosen a low density of magnetization in the field frame, and for this reason we have, in consequence, a large magnet and a small exciting coil. Copper is cheaper than iron, and hence the practice is desirable, where weight is not a consideration. We must further remember that the coils are circular, whereas the pole pieces would naturally demand a rectangular coil, due to the fact that they are somewhat elongated. The armature is 11 ins. long, and as we are looking at an end view of the field, its squatty appearance is thereby enhanced. The machine is 16 ins. high and the center of gravity of the armature is very low, which would make it run very satisfactorily and without vibration. The circular field coils are very economical in the amount of copper they use, whereas the rectangular field coils use slightly more; the circular field coils are also very easy to wind. On the other hand, a constructional advantage enters here. If the field coils are rectangular, the pole piece can be shaped so that the coils will slip over it, whereas if they retain their present circular form the pole pieces will overlap at the ends and therefore joints will be introduced into the magnetic circuit, which are very expensive to machine. Moreover, the poles are naturally much narrower than the diameter of the magnet waist, and they would be obliged to slope to reach its outer edge, as shown. Therefore, it is well to recalculate this frame, assuming a rectangular coil.

If we adopt this type of field frame, we shall find that the distance between the magnet waists becomes fixed, if each pole piece is to surround a third of the circumference and that distance is, of course, equal to the length of the chord of an arc equal to one-sixth of the circumference. The polar bore is 6.6, and the length of a chord spanning 60 deg. is equal to the radius, or 3.3, the available distance between magnet limbs. Of this we will allow .3 for clearance and divide the balance between the spools for winding depth. From the 1.50, thus allowed, we subtract .25 for insulation and have available for wire 1.25 ins.

The breadth of the core is obviously 11 ins., and as its area is 55.02 its width is 5 ins. The maximum length of turn figures out 44 ins., and the minimum 34 ins. The mean is 39 ins., and as its resistance must be by previous calculation .029 ohms, it is easy to determine that No. 19 B. & S. is the nearest standard gage which will fill these conditions. Now, 1.25 ins. will contain twenty-five layers of No. 19 double cotton wire and as there are 1185 turns per spool, there are forty-seven turns per layer. This will occupy a length of 2.4 ins. To this we add 1.1 ins. for spool heads and series coil and obtain a total length of 3.5 ins. for the field spool. A drawing of such a field frame is shown in Fig. 2, and the lines are very much more compact than those in Fig. 1, although the machine requires a little more copper to get the same magnetization.

The connection yoke below the magnet coils is rather thick, and its depth can be reduced by extending it into the base towards the bearing pedestals. The amount of this reduction can best be determined when the bearing pedestals are designed, but it will probably be equal at least to 25 per cent. The field frame is still quite heavy and could be still more reduced in weight by choosing a higher density of magnetization and winding on a more powerful magnetizing coil. This will impair the efficiency of the machine somewhat and would probably add to its total cost, as copper is more expensive than steel. We may therefore accept these dimensions as being satisfactory.

We now have a field magnet and armature which are approximately of the correct dimensions, and can accurately calculate the leakage and the necessary magnetizing turns, both for series and shunt coils. Our previous figures have been only approximate, but we may be reasonably confident that any changes which the more accurate calculations will entail will be of a minor character.

Letters on Practical Subjects

The Cost of Feeding Boilers.

To the Editor of American Electrician:

Sir—I recently had a discussion with the engineer of a large plant regarding the cost and deficiency of several methods of injecting feed water into steam boilers. Like many other men this engineer was aware that the cheapest possible way of feeding a boiler was by means of a pump driven from the engine or from some convenient part of the shafting.

He also knew that it was rather expensive to feed with a steam pump, just how much more expensive he was not aware. For his information and for the satisfaction of other people who are interested, it may be stated that the triple expansion engines, run condensing, will use from 11 to 14 lbs. of coal per h.p.-hour, while the ordinary compound condensing engine uses from 14½ to 18 lbs. of coal.

The best Corliss engine in use, run condensing with a single cylinder, uses about 20 lbs. of coal; non-condensing, the same engine will use 28 to 30 lbs., while the ordinary simple engine, run non-condensing, uses 30 to 40 lbs. of coal.

The best steam pumps in the market, after they have been a few months in use, will rarely use less than 250 lbs. of coal for each and every h.p. generated per hour, but pumps usually consume more coal than this amount. It is not unusual for a pump to consume 400 lbs. per hour. This makes an exceedingly costly power, a thing which no engineer should tolerate.

He spends time and energy unlimited in increasing the efficiency of every part of his steam plant, but lets the old duplex pump bang away at the feed pipe and bleed the boiler one hundred-fold more than it should. A great deal more power is consumed in boiler feeding than the average engineer has any idea of.

Take for instance a 100-h.p. boiler where the engine is using 30 lbs. of steam per hour; figure out the amount of energy required to raise the amount of water consumed to the level of the boiler, and then to force it into the boiler against steam pressure, and it will be found that a great deal of energy is being consumed in the operation.

I will not discuss this matter in detail, but will content myself with giving a few hints, leaving the engineer to think out the matter at his leisure. First, there is a stated amount of h.p. to be used in putting the water into the boiler. Second, there is the choice of several methods of applying the necessary power. Third, there is the almost entirely neglected exhaust injector, which will feed a boiler without using either live steam or power from the engine—why this method is not universally applied is another question the engineer must answer. Fourth, there are other ways of feeding a boiler than by pump or injector. There are at least two appliances which force water into the boiler by gravity.

In practice each of these instruments has a vessel which is filled with water. Then the pressure on both sides of the liquid is equalized by the admission of steam, whereupon the water gravitates into the boiler. Fifth, the amount of steam used by these appliances—no data are at hand to determine the amount—it certainly cannot be more than once or twice the bulk of water injected into the boiler.

It must also be borne in mind that with both of these appliances, together with the injector family, all the thermal units contained in the steam, or nearly all of them, are returned into the boiler.

I would like to hear electrical station engineers discuss this matter. It is a question well worthy of being shown up in every possible light.

JAMES F. HOBART.

Water Rheostats.

To the Editor of American Electrician:

Sir: It was with considerable interest that I noticed the article by Mr. J. R. Perkins in your July issue, describing the water rheostat which he had constructed for use with his lathe.

I have found that while rheostats of this kind can be relied upon for experimental work which requires their use but a few moments, they are extremely unreliable when used for any length of time, on account of the fact that the resistance is constantly on the decrease, and this is particularly apparent where salt is used instead of acid.

During my lecture tours my operator has frequently burned out the rheostat which he used in connection with his stereopticon. It therefore became necessary for me to provide some kind of rheostat for immediate use, and in order to do this I constructed a water rheostat, using an ordinary water pail containing water and a little salt, the connection being made to two pieces of ¾ in. galvanized iron pipe, one being placed on each side of the pail and securely tied to it. While the operation of this rheostat was always excellent at the start, I found that in every case the resistance decreased so rapidly after the first fifteen minutes working that it was necessary to remove considerable of the solution from the pail and replace it with clear water in order to prevent blowing the fuse, which, as you can well understand, would have been a very unfortunate accident in such a case.

New York. W. J. CLARKE.

ELECTRICA CATECHIS

241. How can one instrument be used to measure currents in different circuits?

By having a double pole switch with several sets of terminals, like a voltmeter switch, the galvanometer may be connected around definite points on several circuits. It is necessary that the switch be made with great care, so as to have negligible resistance and so as to make sure and uniformly good contacts. If desired, the same galvanometer may be arranged so as to have a variety of ranges.

242. How can the range of current measured by a galvanometer be varied?

The range of the galvanometer may be varied by simply changing the ratio of the resistance of the coil with its connections, as compared with that of the "shunt." A given deflection or motion of the coil in the galvanometer is always caused by the same current; but that current may be any desired fraction of the whole curent in the main circuit, since the whole current divides itself between the "shunt" and the galvanometer circuit in inverse proportion to their relative resistances. If the resistance of either circuit is changed while that of the other remains constant, the ratio of the currents changes accordingly. Usually it is not desirable to change the resistance of the galvanometer circuit; the only alternative is to change that of the shunt. For a simple example, suppose that when the galvanometer is shunted around 1 ft. length of a bus bar or other conductor, 80 amps. give a full scale deflection of the galvanometer needle; if the same galvanometer is shunted around 10 ft. of the same conductor the relative resistances have changed so that the same current as before is sent through the galvanometer when the whole current is a trifle more than 8 amps. In the same way, if the galvanometer is shunted around 100 ft. of the conductor the galvanometer will give a full scale deflection when the whole current is a little more than 0.8 amp. The simplest way of finding the exact length of conductor to take as a shunt for a given range of current is to "cut and try," although the method of calculating it mathematically is not very difficult.

243. What is the difference between an ammeter and an amperemeter?

There is no difference; some prefer one word and some prefer the other. Amperemeter is more correct from an etymological standpoint, but most people seem to prefer the abbreviated form.

244. What is the difference between an ammeter and a current indicator?

A current indicator is usually a cheap form of ammeter whose readings are not claimed to be very accurate. For most plants it is not necessary to know the current exactly and a cheap ammeter is good enough. The voltage is the factor of importance, and it is better to put more money into a good voltmeter and less into the ammeter.

245. Is there any difference between a voltmeter and a voltameter?

Yes; there is a wide difference. A voltmeter is an instrument similar to an ammeter, except that it is arranged to measure voltage or pressure. The voltameter, on the other hand, is an instrument based upon the chemical effects of the current and measures the product of current by time. The Edison chemical meter is an example of a voltameter used to determine the ampere-hours of current used by a consumer.

246. What is the arrangement of voltmeters that have different scales corresponding to different binding posts?

Such instruments usually nave only one galvanometer coil, but have a number of different resistances in series. One terminal connects directly with the galvanometer coil; the terminal for the lowest scale is connected directly to the other terminal of the coil, or often to a small adjusted resistance coil in series with the coil; the next higher terminal connects with the circuit after it has passed through a second and higher resistance. The theory of the instrument is as indicated above in No. 246. A certain current is required to move the pointer to a certain mark; but the pressure or voltage necessary to send such current through the instrument depends upon the resistance of the circuit; hence each terminal governing the resistance in series with the galvanometer coil determines which scale shall be read for the true voltage.

QUERIES AND ANSWERS

Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied. The privilege of this department only extends to subscribers, and queries must be accompanied by name and address to secure attention.

What is the resistance of a standard telephone bell ringer? D. W. M.

The resistance of such an instrument varies, according to the maker, from 100 to 500 ohms.

I am running a 200-volt G. alternator, and the collector rings are cut very badly. It does no good to turn them down. What is the cause and remedy? W. B. P.

The cause is undoubtedly due to grit in the brushes themselves. Take your brushes off, clean them thoroughly and replace them. If you start with smooth collector rings they will probably remain so.

1. I have an electro-dynamometer which is wound with 150 turns of No. 30 copper wire, but is not sensitive enough. How can it be made more sensitive?

2. Do the lines of force increase in direct proportion to the ampere turns, if the circuit contains no iron?

1. Rewind the dynamometer with No. 36 copper wire.

2. Yes.

Will a gramme ring armature, wound and connected similar to Fig. 4, page 101, March number of the "American Electrician," operate in a field having any number of poles? A. P. K.

The armature referred to will operate in a field having any even number of poles, provided that there are as many brushes applied to the commutator as pole pieces and that alternate brushes are connected together.

Can I charge a storage battery from an arc circuit running 30 lamps at 8½ amperes? C. K. B.

Yes, provided that the charging rate of the battery is equal to or greater than 8½ amperes. The current that the battery absorbs may be varied by shunting a resistance around it. An ammeter placed in the battery circuit will show how much current is flowing, and this should be varied according to the regular methods in charging storage cells.

What is the resistance of the fields and armature of an ordinary 25-h.p. railway motor? Also the amount of resistance the controller cuts out at each move of the handle? C. W.

The resistance of such motors varies. The following are average figures: Fields, .84 ohms.; armature, .78 ohms. The resistance in the controller handles should be such that when the motor is stationary the current should not exceed 120 amperes, the volts being 500. It should be cut out in equal sections.

In a 3-phase converter, what is the cause of the e.m.f. current sometimes being displaced in phase? I. R. T.

If your field of the converter is weak, the back e.m.f. will be correspondingly small and the armature winding will act as an inductive resistance, which, of course, displaces the phase of current and e.m.f. By strengthening the field this displacement may be corrected and reduced to zero, or the phase may be displaced the other way, causing what is known as leading currents.

1. Will an X ray coil work on alternating currents?

2. Is an alternating current good for cautery purposes? S. J. S.

1. Yes. Omit the vibrator and send into the coil pulses in one direction only, cutting out the others by means of a suitable commutator, driven either by a synchronous motor or by direct connection to the alternator shaft.

2. In cauterizing a heated wire is used, and it is only necessary that the wire be sufficiently heated, therefore an alternating current will answer excellently.

Numerous bicycle lamps have been advertised which are fed by means of a little dynamo driven by the wheel and which keep constant voltage whatever the speed. What devices do they use to obtain this result?

There are a number of devices that can be used. The field magnet of the dynamo might be wound with a demagnetizing coil, which reduces the strength of the field as the speed increases, thus keeping the voltage constant. Again, the armature might have several coils which would successively be cut out by means of a suitable centrifugal governor as the speed increased. Both of these devices have been used.

1. How many feet, and what size of German silver wire will it take to build a small heater to boil coffee upon, to be used on a 52-volt circuit?

2. We have a 2-horse power motor which we wish to use as a dynamo. How many 16 power lights will it carry? L. A. V.

1. Your heater will require about 400 watts, and will take 8 amperes at 50 volts, which resistance should therefore be about 6 ohms. About No. 20 wire, Brown and Sharpe, should be used, and of this there will be required about 45 ft. This will generate heat enough, if properly applied, to boil a quart of water in 5 or 6 minutes.

2. About 20 lights.

I wish to charge a storage battery with a shunt wound dynamo by wind power. What instruments should I use so that the battery e.m.f. will not force current into the dynamo when the latter is runnng too slow? D. W. M.

Use a cut-out which is held closed by means of a magnet in shunt to the dynamo. When the e.m.f. of the dynamo falls the cut-out will fall open, and when it rises to the proper value it will close again. Such a device must be accurately adjusted, for it must fall open and must close at pressures the difference between which is about 20 per cent of the battery voltage. Often a series coil is added, so connected that a current from the battery to the dynamo will oppose the shunt coil.

I have an automatic switch, which opens and closes the circuit continuously under the action of an electromagnet, the current in which is automatically interrupted by suitable means. After running for an interval the magnet seems to lose its grip; it will not pull as hard and its range is notably less. If allowed to remain idle for a while, when used the magnet will regain its former strength. Does the iron of the magnet become exhausted after repeated use, and, if not, what is the cause of this? A. L. S.

The reason probably is that the wire in your magnet becomes heated, due to continuous working, and its resistance in consequence rises. While it is in this condition less current can enter the magnet with a given voltage, and its pull, of course, will be less. As soon as it becomes cool it regains its former strength.

1. What are the advantages of two-phase currents over single phase?

2. Describe the action of a rotary transformer. A. B. W.

1. The advantage of two-phase over single-phase currents lies in their ability to operate alternate-current motors. There is no satisfactory single-phase motor at the present time.

2. A rotary transformer armature is connected exactly as a direct-current armature and its field excitation is similar. At equidistant points on the winding there are led in 2, 4, 6, 8 or 12 leads, the number of leads being dependent on the number of poles and the number of phases. Alternate currents are led into the armature and distribute themselves through the wires in such a way as to drive the machine as a motor. The current distribution is uneven in the various wires on the surface of the armature, some of the wires serving to drive, some being driven; but the potential difference at the places where the direct-current brushes take off the current is practically constant, and equal to a function of the alternate-current voltage supply.

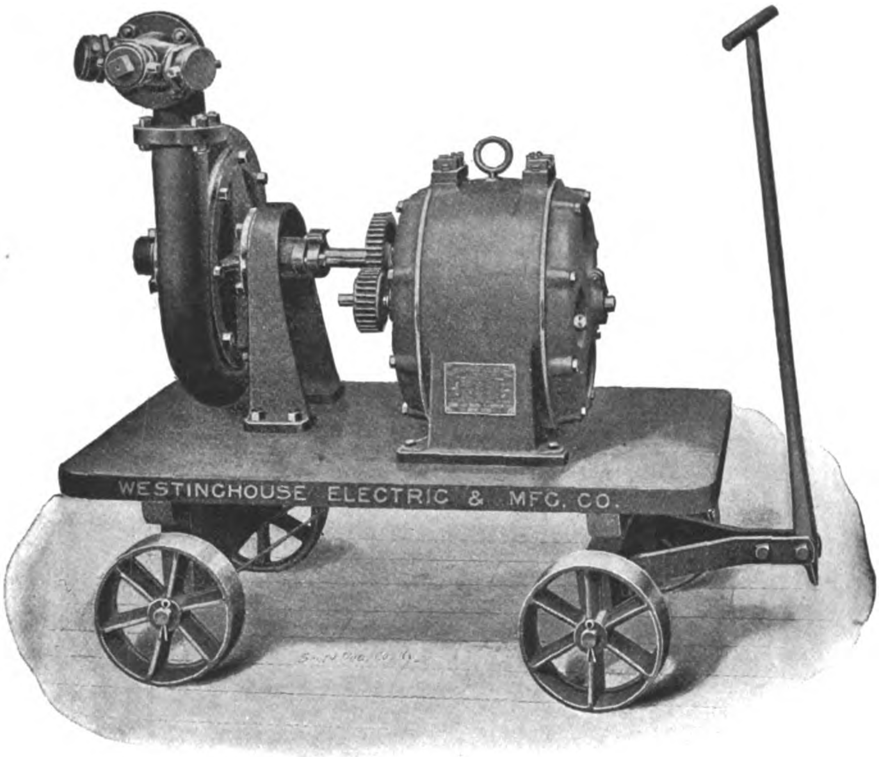
I have a T-H arc dynamo, which has suddenly ceased to work properly. On starting it will give eight amperes, the controller magnet seeming to work perfectly. After the machine has been running the current drops to five amperes, and it is not possible to get more. The controller magnet gives no sign of moving. The machine has been thoroughly tested with the magneto for short circuit. The connections appear to be tight and clean, and the speed is what it should be. H. A.

Lower the controller arm by hand and see if the current increases to nine amperes, as it should. If it does, the trouble is in the controller mechanism. If the controller magnet is all right, look at the wall controller. Make sure that the contacts on the wall controller are clean. It may close circuit apparently, but fail to shunt the machine solenoid and cause it to drop its plunger. If the controller is all right, it may be that the machine is overloaded; that there are too many lamps on the circuit; and that its voltage is therefore not sufficient to force nine amperes through them. The overload may be some fault in the line, or in some of the arc lamps. Frequently a dirty commutator, even, on an arc machine, will cut down its voltage capacity. On a Brush machine this has been known to reduce the voltage output 100 volts.

Apparatus and Appliances

A PORTABLE ELECTRIC PUMP.

An interesting application of electric power is illustrated in the accompanying cut, in the form of a portable electric pump. This combination has been designed to be used in the California Winery, of Sacramento, but it is one that may be applied to other purposes where fluids are similarly handled. The outfit consists of a Westinghouse alternating-current induction motor of 2 h.p.-capacity, direct-connected to a centrifugal pump. The machines are mounted upon a suitable truck, whereby they may be transferred from place to place for the purpose of pumping wine from one vat into another. Receptacles for the electrical connections are provided at convenient points throughout the building, to which the motor is connected by means of flexible cables. The power is taken from the circuits of the Central California Electric Company, and is generated at Newcastle, 30 miles distant from Sacramento. The simplicity of the pump and motor render them ideal in construction. The motor has neither commutator nor brushes; there is no connection between the revolving part and the electric circuit. It may be handled by the most inexperienced persons with perfect safety.



PORTABLE ELECTRIC PUMP.

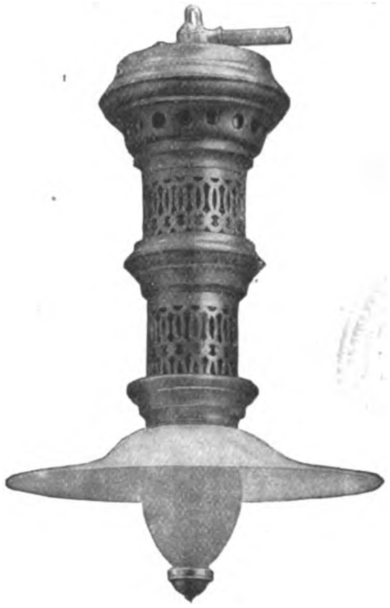
The centrifugal pump is adapted to handle liquids under most difficult conditions, even though they contain 20 to 40 per cent of solid matter and are at high temperature. Thus, it will be seen that the applicability of the device may be extended to the more arduous duty of pumping muddy accumulations in electric subway manholes, tannery liquids, dyes, bleaching solutions, vinegar and brine, liquids used in pickling, and is otherwise applicable to a multitude of services in the arts. The combination is the production of the Westinghouse Electric & Manufacturing Company, of Pittsburgh.

A MINIATURE ARC LAMP.

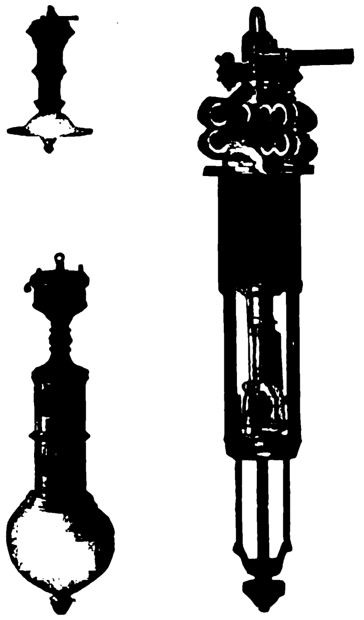
The inclosed arc lamp has been the cause of a considerable extension in the arc system of electric lighting, and the miniature arc lamp of the General Electric Company promises yet another advance in electric illumination. For interior use the objection to the arc lamp has been that the light has been too concentrated. With low ceiling rooms, such an intense light over-illuminates the parts directly beneath it, while the other localities of the room are left comparatively dark.

In the new lamp, herewith illustrated, the illuminating power and the current consumed are much less, so that several smaller lamps, which are not more expensive to operate than one large lamp, may be used to much greater advantage. It is of the single globe and reflector type, the light of the arc being thrown down from the polished surface of the reflector. This lamp was designed for 110-volt direct current circuits, and in view of the fact that it is frequently required to operate at higher or lower voltages it has been provided with adjustable resistance, which adapts it for any voltage from 100 to 120. The standard current required by this lamp is 2½ amperes, but a loop in the magnet coil permits an adjustment for 3 amperes. The potential at the arc is from 73 to 75 volts, and when adjusted for 2½ amperes, with a line voltage of 110, the energy at the terminals is 275 watts, and for 3 amperes the energy is 330 watts. The life of a trimming is from forty to forty-five hours with standard current and from thirty to forty hours with 3 amperes.

The mechanism of this lamp operates on the well-known General Electric carbon-feed principle. The carbon passes through a brass tube extending through the center of the magnet coil, and is fed by a double cam clutch operating directly upon it. Special attention has been given to the design of the holders and general arrangement of the frame to permit of rapid trimming. The principal dimensions of the miniature lamp are: Length over all, 18½ ins.; inclosing globe, top diameter, 2 ins.; maximum diameter, 3 ins.; porcelain shade, 4 ins.; weight, 9½ lbs. No outer globe is used. Each lamp is provided with a cut-out switch.



MINIATURE ARC LAMP.

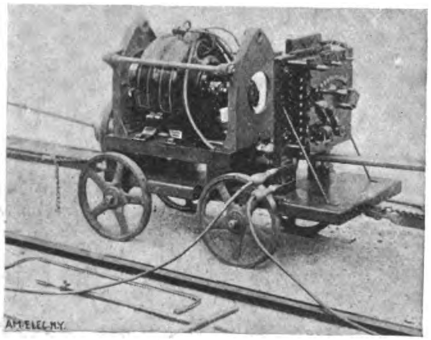


MECHANISM OF MINIATURE ARC LAMP.

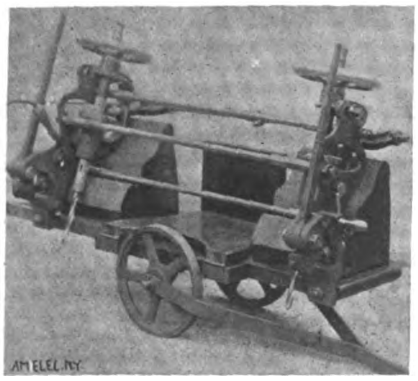
Several hundred of these lamps have been introduced among central stations within the past sixty days, and if increasing demand is a criterion they have been favorably received.

AN INGENIOUS DRILLING DEVICE.

In the accompanying illustration we show a portable electric drill, which is used by the Harrington Rail Bonding Company, of New York, for installing their diagonal bonds. This equipment consists of a 500-volt Lundell 3-h.p. motor and standard automatic starting box provided with an electro-magnetic release, mounted on a little truck. It receives its current from the overhead trolley through one lead and conducts it to the rail by the other. These leads are simple flexible wires tipped with handles carrying plugs which can be readily disconnected. This truck is connected with two other trucks by very long space bars sufficiently long to span a thirty-foot rail. On the other two trucks are mounted the drilling devices which are shown in Fig. 2. The motor is geared to a shaft beneath it, from which extend two telescope shafts with universal joints, which supply power to the two sets of drills. On each truck are mounted two drills provided with means of feeding by screw pressure. In this way four holes can be drilled at a time, which provides for two bonds. The bond used is what is known as the diagonal type, which connects with the rail at the junction between the lower flange and the web, where there is considerable metal, and where a hole so drilled at an angle will expose a considerable area of contact, more, indeed, than in any other part of the rail. The angle at which the drills are manipulated is such that it is only necessary to remove a single paving block to drill the hole, and a single row of paving blocks to install the bond. The drilled holes are accurately reamed to fit the conical terminals on the end of the bonds, which are then very tightly driven into place by means of a suitable tool. In this way the contact is sure, electrically and mechanically. By means of this and other ingenious devices the Harrington Rail Bonding Company can install their bonds with great expedition, and at the same time in a most thorough manner, and as the installation is a very large proportion of the cost of bonding, this should interest street railway managers.



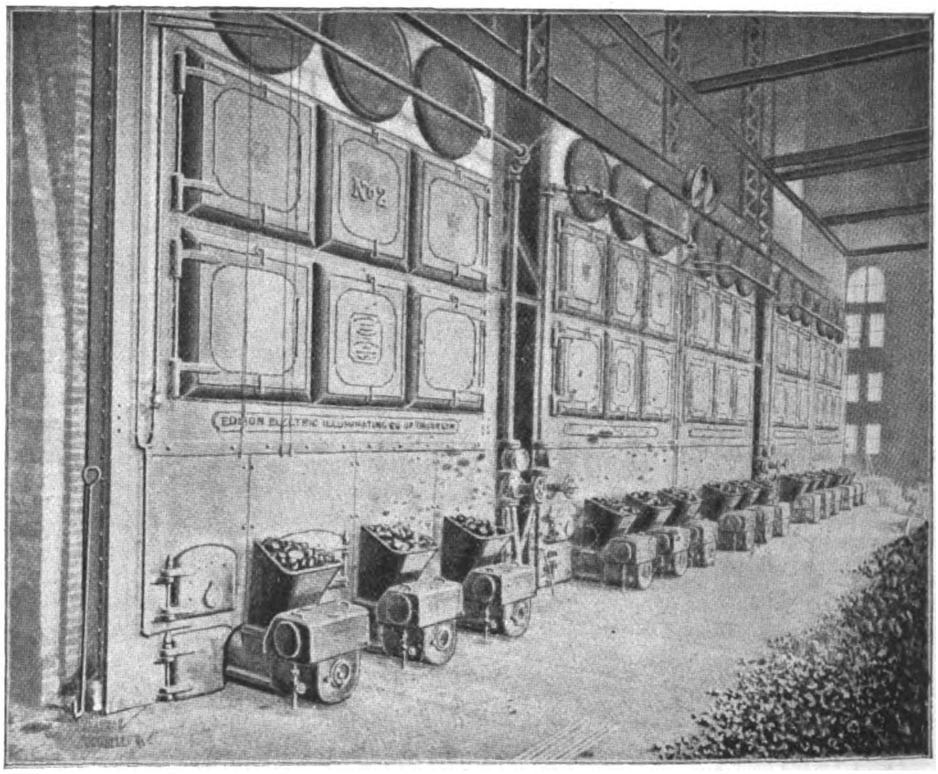
PORTABLE DRILLING MOTOR.



DRILL PRESS FOR PORTABLE MOTOR.

A MECHANICAL STOKER.

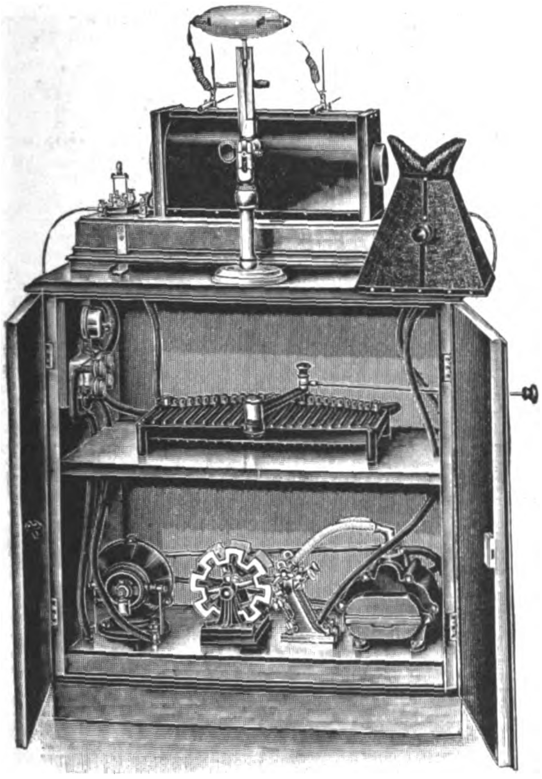
In the accompanying cut is shown an underfed mechanical stoker system in the boiler room of the Edison Electric Illuminating Company's station at Brooklyn, N. Y. This plant is to have an ultimate capacity of 60,000 h.p., but at the present time only one-fourth of the apparatus has been installed. The boiler room is 198 ft. x 46 ft. and is equipped with 500 h.p. boilers of the Cahall water tube type, each furnace being supplied with three stokers, independently driven. The slack coal used for fuel is carried from the dock by cars to storage bins, from which it is lifted to smaller bins just above the boiler floor. From these it is distributed through chutes to several conveyors, which carry it to the stokers. The chutes leading from the boiler house bin terminate in weighing apparatus, which registers the amount of coal that passes. Immediately beneath the coal hopper is a conveyor pipe which communicates with the coal magazine placed in the furnace. A screw conveyor, or worm, is placed in this pipe and extends the entire length of the magazine. The wind box is located beneath the conveyor pipe, and has an opening beneath the hopper through which the air supply for the furnace is forced. The other end of this air box opens into the air space between the outer casing and the magazine, the upper edge of which is surrounded by tuyeres, or openings for the discharge of air. Each stoker is entirely independent, being driven by a small steam motor located in front of and beneath the hopper. This motor has a simple recipracating piston which is connected so as to turn the conveyor shaft, which forces the coal into and through the magazine. The rate of feeding coal is controlled by the speed of the motor, which in turn is controlled by throttling the steam supply. The coal, after being fed into the hopper, is carried by the conveyor into the magazine, from both sides of which it overflows and spreads out upon the surface of the grates. The operation is continuous, and as the coal approaches the fire it is roasted and delivered as coke on the grates above, the gases which are thus released mingling with the fresh air entering through the tuyeres and becoming ignited. Every pound of coal fed into the hopper is subjected to this gas making process, and there is no loss of coal through grates by reason of the use of dead grates in the furnace in place of open grate bars. This method of igniting completely consumes all the combustible components of the coal, and the stacks are almost entirely smokeless. These stokers were manufactured and installed by the American Stoker Company of New York City.



A PLANT OF MECHANICAL STOKERS.

A HOSPITAL SHIP X-RAY OUTFIT.

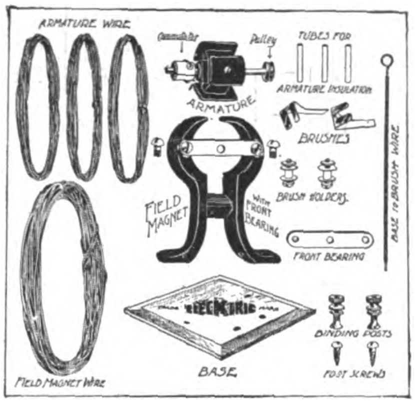
The U. S. Navy hospital ship "Solace" has been equipped with a portable cabinet X-ray outfit, which is herewith illustrated. The cabinet is made of quartered oak of massive construction and occupies a floor space of 2 ft. 8 ins. x 1 ft. 8 ins., and is provided with four wrought iron angles screwed on to its base, by which it can be rigidly fastened to the deck, to prevent damage in heavy weather. The coil is similarly mounted on top of the cabinet, to which it is secured with brass angles, and the base of the adjustable focus tube stand is similarly screwed to the top of the cabinet. The upright part of the stand has a wooden screw by which it is attached to the base, and which permits of its removal when that is desirable. A distinctive feature of the outfit is the absence of the vibrator on the induction coil, its place being taken by the instantaneous air break wheel device shown in the bottom of the cabinet. This consists of two toothed wheels mounted on the same shaft. The teeth make contact with two flat brushes, which bear upon the outer peripheries through which the current enters and leaves. These wheels are rotated at high speed by a small direct-current motor, which also runs a pressure blower. The air blast from this blower enters a bifurcated tube and is conducted to two flat nozzles immediately over the contact brushes. When the machine is set in operation by starting the motor, the primary of the induction coil is connected in series with the breaking device, the spark at the contact brushes is blown out by the air blast, very much shortening the time of breaking circuit and correspondingly increasing the rapidity of the demagnetization of the core. This very much augments the e.m.f. of the secondary coil. The controlling rheostat is shown on the upper shelf of the cabinet and is used to vary the current in the primary coil. The lever arm of the rheostat is connected to an extension rod so that it may be actuated from without. The main switch is situated on the left hand side of the cabinet near the top and the cutouts directly underneath. The enclosed arrangement of the apparatus is an advantage, as it is impossible for unauthorized persons to use the apparatus. The coil is protected by a polished oak cover, not shown, which entirely protects the apparatus when not in use. In cases where the patient is seriously wounded, and it is necessary for him to maintain a reclining position, the focus tube is attached to a portable holder, shown in Fig. 2. The holder is made of rubber, so that it can be handled easily and without fear of shock to the operator. Special heavily insulated wires are provided for connecting. In use it is placed underneath the cot or operating table, and the surgeon makes his examination by looking through the patient from above. The apparatus is portable and can be provided with heavy casters to enable its ready removal from place to place. It is connected with the source of power by an attachment plug and cord, which may be screwed into a convenient receptacle or socket. The construction of the apparatus is very thorough, and it is said to be very satisfactory. It is manufactured by the Edison Manufacturing Company, of New York City.



X-RAY OUTFIT.

MOTOR FOR AMATEURS.

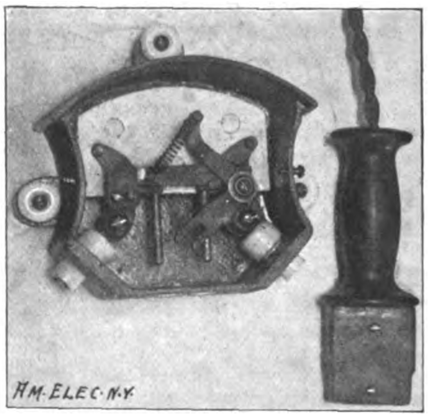
The Knapp Electric & Novelty Company of New York is manufacturing a small motor, intended for amateur use, which is sold complete for one dollar, and the parts of which are shown in the accompanying illustration. It consists of a three-pole armature, which will start from any position without assistance. It is claimed to be a considerable advance upon the motors usually sold for that low price. Many students and amateurs prefer to purchase and assemble the parts of small motors rather than to secure the complete machines, and the Knapp Company is prepared to fill all demands of this character. The company produces larger motors as well—namely, types B, C and D, which are designed for driving fans or light machinery. In the two larger types drum armatures are used, which render them suitable for continuous running on power circuits.



SMALL MOTOR PARTS.

A NEW ARC CUT-OUT.

The apparatus herewith illustrated has been especially designed to meet the demand for a cut-out that can be used on iron poles carrying high voltage currents. The construction is such that by manipulating the handle to which the cable is attached, the loop is first closed and then entirely disconnected. In cutting them in again the motion of the handle is reversed, which first short circuits the loop, and then opens it into the main current. The spring, which is attached to the top of the arm and to the outer end of knife blade is the operating force on the switch jaws, and when given a tension by the handle it moves the jaws with a quick motion entirely beyond the control of the operator. These cut-outs are finding great favor, both in central stations and for pole use in street lighting. They are manufactured by the Philadelphia Electrical & Manufacturing Company, of Philadelphia, Pa.



NEW ARC CUT-OUT.

THE LARGEST DYNAMO IN THE WORLD.

The rapid development of electric power for various purposes has made a demand for larger and larger units in the generating stations where this power is produced. A few years ago generators of 100 to 200-k.w. capacity were considered enormous machines. There soon appeared, however, direct-driven generators of 750 k.w., to be used in large railway plants in such cities as Chicago, Boston, St. Louis and Brooklyn. At the World's Fair, in 1893, the first 1500-k.w. generator made its appearance in the Intramural Railway station. This machine was then considered a monster. This unit was soon adopted for many of the large street railway stations, notably in Chicago and Boston, and finally machines of 1600 k.w. were placed in the Kent Avenue station in Brooklyn. Still later Louisville, Ky., purchased a 2200-k.w. generator. The Metropolitan Street Railway Company, of New York, has recently placed an order for a number of 2500-k.w. alternating machines, and but a few months ago the Boston Elevated Railway Company, which succeeded the West End Street Railway Company of that city, gave to the Walker Company, of Cleveland, the order for a 3000-k.w. machine.

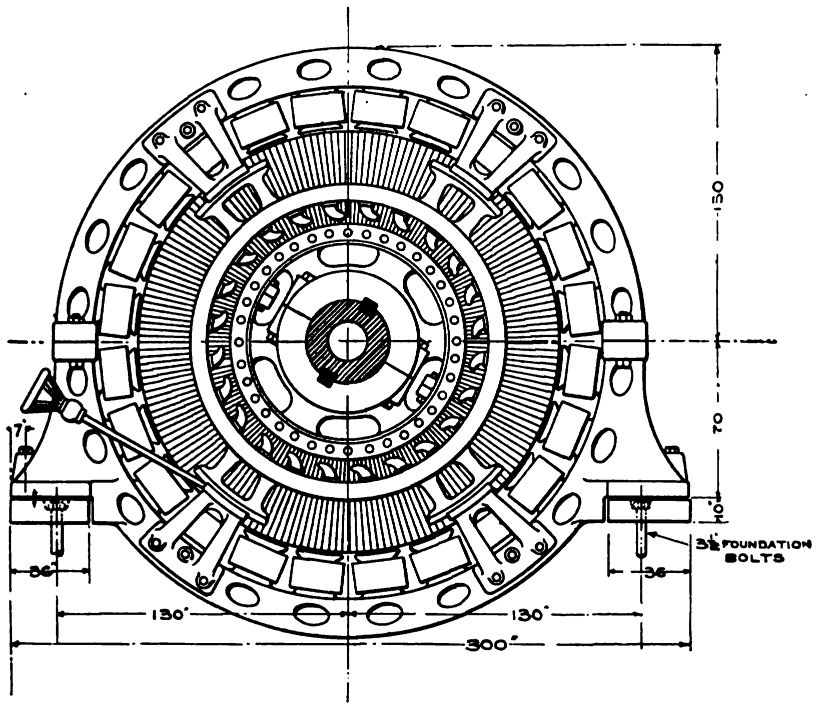
All of these large machines are made to run at the very slow speed of from 75 to 80 r.p.m. The alternating current machines built for the Cataract Construction Company at Niagara Falls have an output of 5000 h.p. each, while that ordered by the Boston Elevated Railway Company has an output of but 4000 h.p. Nevertheless the 4000-h.p. machine being built by the Walker Company is much larger than the alternators in use in the Niagara Falls power house, because the speed of the Boston machine is 75 r.p.m., while that of the Niagara machines is about 300 r.p.m.

If the Boston machine were run at the speed of the Niagara machines its output would be something over three times that of the latter, or about 16,000 h.p.

As the construction of this 4000-h.p. generator marks an era in the development of dynamo-electric machines, it may be interesting to electrical engineers and those using electrical apparatus, to know its dimensions and general design. We therefore devote some space to its illustration and description.

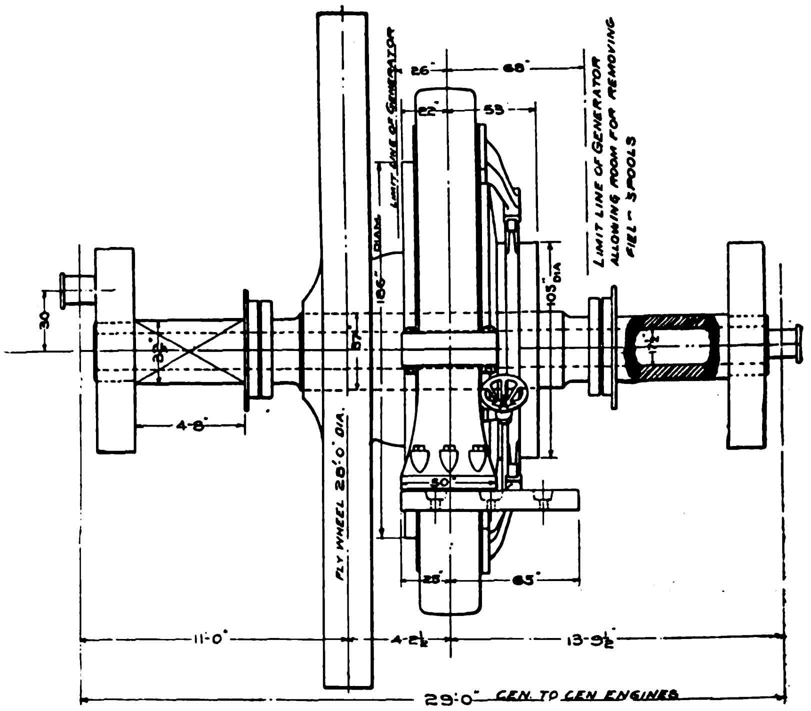
The total weight of the complete machine is 250,000 lbs. The frame is made of cast steel and is circular in form, the diameter over all being 21 ft. 7 ins. The weight of the frame alone, without the field magnet cores for magnet spools, is 50,000 lbs. To the inside of the magnetic ring or frame are bolted twenty-four laminated steel magnet cores or pole-pieces, the total weight of which is 30,000 lbs. The inside diameter of the bore of these pole-pieces, completed, is 15 ft. 6 ins.

The magnet cores are each provided with spools wound with shunt and series coils in the usual way. The pole shoes are arranged to hold the magnet spools in place and each core is bolted by four 3-in. bolts to the inner surface of the magnet frame. The magnet frame is divided in halves, on a horizontal plane, and is mounted upon the foundation plates in such a manner that the whole frame may be made to slide lengthwise of the engine shaft far enough to uncover the armature windings, or to allow the individual magnet cores or field spools to be removed without separating the magnet frame.



SIDE ELEVATION OF GENERATOR.

The armature spider of this machine is made in halves, like the hub of a fly wheel, to be bolted together upon the shaft of the engine after it reaches its destination. If it had been made in one piece no railway car could be found large enough to ship it from Cleveland to Boston. The armature hub weighs, complete, 40,000 lbs., and has an outside diameter before the laminations are in place of 13 ft. After the engine is upon its foundations in Boston this armature spider will be mounted upon the engine shaft, which is itself 37 ins. in diameter. The laminations which form the armature core, the total weight of which is 30,000 lbs., will then be built upon the periphery of the armature spider. The slotting in the armature laminations will register accurately, and provide, when completed, 594 slots. The insulation and windings will then be fitted into the slots and connected with the commutator.



END ELEVATION OF GENERATOR AND SHAFT.

The commutator itself is made up of 1188 bars and is 105 ins. in diameter. It is divided into halves for the purpose of shipment and ease of handling, and will be placed upon an extension of the armature hub after the latter is secured to the engine shaft.

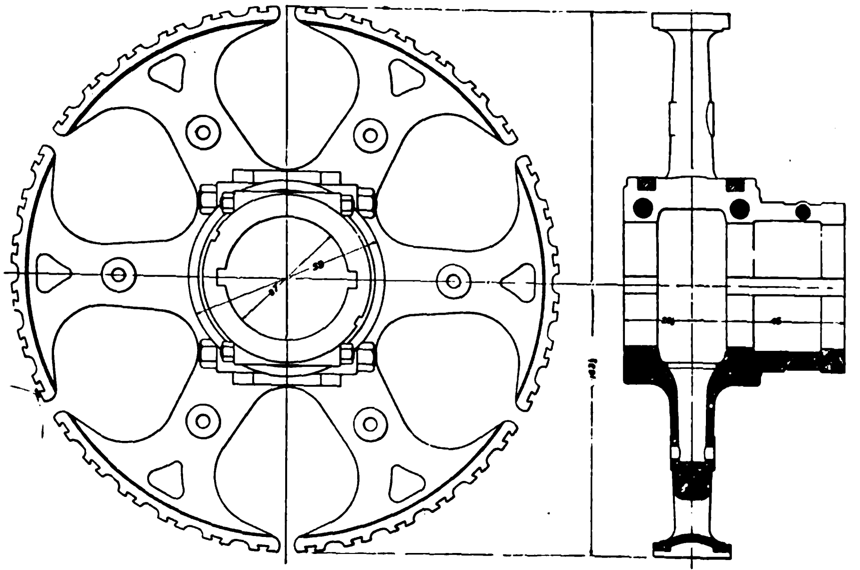
The fly wheel of the engine will be bolted directly to the armature hub near its periphery, in order that the regulating force of the wheel shall not be transmitted wholly through the shaft of the engine. This will relieve the armature shaft and its keys from strain to which they would otherwise be subjected.

The machine has been most carefully designed and an unusually large factor of safety provided for every part subjected to mechanical or electrical strain. Because of this the machine will be able to take twice its normal load for short periods of time without injury, and to carry a 50 per cent overload for several hours.

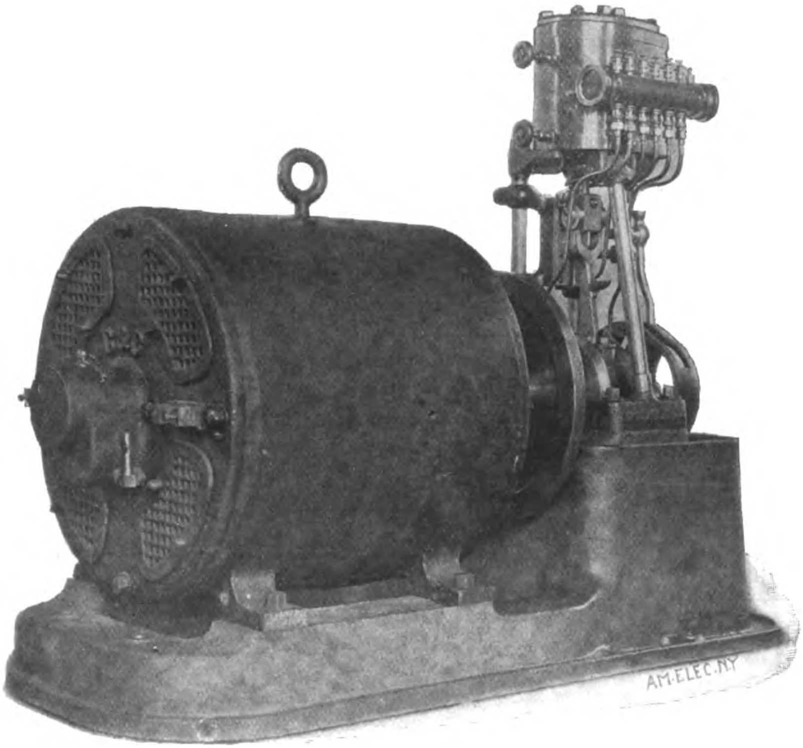
The greatest care has been taken to secure from the generator a higher percentage of efficiency than has thus far been attained in units of large size.

A MARINE GENERATING SET.

In the accompanying illustration is shown a 3-k.w. C & C ironclad dynamo direct-connected to a Forbes engine. This generating set has been recently installed in one of the vessels of the Boston Towboat Company for lighting purposes. The outfit is claimed to be an ideal type for marine use, as it is very light and its ironclad construction renders it impervious to moisture, important considerations in electric machinery for installation on small crafts which often encounter rough weather. These sets are supplied in various capacities ranging from 2½ to 15 k.w. In the larger sizes the dynamos are direct-connected to the Case vertical engines, and two of these units are now being built for the United States Government. These units are very compact, they are mounted on a single sub-base and provided with self-oiling bearings, and are otherwise constructed so as to require a minimum of attention.



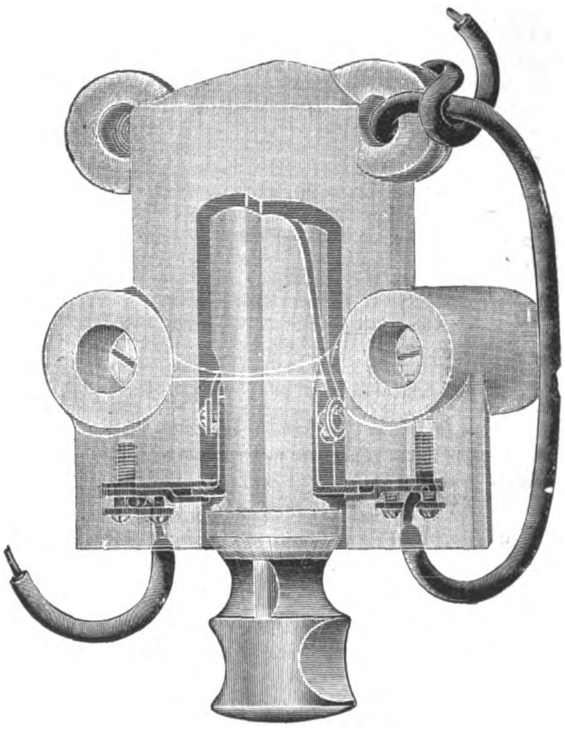
SIDE AND END ELEVATION OF ARMATURE SPIDER.



A MARINE GENERATING SET.

A CONVENIENT HIGH VOLTAGE FUSE BOX.

The accompanying illustration shows a convenient and substantial junction box and motor cut-out. It is built entirely of porcelain and contains an ample fuse chamber. It will accommodate a 5-in. fuse. The fuse is bent around a plug which is thrust into the socket provided for it, and connected into the electrical circuit by means of a quarter turn. The plug can be removed and safely replaced. It is fastened to its support by lag screws or wood screws, which are furnished with the cut-out. I is very conveniently adapted for making proper wire connections, and especially recommended for 500-volt motor and for transformer service. The utility of the device is apparent at once on inspecting the cut, and its simplicity and low price have found it many friends among those who do consruction work. Messrs. Pass & Seymour, of Syracuse, who manufacture this article, find the demand for it very brisk. It is particularly well adapted for primary circuits working at pressures as high as 2200 volts.



HIGH VOLTAGE FUSE BOX.

NEW BOOKS.

The Electro-dvnamics. The Direct Current Motor. By Charles Ashley Carus Wilson, M. A. Longmans, Green & Company. 298 pages, 71 illustrations. Price, $1.75.

This book is a contribution to dynamo design. It sets forward the author's methods in concise style, and frequently illustrates by practical example. Like most dynamo designers, the author has methods of his own which he uses in preference to others. The aim of the book is particularly to discuss direct-current motor design. The writer has taken for granted a certain acquaintance with the use and design of motors, but as the book is intended to have a general service to engineers, unexplained technicalities have been avoided as far as possible. In addition to the instruction in dynamo design which the book contains there is also a great deal of valuable data, the outcome of the practical experience of engineers.

Electrical Testing for Telegraph Engineers. By J. Alton Young. 249 pages, 91 illustrations. E. Van Nostrand & Company. Price, $4.00.

This book was prepared with a view to supply the want felt by submarine cable electricians, and is devoted exclusively to their work. In carrying this out, however, the subject of overland line testing has necessarily been included as a part of the study; the same theory applies to both, the difference being merely a practical one and consisting simply in the fact that the refined measurements necessary in cable testing have been largely dispensed with in aerial line testing.

The localization of faults has been very fully investigated, including the different degrees in which the various methods are affected by the presence of a second fault, or general leakage. The reader is presumed to possess a slight prior acquaintance with electrical science and to understand elementary mathematics. Although the book is written with the idea that the student is cognizant of electrical matters to some extent, yet wherever there seems to be a doubt in the matter he is given the benefit thereof, and the apparatus or theory employed in the method of testing is described or explained. Aside from the reputation which its author's signature affords, it has been reviewed before publication by other prominent electricians, and should be very accurate and reliable.

THE "PRACTICAL ENGINEER" POCKET BOOK FOR 1898. Manchester: Technical Publishing Company, Limited. 374 pages, illustrated. Price, 1s. 6d.

The ninth edition of this excellent steam engineer's handbook (compiled annually in the office of the *Practical Engineer*) contains some new matter on the boiler and engine, and in the electrical section. The latter section now comprises 75 pages—mostly matter of direct practical value.

PERSONALS.

MR. MORGAN BROOKS of Minneapolis has been appointed to the professorship of electrical engineering at the University of Nebraska, which is located at Lincoln. This position was vacated by the resignation of Prof. R. B. Owens. Mr. Brooks is well qualified for the work, being a graduate of Brown University and of Stevens Institute. Mr. Brooks is president of the Electrical Engineering Company of Minneapolis, which office he will retain.

MR. F. E. DRAKE has been appointed electrical adviser to Mr. Ferdinand Peck, the Commissioner-General of the United States to the Paris Exposition of 1900. Mr. Drake has had a very extensive experience in electrical matters, and his appointment to this position will be of great advantage to the American exhibitors and to the Commission. He began his connection with electrical interests as a railroad telegraph operator when but 14 years of age. After several years in the operating service, he was transferred to the civil engineering department, and served in several capacities, including that of assistant division engineer. Since 1890 he has been directly connected with the manufacturing industries, having acted as manager of the Standard Electric Company, a concern which played a most important part in the lighting of the World's Columbian Exposition, and in 1896 he formed a partnership with W. D. Ball, of Chicago, under the name of W. D. Ball & Co., electrical and mechanical engineers. This connection he severed in the early part of 1897 to accept the position as assistant to the manager of the Walker Company, where his former varied experience in electrical and mechanical matters has been of great service.

TRADE PUBLICATIONS.

THE BURTON ELECTRIC SMELTING COMPANY, of Boston, Mass., has issued a catalogue which will be of great interest to central station managers. It comprises a complete description of the numerous varieties of forges and smelting machines that it manufactures. The encouragement of the use of electricity for purposes of this nature is a very satisfactory solution of the day load problem in central stations.

"HELPS IN BRAZING."—The Dixon Crucible Company of Jersey City, N. J., has published a little pamphlet with this heading. It especially treats of the process of brazing by the dipping method, or "liquid brazing," as it is called. The brazing crucible is described, together with instruction and caution in regard to its use. Instructions are given how to build and set the necessary furnace, time required for brazing, etc. This pamphlet is of interest to all who do brazing. It is sent free of charge.

THE ELECTRIC STORAGE BATTERY COMPANY, Philadelphia, in Circular No. 44, describes the installation of chloride accumulators in the Chicago Edison plant. The battery has a capacity of 22,400 ampere hours, an 8-hour rate, and is able to discharge 11,000 amperes for about 1¼ hours. Central stations are rapidly beginning to realize the fact that the storage battery has been commercial for a considerable period, and is a most valuable auxiliary, both as a regulator and as a means of solving the pertinent day load problem.

THE INTERNATIONAL CORRESPONDENCE SCHOOLS of Scranton, Pa., are mailing a little pamphlet describing their methods of instruction, which are illustrated by practical examples in numerous cases. They bring out the fact that any industrious person who can read and write, can, by careful study, become an electrical engineer, and that correspondence instruction is an immense advantage in his task of securing an education. The fees of the various courses of instruction are given on the last page of the pamphlet. The school has also issued a booklet containing a synopsis of its instruction papers on telephony by Kempster B. Miller, the well-known expert.

THE AMERICAN SCHOOL OF CORRESPONDENCE of Boston, Mass., offers an electrical engineering course, which is carefully supervised by electrical experts, in close touch with the developments in the science. The instruction is graded and thoroughly practical and scientific, and is intended to give to electrical students and engineers a complete training. The students' work is carefully inspected by well known electrical experts. Among the gentlemen connected with the school is Mr. Charles Thorn, chief of the Quadruplex Department of the Western Union Telephone Company. The school is chartered by the Commonwealth of Massachusetts, and is an educational institution, and not a money making enterprise, therefore the tuition fee is placed within the reach of all wage earners. The school has been warmly indorsed by leading educators and engineers throughout the country.

AN INTERESTING ADDITION to Westinghouse trade literature is entitled "Electric Street Railway History," in which the Westinghouse Electric & Manufacturing Company's many types of street railway motor are reviewed and illustrated, beginning with the No. 1 Bipolar type, and coming down to modern practice. Special attention is called to the No. 3 motor, which contains most of the modern features in modern street railway motor practice, viz., single reduction gears, salient four-pole field, slotted drum armature, machine-wound armature coils, insulated before being placed on the core, and the two circuit armature winding. Throughout the book the company frequently calls attention to features which are now modern motor practice, and put themselves on record as adopting them at such early dates that it would be difficult to dispute their prior claim to these improvements. Beside the motor description, which is profusely illustrated by elegant half tones, the subject of generators is taken up, and the Westinghouse engine and belted type machines are illustrated and described. Following the printed matter are views of the Westinghouse works and of large plants that the company has installed. The book is tastefully gotten up, and is interesting reading matter.

BUSINESS NEWS.

"THE SCIENTIFIC MACHINIST" of Cleveland has recently purchased "The Engineer" of New York, a journal seventeen years old whch is devoted to steam engineering. "The Scientific Machinist" and "Engineer" will be combined and published hereafter under the name of the latter.

THE CENTRAL ELECTRIC COMPANY of Chicago states that it is headquarters for all the mica products, including mica, mica segments, micanite segments, micanite cloth, empire cloth and M. I. C. compounds. These goods in all the various forms and types are carried in Chicago stock, and can be supplied immediately.

THE CUTLER-HAMMER MANUFACTURING COMPANY of Chicago reports that its sales for August were larger than any preceding month in the history of the company, which is considered evidence of an increase in the business of the motor manufacturers, to whom most of the company's goods are sold. The company states that it is preparing for a large fall business.

THE WARREN-MEDBERY COMPANY, Sandy Hill, N. Y., manufacturers of inductor alternators, reports a very large increase in sales. They have made recent sales in the following places: Two in Canada, two in New York, one in San Francisco, one in Manitoba, three in Pennsylvania, one in New Jersey, two in New England, three in Texas, one in South Carolina, and one in Tennessee.

THE TRIUMPH ELECTRIC COMPANY, Cincinnati, Ohio, states that in a suit brought against it by the Westinghouse Electric & Manufacturing Company, for infringement of patent, U. S. Judge Clark, of the Southern District of Ohio, rendered a decision in favor of the Triumph Company, and declared void the patent on which the Westinghouse Company based its claims.

THE S. & H. ELECTRICAL COMPANY, of Skaneateles, N. Y., has issued a number of circulars describing its small hand and power dynamos. These machines are simple and low priced. Most of them are intended for experimental work, but the larger sizes are said to be excellent for plating or for running very small electric light plants in machine shops and similar places where power is to be had.

THE LUDEWIG-THURBER MANUFACTURING COMPANY, Pittsburgh, Pa., has removed to more commodious quarters, and has a fully equipped shop and skilled labor for electrical repair work, field and armature winding, refilling of commutators, etc. The company is also conducting a trade in second-hand machinery. Mr. J. Ludewig is the president of the company; Mr. Wm. Ludewig, vice-president; Mr. J. B. McGinley, general manager, and Mr. G. P. Thurber, secretary and treasurer.

NEW ELECTRIC RAILWAY COMPANY INCORPORATED.—The Safety Third Rail Electric Company of New York, capital $1,000,000, has been incorporated to manufacture and deal in electrical appliances and properties of every description in New York City. The directors are Emerson McMillan, Emerson McMillan, Jr., W. F. Douthirt, C. T. Schoville, R. H. Beach, William M. Keepers, David F. Halsted, John McLeod Murphy and Louis Steckler of New York City.

THE OTTO GAS ENGINE WORKS, Philadelphia, report an excellent business among recent large electric light installations. Among these may be mentioned a plant at Stockton, Cal., with two 120-h.p. engines, and one of equal capacity at Sisterville, W. Va. The Danbury & Bethel Gas Company is still using three 100-h.p. Otto engines installed for it over six years ago, and the Otto Gas Engine Works are now erecting a plant in the western part of New York, which will have two 120-h.p. engines and a 60-h.p. engine, the power being used for railway service and street lighting.

EUGENE MUNSELL & COMPANY, of New York and Chicago, importers and wholesale dealers in mica, report a very gratifying demand for their India mica. They carry a large stock at both their warehouses in New York and Chicago, and are, therefore, in a position to execute orders promptly. This concern was one of the pioneers in the preparation of mica for electrical purposes, having sold to the Edison Company at a time when it was engaged in the manufacture of electrical apparatus to such an extent that it required but two armature winders, dating back in the 80's.

THE TRIUMPH ELECTRIC COMPANY of Cincinnati, Ohio, calls attention to the fact that the Giant See-Saw, one of the unique amusement devices at the Omaha Exposition, is operated by a special motor of its construction. This see-saw employs an immense girder pivoted in the center and built entirely of steel. At either end of the girder is carried a car, and as the tower on which it is pivoted is 100 ft. high the maximum elevation of the car is about 200 ft. At night two large Rushmore searchlights, operated on either end of the beam, add greatly to its imposing appearance.

THE K. & W. COMPANY, of Pittsfield, Mass., reports a fine trade in its supplies, consisting of the Hardy Incandescent Lamp, K. & W. dynamo brushes, hangerboards, spark arresters, and commutator compound. This compound is said to be more cleanly to handle and easier to apply than any other form of lubricant, and the repeated orders the company has received for it demonstrate that the claim that it prevents sparking and cutting is well founded. The company also states that the Hardy Incandescent Lamp is finding great favor where high efficiency and sustained candle power are desired.

THE M. C. BULLOCK MANUFACTURING COMPANY of Chicago reports the past month a very busy one. It has received many orders for diamond drill supplies from the North and Northwest, and has also filled a number of orders in entirely new fields. Though foreign orders have been generally withdrawn during the war, it has received from abroad orders for four refrigerator plants, and promise of others, and for two central valve engines for direct coupling to dynamos. The company is preparing its works and force to meet an anticipated heavy demands for the various lines it manufactures.

THE C & C ELECTRIC COMPANY, of New York, wishes to call attention to the fact that it manufactures the form of brush holder known as the reaction type, not as licensees but by proprietary right. It has been inaccurately stated in the technical press that this company has used this holder as licensee, under a patent issued to Mr. R. N. Baylis. The principle involved in the reaction brush holder was discovered and patented by Mr. Baylis, who, however, was at the time chief engineer of the C & C Electric Company, and was materially assisted by that company in making the experiments necessary to the developing and perfecting of the device.

THE ELECTRIC APPLIANCE COMPANY of Chicago has taken the general Western agency of the Utility Shade Company, manufacturers of the Utility shades in paper and celluloid. These shades are something quite new in the electrical line, and are destined to find a very large field, as they possess a great many points of merit, among which may be mentioned the following: They are very light in weight, neat in appearance and practically indestructible. They require no separate shade holder, and are low in price. They are made in a number of different shades and colors. The Electric Appliance Company has issued a special catalogue of these goods, which they will be pleased to send to the trade upon application.

THE ROCKWOOD MANUFACTURING COMPANY, Indianapolis, Ind., reports a constantly increasing demand for its paper pulleys, and is arranging for an increase in factory facilities in order to enable it to keep abreast of its orders. Among other large shipments made recently were 130 pulleys to the Munger Improved Cotton Machine Company, Dallas, Tex.; 74 to the General Electric Company, 17 to the Eddy Electric Manufacturing Company, 14 to the Westinghouse Electric & Manufacturing Company, 9 to the Fort Wayne Electric Corporation, 7 to the Thresher Electric Company, Dayton, Ohio; 11 to the Pueblo Electric Street Railway Company, Pueblo, Col.; 6 to the Commercial Electric Company, Indianapolis, Ind., and innumerable smaller orders for one and two pulleys each.

THE ELECTRICAL TRADE will be interested to learn of the recent arrangements made by the Western Electric Company to exclusively represent the Stanley Electric Manufacturing Company in the following territory: Michigan, Ohio, Kentucky, Tennessee, Alabama, Mississippi, Indiana, Illinois, Wisconsin, Minnesota, Iowa, Missouri, Arkansas, Louisiana, Texas, Indian Territory, Oklahoma, Kansas, Nebraska, South Dakota, North Dakota, Montana, Wyoming, Colorado and New Mexico. A complete stock of transformers and other appliances to insure prompt shipment will be carried in Chicago. Correspondence is solicited from intending purchasers of alternating apparatus for any purpose, single phase, polyphase, power transmission, transformers, switchboards, instruments, etc., and all orders and inquiries will have immediate attention.

THE NATIONAL ASSOCIATION OF STATIONARY ENGINEERS held its seventeenth annual convention at Pittsburgh, Pa., from Sept. 5 to 10. The Westinghouse Machine Company tendered the association a banquet, which was served in the testing room of its factory. The big assembly hall was cleared of its engines, and a banquet table for over 600 was spread. A tasteful menu was distributed to the guests. Following the banquet were many appropriate toasts, Mr. George H. Brown of the Philadelphia Gas Company acting as toastmaster. Sept. 7 was set aside as Westinghouse day, and the programme which was circulated will convey at once to the non-attendants at the convention an idea of the thoroughness with which the Westinghouse Machine Company undertook the task of entertaining its guests. Such entertainments as these tendered by the large manufacturing firms tend to put the makers and users of the apparatus in closer touch, and to enhance personal regard.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING COMPANY of Pittsburgh, Pa., has just executed a contract for the Snoqualmie Falls Electric Power Company. The power station is located at Snoqualmie Falls, Washington, forty-five miles from Tacoma and thirty-one miles from Seattle, to which places current is transmitted and then utilized by Westinghouse motors. The contract involves the building and delivery of four three-phase rotary armature generators having an aggregate capacity of 600 k.w., which are to be direct connected to water wheels, and two 75 k.w. kodak exciter dynamos, also to be direct connected to water wheels. In addition the contract called for high and low potential switchboards for the various stations and sub-stations, involving seventy-six marble panels, with all necessary instruments. There will also be installed 10,875 k.w. capacity in high tension oil insulated static transformers, together with rotary transformers of a total output of 2700 k.w. and six type "C" motors developing 1600 h.p. Adequate lightning protection at both ends of the line is provided. The line potential will be 25,000 volts, and the current will be carried over bare aluminum wires to substations, where step down transformers will sufficiently reduce the voltage for safe transmission within the corporate limits of the two cities.

JOHN A. ROEBLING'S SONS COMPANY, of Trenton, N. J., has recently completed a large addition to its electrical wire plant. This firm has been for years a large manufacturer of electric wires of all kinds, and underground and submarine cables, but has not heretofore made its rubber insulating compounds in its own factory, that work having been delegated to the Crescent Company. The addition to the wire plant will enable the Roebling Company to enter this particular field of manufacture and produce a wire that is wholly "Roebling." The insulating plant is contained in a large three-story brick building, about 60 ft. x 160 ft., situated conveniently near the other buildings of the company, which are used for the manufacture of wires. Railway tracks pass immediately in front of the building, affording ample shipping facilities. The equipment consists of the latest and best machinery for the different manipulations of the rubber, and includes appliances for making all varieties of rubber insulation for conductors, including house wires and cables, wires and conductors for street cars, feeders and taps, and heavy lead incased cables for high tension currents. The machinery is mounted on several floors of the building, and ample storage and drying room is provided. Skilled operatives and experienced foremen have been engaged to maintain the high reputation of the Roebling Company. The factory is now in full operation, and prepared to furnish everything in the line of rubber insulated wires or cables.

THE HAZELTON BOILER COMPANY of New York, sole proprietors and manufacturers of the Hazelton or Porcupine Boiler, has orders from the following concerns: 500 h.p. for the Morris County Electric Company, Morristown, N. J.; Brookline Gas Light Company, Boston, Mass., 750 h.p.; American Gas Company, Philadelphia, Pa., 2.0 h.p., for its plant at Port Chester, Westchester County, N. Y., in which there are already three boilers of the same type; Newark Gas Company, Newark, N. J., 300 h.p. (fifth boiler same type); Olcott Falls Company, paper manufacturers, Wilder, Vt., 800 h.p. (third order); Rochester Gas & Electric Company, Rochester, N. Y., 500 h.p. (tenth order), mak-4500 h.p. of these boilers in that very complete plant. The Rochester company has also recently purchased a 500-h.p. boiler from Syracuse, N. Y., Heat & Power Company, which will shortly be moved to Rochester, and erected in its electrical department. The Oakland Gas, Light & Heat Company, Oakland, Cal., has purchased a new steel jacket for a 200-h.p. Hazelton Boiler erected about ten years ago, and now to be equipped with all the latest improvements; Wagner Palace Car Company, Buffalo, N. Y., steel jackets for five 150-h.p. Hazelton Boilers, which were erected in circular brick settings about eight years ago. The Gilbert & Bennett Manufacturing Company, Georgetown, Conn., has purchased steel furnace casings for two 500-h.p. Hazelton Boilers in their western plant at Wireton, Ill.; Messrs. Bartlett, Hayward & Company, engineers and founders, Baltimore, Md., 100 h.p. for a gas works plant at Jamaica, L. I.; Goodyear's India Rubber Glove Manufacturing Company, Naugatuck, Conn., 300 h.p. (third order); South Middlesex Street Railway Company, South Framingham, Mass., 150 h.p. (third order); Messrs. Wm. P. Youngs & Bros., planing mill, New York City, 100 h.p.; and Messrs. Zahn & Bowly, 50 h.p. for their factory at Rutherford, N. J. All of these boilers are to be equipped with the new brick-lined steel jacket, with square furnace and square-grate surface lately introduced by the Hazelton Boiler Company.

CONVENTION NOTES.

THE CENTRAL ELECTRIC COMPANY, of Chicago, was represented by its president, George A. McKinlock.

THE EDDY ELECTRIC MANUFACTURING COMPANY, of Windsor, Conn., was represented by Mr. G. M. Angier.

THE OKONITE COMPANY, LTD., of New York, sent Mr. Romaine Mace to look after its interests at the convention.

THE CENTRAL ELECTRIC COMPANY, of Chicago, was ably represented by its well-known president, Mr. Geo. A. McKinlock.

THE H. B. CAMP COMPANY, Aultman, Ohio, sent Mr. A. L. Daniels to the convention to look after the interests of its well-known conduits.

THE JOHN A. ROEBLING'S SONS COMPANY, of Trenton, N. J., had its interests looked after by Messrs. A. M. Whitaker, G. W. Swan and R. W. Welch.

THE PHILLIPS INSULATED WIRE COMPANY, Pawtucket, R. I.—Mr. Henry C. Adams, Jr., secretary of the company, looked after its interests at the convention.

THE JOHN STEPHENSON COMPANY, LTD., New York, exhibited a model of the car bodies it is supplying to the Metropolitan Street Railway Company, of New York.

THE PARTRIDGE CARBON COMPANY, Sandusky, Ohio.—Mr. James S. Speer, secretary of the company, interested many of the delegates in the merits of the Partridge self-lubricating motor brushes.

THE CHICAGO RHEOSTAT COMPANY, through E. R. Harding, showed one of its motor rheostats, which attracted considerable attention from those convention goers who were also interested in electric lighting.

THE "KERITE" WIRES AND CABLES of W. R. Brixey, New York, had their merits ably expounded to convention delegates by the company's secretary, Mr. Geo. F. Porter, secretary of the National Electric Light Association.

THE GARTON-DANIELS COMPANY, of Keokuk, Ia., showed lightning arresters through its agents, Elmer P. Morris, Pettingell-Andrews Company and the Ohio Brass Company. The secretary of the company, J. V. E. Titus, from the home office, was present.

THE STANDARD PAINT COMPANY, of New York, manufacturers of the well-known P. and B. paint and insulation, distributed at the convention as a souvenir of the occasion a very tasteful pocketbook, which was one of the most popular gifts presented during convention week.

THE JOSEPH DIXON CRUCIBLE COMPANY, of Jersey City, was represented by Messrs. Baird, Haasis and St. John, who distributed souvenir pencils to all visitors, and exhibited samples of Dixon's wood grease for gears, silica graphite paint for trucks, and graphited track grease for curves.

GEORGE A. PARMENTER & COMPANY, of Cambridgeport, Mass., exhibited a fender, wheel guards and track cleaners. The Parmenter feeder is in use in a number of cities throughout the country, and it is stated that not a single serious accident has been caused by cars equipped with this device.

THE CAHALL SALES DEPARTMENT, of Pittsburgh, Pa., exhibited a flowed steel header for boilers and a swinging manhole plate. This company has installed a large number of boilers in electric railway and light stations, and much interest was expressed by the delegates in its exhibit.

THE CUTTER ELECTRICAL & MANUFACTURING COMPANY, Philadelphia, was represented at the convention by its president, Mr. H. B. Cutter, who stated that his company had just completed some 4000-ampere double pole circuit breakers for the Western Electric Company, of New York.

THE ELECTRIC STORAGE BATTERY COMPANY was represented in large force, although it made no regular exhibit. Those present in its interests were F. H. Clark, of Chicago; F. J. Stone, of Boston; Charles Blizard, of New York; J. R. Williams, of Philadelphia, and J. L. Woodbridge, of Boston.

THE KEYSTONE ELECTRICAL INSTRUMENT COMPANY, of Philadelphia, had on exhibition a railroad switchboard, including a generator and eight feeder panels, equipped with Keystone instruments. Mr. J. F. Stevens, president of the company, also showed on another board various different styles of his instruments.

THE JANDUS ELECTRIC COMPANY, of Cleveland, with the Creaghead Engineering Company, of Cincinnati, displayed several well-known types of its lamps, including five in series, for street railway circuits, 110 volt, and alternating circuits. The company claims that it has more lamps in use on street railways than any other lamp concern.

THE STERLING SUPPLY & MANUFACTURING COMPANY, of New York, was represented by John H. Carson, president; F. A. Morrell and L. P. Nelson, and its exhibit was largely visited during the progress of the convention. The company has engaged extensively in the manufacture of street railway supplies, and each branch of its business was fully represented.

AMERICAN ELECTRICAL WORKS, Providence, R. I.—Mr. W. J. Watson, the company's New England representative, looked after its interests at the convention. The following officials of the company were also present on various occasions: General Manager Eugene F. Phillips, President Frank N. Phillips, Secretary C. R. Remington, Jr., Treasurer Waggensell, New York Agent P. C. Ackerman, and Chicago Agent Frank E. Donohoe.

THE WAGNER ELECTRIC MANUFACTURING COMPANY, of St. Louis, Mo., made an extensive display of switchboard instruments for street railway work; also carbon brushes, switches and standard transformers. A number of large photographs were shown illustrating several of the more prominent installations which the Wagner Company has made. E. H. Abadie, manager of sales, of St. Louis, and H. M. Nay, of Boston, represented the company at the convention.

THE STANDARD UNDERGROUND CABLE COMPANY, of Pittsburgh, Pa., had a very pleasant booth where samples of the company's products were exhibited. These included samples of various kinds of cables and insulated wire, rubber, paper and fibre insulated railway feeder cables, aerial weather-proof feeder cables, etc. The interests of the company were cared for by F. A. Rinehart, treasurer; G. L. Wiley, of New York, and T. E. Hughes, of Philadelphia.

ADAM COOK'S SONS, of New York, displayed sample jars filled with Albany grease and Albany electric motor compound. The Albany lubricants are now in use in a large majority of the street railway power stations throughout the country, and have won for themselves an enviable reputation. The electric motor compound especially is giving great satisfaction wherever it is used. Adam Cook and John Engle, of New York, and M. V. Peavey, agent for New England and Canada, were in attendance.

THE CROSBY STEAM GAGE & VALVE Company, of Boston, Mass., had on exhibition a number of Crosby steam indicators, valves, gages, recorders, etc., also a very large three chime steam whistle. The instruments and appliances manufactured by the Crosby Steam Gage & Valve Company are standard in many of the largest power houses in the country, and in workmanship and accuracy they are all that can be desired. This exhibit was in charge of Robert Pirie, Charles M. Gibbs and S. G. Reed.

THE SHAWMUT FUSE WIRE COMPANY, Boston, Mass., had a very complete exhibit of its copper terminal fuses, suitable for railway work, and also showed a new specialty in the shape of an inclosed fuse, the inclosure being a fibre tube, with asbestos ends, an air space in the center, and a magnesia powder packing to absorb the vaporized lead. This fuse was constructed under the Cartwright patents. The company also showed some of its new quick-break switches. The exhibit was under the direction of Mr. H. P. Moore.

THE BILLINGS & SPENCER COMPANY, of Hartford, Conn., exhibited a number of sample boards of commutator segments, also several samples of overhead material. There was also shown what is thought to be one of the smallest and also one of the largest commutator segments ever made. The large segment shown weighed about 25 lbs., and was constructed for a Westinghouse motor at Niagara Falls. Several drop forgings, made of soft steel for Lundell motors, were also exhibited. W. B. Post and H. E. Billings had charge of this exhibit.

L. A. CHASE & COMPANY, of Boston, Mass., selling agents for the Sanford Plush Mills, made an attractive display of different grades and patterns of plush for upholstering car seats, etc. These plushes are in very general use, being employed almost exclusively by the Pullman Palace Car Company and the Wagner Palace Car Company, and other large car manufacturing establishments. A sample of cattle hair carpet for car floors was also shown in connection with this exhibit. The Sanford Mills were represented by Frank B. Hopewell and George Goodall.

ELMER P. MORRIS, of New York, had, as usual, one of the most extensive exhibits. He exhibited Forest City and Harrington rail bonds, for both of which he is agent. Another interesting portion of the exhibit was that devoted to the Sterling Railroad inclosed arc lamps. In the exhibit of the Keystone Electrical Instrument Company, for which Mr. Morris is also agent, a set of switchboard instruments of different types were shown. These were mounted on a model of a railway switchboard, made up of feeder and generator panels, and equipped with the Keystone instruments.

THE ALBERT & J. M. ANDERSON MANUFACTURING COMPANY of Boston, Mass., was represented at the convention by Albert Anderson and C. B. Pear. This company's regular line of overhead material was shown, including the West End type of hangers, insulators, ears, crossovers, etc. A recent addition has been made to the extensive line of Anderson material in the way of an insulated crossing which is made of steel. This device is in use on the lines of the Union Traction Company, of Philadelphia, and is designed to be extremely light. The Albert & J. M. Anderson Company distributed a very serviceable notebook as a souvenir.

THE DEARBORN DRUG & CHEMICAL WORKS, of Chicago, were represented by Robert F. Carr, who gave away some handsome paper cutters, match boxes and some of the neatest advertising pamphlets seen at the Convention. This company is doing a very successful business with the large manufacturing interests and street railways, treating boiler feed waters for scale formation, corrosion, pitting and the general troubles experienced with boilers. Their laboratories in Chicago are the most completely equipped on the continent, and their lubricating oil department has within the past few years grown to very large proportions.

THE GOLD STREET CAR HEATING COMPANY, of New York, had an attractive location in one corner of the building, and made an interesting exhibit of its different types of electric heaters, the basis of which consisted of the Gold improved support. The company showed its three degree panel heater, large and small sizes, and an assortment of Gold standard heaters for cross seat and longitudinal seat cars, also a number of other types and ornamental heaters for room heating purposes. As a souvenir, the company presented a leather-bound memorandum pocketbook. The interests of the company were well cared for by E. E. Gold, John E. Ward, H. E. Beach, E. H. Mossgrove and Fred D. Weston.

THE SAFETY THIRD RAIL ELECTRIC COMPANY, of New York, displayed in a 21 ft. x 39 ft. space, in the lower exhibition room, a complete miniature working model of its system. Current was conveyed to a one-sixth size, completely equipped car operating over about 150 ft. of track, with all sorts of curves and grades, and the working of the miniature system seemed to be in every way successful. The space allotted to the company was almost constantly occupied by interested spectators, among whom railroad men were very much in evidence. The company was represented by John McLeod Murphy, inventor of the system; E. V. Ballard, who built the model road shown, and by Gustavus Kahn, William Devoe and John J. Cokely. It is stated that a controlling interest in the stock of this company has been purchased by Emerson McMillin & Co., of New York, who will soon construct a full working system of several miles in length as a demonstration of its safety and efficiency.

THE PECKHAM TRUCK COMPANY, of New York, had probably the most elaborate exhibit of any company at the convention. It consisted of the entire system of Peckham single and double trucks. Some of the double trucks shown by Mr. Peckham this year were new, and the fact that he is now in a position to supply double trucks for any character of service made the exhibit particularly interesting, and both styles were very carefully examined by the attending managers. Mr. Peckham does not believe that the same truck is suitable for all classes of work, but believes in selecting for use the character of truck best adapted to the service. For this reason he has completed his line of double trucks shown a year ago by several other forms, so that he is now in a position to supply railway managers with a light or heavy truck, a flexible or a swing bolster, a short wheel base or a long wheel base truck, and an ordinary double, or maximum traction, truck. As a souvenir, Mr. Peckham presented delegates with an exceedingly tasteful pocket memorandum and card case in white leather, and no other souvenir was in greater demand. He also presented a series of very tasteful catalogues descriptive of his apparatus.

THE WALKER COMPANY, of Cleveland, made a very complete display of electric railway apparatus. About the only exception to railway apparatus shown was an exhibit of Walker inclosed arc 100-hour lamps. The railway apparatus shown comprised the following: A three-panel four-circuit switchboard of 1200 amp. capacity; a case of armature parts showing details of construction of armatures and commutator; a stand of armatures showing completely and partially wound armatures, armatures with commutator attached, and plain core; two "33-S" railway motors, 20 h.p., one open and one closed, with controller showing solenoid blow-out; two "15-L" railway motors, 75 h. p. each, with "S-11" controllers, solenoid blow-out and double h.p. equipment; underground conduit—a complete equipment for 60 ft. of track shown, with feeder hatch connections and regular Walker construction. Upon the track was mounted a Peckham truck with a pair of "5-L" Walker motors. The company was very well represented, officials and agents being in attendance from New York City, Cleveland, Philadelphia, Baltimore, Pittsburgh, Buffalo and Boston. Among those were Professor Short, H. McL. Harding, C. F. Black, superintendent of the New Haven factory; H. G. Issertel, M. D. Law, F. W. Sawyer, H. B. Gay, R. A. Byrns, J. Holt Gates, A. T. Moore, W. G. Bain, J. N. Dodd and John D. Moore.

THE BIBBER-WHITE COMPANY, of Boston, Mass., had a very popular exhibit located near the center of the hall in a corner space. The two back walls were fitted up with a complete line of samples, representing goods of this company's manufacture, and also "Cutter" circuit breakers, Forest City bonds and segments, New Haven fare registers, Hope double and single pole quick break switches, for which the Bibber-White Company is agent. Line material was shown manufactured in several different patterns. The company is also placing on the market a corrugated steel trolley pole. The souvenir which was given away to the trade was an aluminum pen-holder, which represented the company's seamless cold-drawn corrugated trolley pole. The souvenir was complete with harp and wheel. The latter was of rubber, to be used as an ink eraser. The company also had on exhibition a phonograph machine, which attracted a great deal of attention, and was heard all over the hall. A large illuminated sign over the booth was also attractive. The two side railings to the space were made of cross-arms complete, with braces, pins and glass insulators. On each side of the entrance was an octagonal pole, and on each pole were attached the different styles of bracket arms manufactured by the company. The exhibit was in charge of H. W. Smith, the manager of the company's railway department. He was assisted by Charles E. Bibber, president; E. L. Brown, treasurer; Thomas H. Bibber, general manager; David W. Dunn, Charles F. White and Chauncey Hight.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING COMPANY furnished one of the most curious and interesting exhibit features which has ever been seen at a convention. The company's space was at the very entrance to the association's meeting room, and attention would first be called to it by a sharp and constantly increasing crackling sound of an odd character. There would then be seen at one side of the exhibit a large board, constructed of thick, heavy glass and bearing on the front, in metal letters, the words, "The Name of Westinghouse is a Guarantee." Those who pushed their investigation far enough found the back of the glass board was covered with large sheets of metal foil. Over in one corner was a rotary converter, which obtained current from the Boston Electric Company's lines at 500 volts direct, and changed it into a 380-volt alternating current, which fed two transformers, whose effect was to still further reduce the voltage from 380 to 200. This 200-volt alternating current thence passed into a high tension transformer, from which a 60,000-volt alternating current issued. The wires from the high tension terminals of this transformer passed one to the metal letters on the board, and the other to the tin foil at the back. On starting the rotary transformer the voltage between the front and back of the glass board would be raised to such a point as to cause "lightning discharges" to pass over the surface of the glass between the letters and the tin foil, and as the voltage was increased these flashes would become almost terrific in their intensity, while the smell of ozone would penetrate to quite a distance from the board. Elsewhere in the Westinghouse Company's exhibition space were found a number of features interesting to railway managers, including a complete set of apparatus for operating power station switchboards by compressed air. There were also exhibited the Westinghouse No. 49 (35-h.p.) railway motor, open, and with a separate armature, the Westinghouse 38 B (50-

IN GOING TO ST. PAUL AND MINNEAPOLIS

The wise traveler selects the Chicago, Milwaukee & St. Paul Railway.
Why?
It is the best road between Chicago and the Twin Cities.
It has the most perfect track.
Its equipment is the finest.
Its sleeping cars are palaces.
Its dining car service is equal to the best hotels.
Its electric-lighted trains are steam-heated.
Its general excellence has no equal.
It is patronized by the best people.
It is the favorite route for ladies and children as well as for men.
It is the most popular road west of Chicago.
For further information, apply to nearest ticket agent or address Geo. H. Heafford, General Passenger Agent, 410 Old Colony Building, Chicago, Ill.

I-T-E
CIRCUIT BREAKERS
are not only the best, they are also the cheapest, no matter how cheap others are sold, because they do not get out of order and they do the work for which they were designed. Besides, they protect apparatus much more expensive than themselves, and second-class protection usually is no protection at all.

h.p.) railway motor with parallel side bar suspension, the Westinghouse 12 A (25-h.p.) railway motor, several controllers, a tank lightning arrester, a Wurts lightning arrester, a street car choke coil, a street car main switch, the new Westinghouse street car canopy circuit breaker, the K-11-A diverter, a new Westinghouse fuse block, a switchboard operating the exhibition plant, a rotary transformer switchboard, an alternating current motor, and an exciter connected with the rotary transformer. There were also a number of electric fans in operation in the exhibit, including the new Westinghouse direct current fans just put upon the market. A large variety of the Sawyer-Man electric lamps was also shown, together with a number of detail appliances of greater and less interest. The company had on exhibition in the basement two No. 49 Westinghouse motors mounted on a Peckham truck. The representatives of the Westinghouse Company present at the convention were fourteen in number, as follows: Frank H. Taylor, general sales manager; L. E. Imlay, W. M. Alexander, N. W. Storer, H. D. Murdock, Maurice Coster, of Chicago; Charles A. Bragg, manager Philadelphia office; Calvert Townley, manager Boston office; R. S. Brown, H. M. Southgate, of Boston; H. C. Farnsworth, manager Boston office Sawyer-Man Lamp Company; J. R. Gordon, of Atlanta; C. C. Frenyear, of Buffalo, and Thomas Ahearn, of Ahearn & Soper, Ottawa, Canada.

THE GENERAL ELECTRIC COMPANY did not consider it necessary to make any special exhibit of its apparatus, as all the great dynamos now used to furnish current to drive the street cars of Boston were built in its works; many of the motors were of its manufacture, and, with few exceptions, every switchboard and controller. The company, therefore, decided to show in the convention hall not so much great facilities as the world-wide use of its apparatus. Consequently, a huge globe representing the earth was built up of papier maché upon a framework of wood, and placed at the end of the hall, where nothing intervened between the floor and the roof. This globe rested upon a black pedestal picked out with gold. The continents and oceans were plainly depicted by the scenic artist of the Tremont Theatre. The globe was built in fifty-four distinct sections to a scale of 312 miles to 12 in.; was 25 ft. 2 ins. in diameter, and weighed 3 tons. The pedestal was 16 ft. in diameter, and the globe was placed in exactly the position occupied by the earth itself in the solar system, the north pole being indicated by an incandescent lamp of 100 c.p. Two thousand seven hundred square yards of papier maché, in 9 layers of 300 sq. yds. each were employed in the construction of the globe, the building of which occupied just two months. Dotted over the globe, thickly in the United States, less thickly in Europe, and sparsely in the less civilized countries, were small incandescent lamps of different colors, each lamp representing the location of some city in which the General Electric Company has some typical installation; 400 lamps were employed. Each country was indicated by its national flag, and the Stars and Stripes fluttered not only over the United States, but also over Cuba, Porto Rico and the Sandwich and Philippine Islands. The interior of the globe was richly upholstered, the decorative color scheme being worked out in pink and green. The air was kept cool by revolving electric fans, and the lighting of the interior was all indirect. An aurora borealis effect was secured over the north pole of the globe, both inside and out, by groups of small orange red lamps, and the southern polar light was represented by a row of lamps concealed between the globe and the pedestal. The course of the sun around the globe was marked by a small track occupying the plane of the elliptic, upon which once in a minute traveled a miniature trolley car, labeled "world circuit." The globe will remain in place during the Mechanics' Fair, and will then be taken down and sent to Paris, where it will occupy a prominent position in the Electrical Building at the Exposition of 1900. The space behind the globe was set out with comfortable chairs for the benefit of visitors. Here also was set up a model plant to show the practical working of the Thomson car recording meter, consisting of a G. E. 800 motor, an R-11 controller and the necessary resistances, the car meter, fuse and a form M circuit breaker. Behind this plant was an instrument board on which were exhibited the latest types of astatic volt and ampere meters, inclined coil switchboard and portable instruments, motor vehicle meter, and edgewise ammeter, all grouped around a type M station recording wattmeter reading to 8000 amps. Let into the pedestal of the globe were two spaces fitted with shelves, on which were the most recent types of overhead material, circuit breakers, lightning arresters, etc. The entire convention hall was lighted from G. E. inclosed arc lamps. Headquarters were established in the Hotel Brunswick, where, in the Venetian room, several albums containing photographs showing the wide diversity of General Electric work and a fine collection of medals and diplomas were set on the tables. W. J. Clark, general manager of the railway department, had the interests of the General Electric Company in his care.

New Wabash Fast Train East.

"The Continental Limited," a new fast train on the Wabash, now leaves Chicago daily at 12:02 noon for Detroit, Niagara Falls, Buffalo, New York and Boston. This train arrives Buffalo next morning at 5 o'clock, New York at 3:30 and Boston at 5:50 P. M. the next day—only one night on the road. The service including a dining car, is first-class in all respects. Do not fail to ask for a ticket via the "Continental Limited" on your next trip East.

Other trains for the East via the Wabash leave at 8:50 A. M., 3:15 P. M., and 11:30 at night.

TELEPHONE MEN

will be glad to know that a COMPREHENSIVE TREATISE ON TELEPHONY has at last been produced.

American Telephone Practice,

By KEMPSTER B. MILLER, M. E.,

is now in press and will be ready for distribution in a short time.

This work will include all of the matter published during the last two years in the AMERICAN ELECTRICIAN under the same title, revised and brought strictly UP TO DATE, together with a large amount of matter never before published.

Mr. Miller's experience as telephone expert in the United States Patent Office, and his subsequent experience as chief electrician and superintendent of one of the largest telephone manufacturing companies in this country, has enabled him to write on the subject from its practical as well as its theoretical side.

It will cover the PRACTICAL FEATURES OF TELEPHONE WORK with an attention to detail not found in any other book.

BACK NUMBERS WANTED

We desire to obtain the following back numbers of the AMERICAN ELECTRICIAN. In exchange for such clean copies as may be sent us we will extend your subscription the number of months specified in the following list. The postage must be prepaid (at the rate of one cent for each four ounces.)

May,	1896	2	months' subscription.
June,	"	2	" "
August,	"	2	" "
January,	1897	2	" "
February,	"	2	" "
March,	"	2	" "
April	"	1	" "
June,		2	" "
August,	"	1	" "
September,	"	1	" "
October,	"	1	" "
November,	"	2	" "
December,	"	2	" "
JANUARY.	1898	3	" "
February,	"	1	" "

If you have any of the above copies which you do not wish to keep and will forward them to us with a letter informing us that you have sent them, we will send you a receipt and extend your subscription the correct number of months. Be sure to put your name on the package containing the papers.

THE RECOGNIZED AUTHORITY ON WIRING AND CONSTRUCTION.

"Standard Wiring"

For ELECTRIC LIGHT and POWER.

By H. C. CUSHING, Jr., A. I. E. E.
Electrical Inspector Fire Underwriters' Tariff Association of New York.

The Universally adopted NATIONAL ELECTRIC CODE Explained and Illustrated in this year's edition of the Hand-Book.

Adopted by the Fire Underwriters of the United States.

It contains every table, formula and rule necessary for all systems of outside and inside wiring, together with thirty illustrations of the newest and safest methods for the installation of Pole Lines, Dynamos, Motors, Switchboards, Transformers, etc., etc, as required by insurance inspectors. *It settles disputes* and, if referred to during the process of the electrical construction, *will prevent disputes* and consequent expense for alterations.

Flexible Leather Cover (pocket size), $1.00.

Sent postpaid, upon receipt of price, by

THE AMERICAN ELECTRICIAN CO., Havemeyer Bldg., NEW YORK CITY.

This work is an authority on electric light and power wiring from the Fire Underwriters' standpoint, and is kept strictly up to date.

OVER 16 000 COPIES IN USE.

Experimental Science.

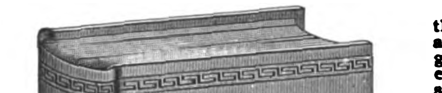
By GEO. M. HOPKINS.

Seventeenth Edition, Revised and Enlarged. 340 Pages. 800 Illustrations. Elegantly Bound in Cloth.

Price, by mail, postpaid, $4.00; Half Morocco, $5.00.

This is a book full of interest and value for all who desire to obtain a practical knowledge of physics.

What is said of "Experimental Science."



"The electrical chapters of the book are notably good, and the practical instruction given for building simple electrical machinery may be safely carried out by those—not a few—who like to make their own apparatus."—*Electrical World.*

"All teachers of science are aware that real knowledge is acquired best by the student making experiments for himself, and any one who points out how those experiments may be easily made is doing excellent work."—*English Mechanic and World of Science.*

"The work bears the stamp of a writer who writes nothing but with certainty of action and result, and of a teacher who imparts scientific information in an attractive and fascinating manner."—*American Engineer.*

"The portion of the book devoted to dynamic electricity covers over one hundred pages, and is extremely interesting and valuable."—*Brooklyn Standard-Union.*

Mr. Thomas A. Edison says: "The practical character of the physical apparatus, the clearness of the descriptive matter, and its entire freedom from mathematics, give the work a value in my mind superior to any other work on elementary physics of which I am aware."

Prof. D. W. Hering, University of the City of New York, says: "I know of no work that is at the same time so popular in style and so scientific in character."

Prof. W. J. Rolfe, of Cambridgeport, Mass., writes: "The book is by far the best thing of the kind I have seen, and I can commend it most cordially and emphatically."

Hundreds of cordial recommendations from eminent Professors and Scientific men.

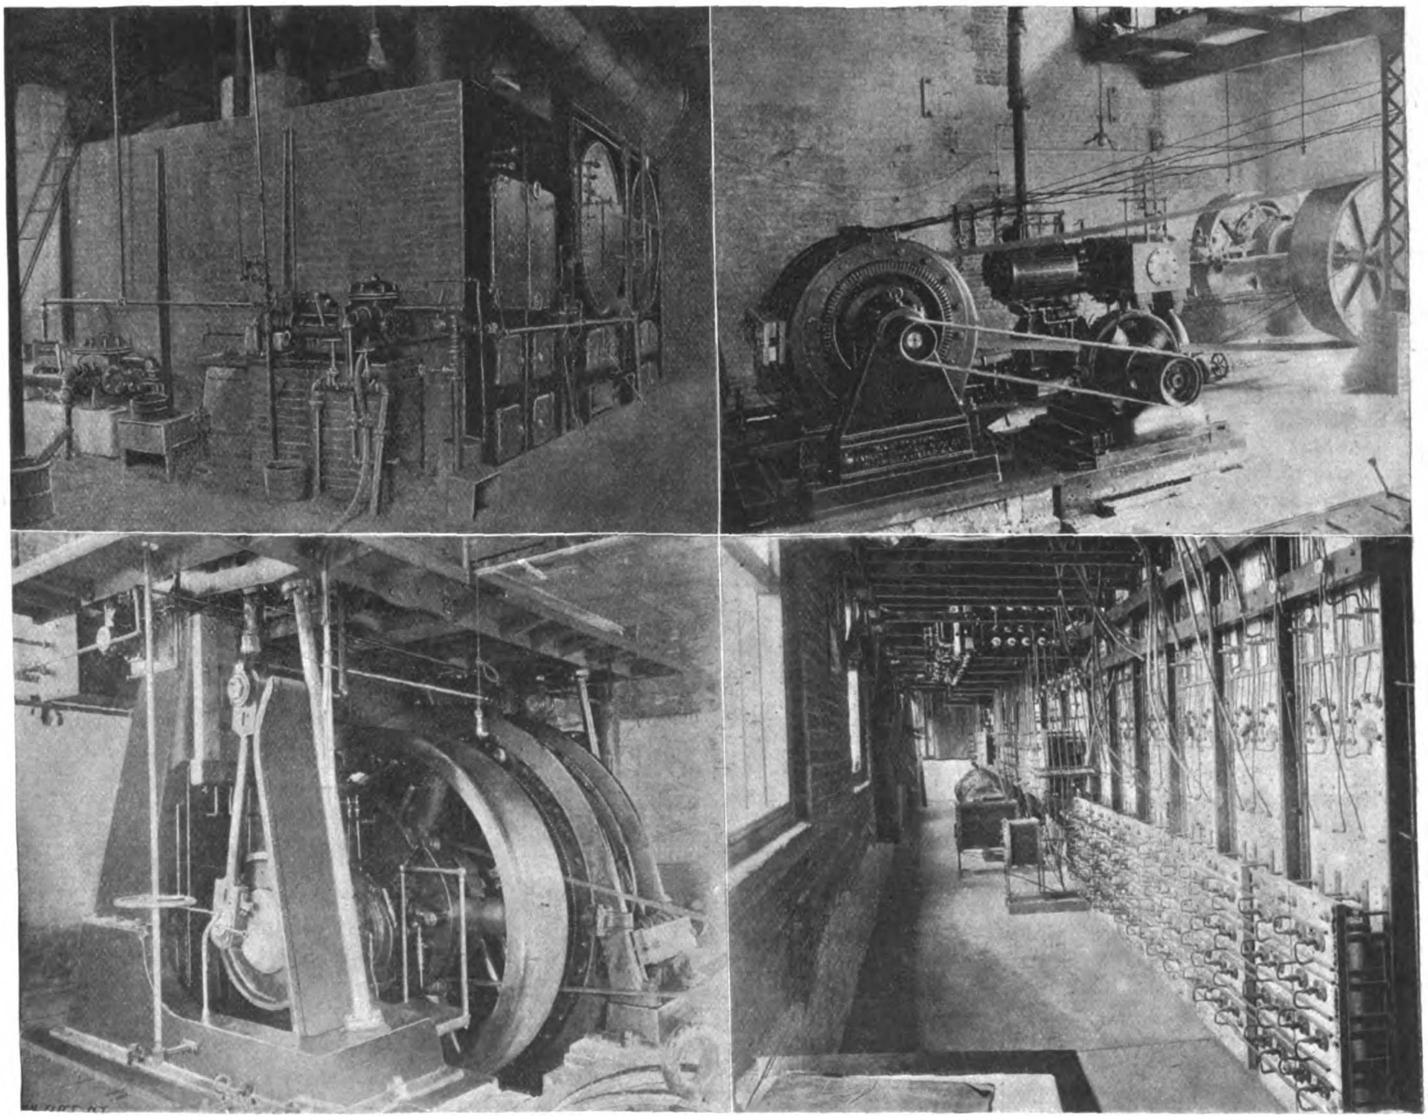
Vol. X. New York, November, 1898. No. 11.

POLYPHASE PRACTICE IN SMALL STATIONS AT THE PLANT OF THE HACKENSACK GAS AND ELECTRIC COMPANY.

The plant of the Hackensack Gas & Electric Company, Hackensack, N. J., has recently undergone a complete remodeling and is now equipped with the highest grade of modern machinery. It is an excellent example of a small multiphase installation, and a description of its equipment and its service will be of interest to managers of small plants similarly situated.



FIGS. 1, 2, 3 AND 4.

BOILER ROOM.
LARGE GENERATOR.

BELTED GENERATOR.
BACK OF SWITCHBOARD.

The original electric service was remarkable chiefly for its variety. No less than three different currents were supplied for purposes of power and light. The equipment represented the gradual accumulation which a slowly increasing business always begets. There were two 30-k.w. belted General Electric direct-current generators and two 12½-k.w. machines of the same type. These were four pole dynamos and supplied current to points within a short distance of the station. For long distance service two 60-k.w. General Electric alternators operated at 125 cycles per second were used.

An Edison Sperry series arc machine with a capacity of thirty-two 9½ ampere lamps supplied arc lights. This motley collection of machinery was driven by a large countershaft, which in turn was belted to several high speed engines. The use

Eng Soc, Library

of so many small units of such widely diversified types cannot be attributed entirely to the engineering judgment of the former managers of the station, for a few years ago the station was totally destroyed by fire, and the necessity of immediately restoring the service prevented the installation of a plant laid out on the lines of best economy by compelling the erection of one which would soonest be fit for service.

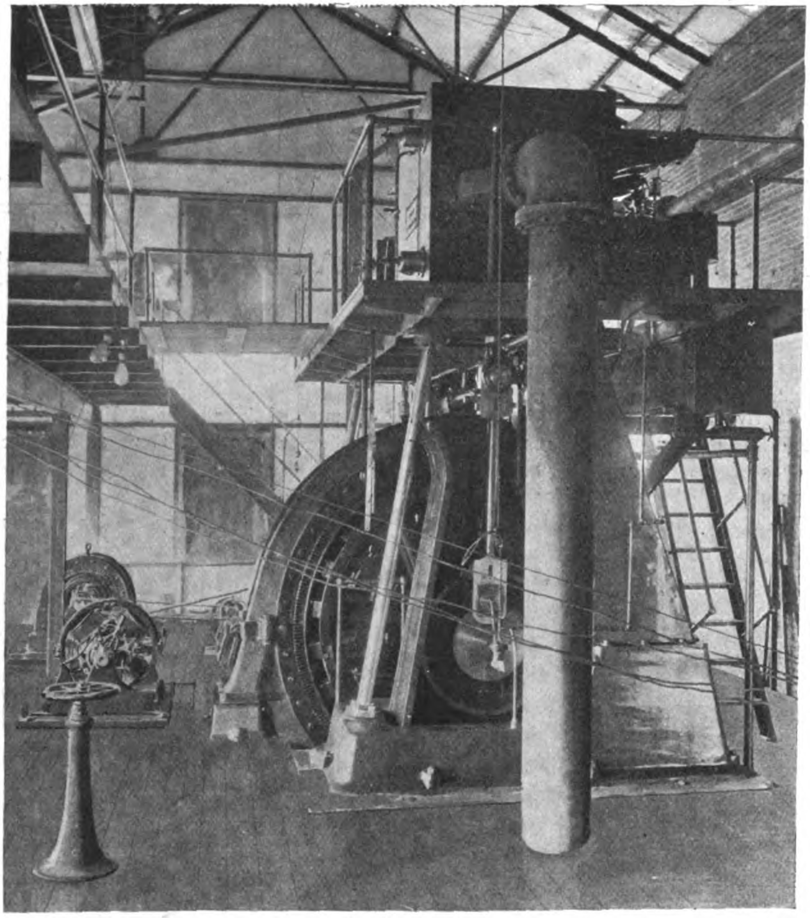


FIG. 5.—GENERAL VIEW OF LARGE UNIT.

It remains to be said that, conditions considered, the machinery was disposed with no little ingenuity in the building and amply fulfilled its object, that of maintaining the service until a modern station could be planned.

The new station service is derived from three generators of the S. K. C. type, this system having been adopted throughout the installation. Two of the generating sets are of moderate size and are intended to carry the day load, while the third is a large direct connected machine and at present can easily carry the entire station load. It is intended that as the plant shall increase the large machine shall be the unit by which the station equipment will be augmented, the smaller machines being intended merely to obviate the necessity of running a large machine lightly loaded.

The boiler room of this plant is adjacent to the main engine room and is fitted with return tubular cylindrical boilers 72 ins. in diameter by 16 ft. long. There are two of these boilers and a smaller boiler, which is presently to be done away with, when three more boilers will be installed, making five in all.

The furnace has a plain cover grate and now burns about 150 tons of buckwheat coal per month, which is fired in a spread fire from 8 to 10 ins. thick. The flue gases escape to a stack 60 ins. in diameter and 70 ft. high. This stack is of steel and is suitably supported by guys.

The station is situated on the shore of a small creek branching from the Hackensack River, which is deep enough to admit a coal barge at high tide. It is intended to erect a coal pocket with a conveyor system on a suitably placed pier, thus greatly decreasing the cost of coal in the boiler room by eliminating the expense of teaming and handling in wheelbarrows. The feed water is drawn from the Hackensack River, and experts have said that it is a fairly good boiler feed water, and that with the assistance of a little carbonate of soda to precipitate the lime salts which it contains, very little scale will be found on the sides of the boiler and that of such a soft and yielding nature that it can be easily removed. The deposit contains salts of lime and iron, and periodically blowing off the boilers and an occasional cleaning is all that is required. The present feeding system is provided for by two pumps, either of which is able to feed the entire battery of boilers. The first of these pumps is of the Worthington make, 6 x 4 x 6. It is supplemented by a Blake pump 7½ x 4½ x 10. The boilers are provided with steam domes, from whence the steam is taken through pipes with long elbows leading to a header. It is believed that these bends are sufficiently long to prevent any trouble that might arise from expansion. The header itself is divided by gate valves.

The steam piping system is constructed with flanged joints exclusively and covered with Monarch pipe covering. In the pipe supplying the large engines is placed De Rycke combined separator and receiver, which is suitably drained. The smaller engines have no separators, but are provided at the throttles with suitable drain cocks, and inasmuch as all the pipes of the engines rise from the upper side of the header there is little danger of the accumulated condensation reaching the engines, provided that the drop to the engine is well blown out before the latter is started.

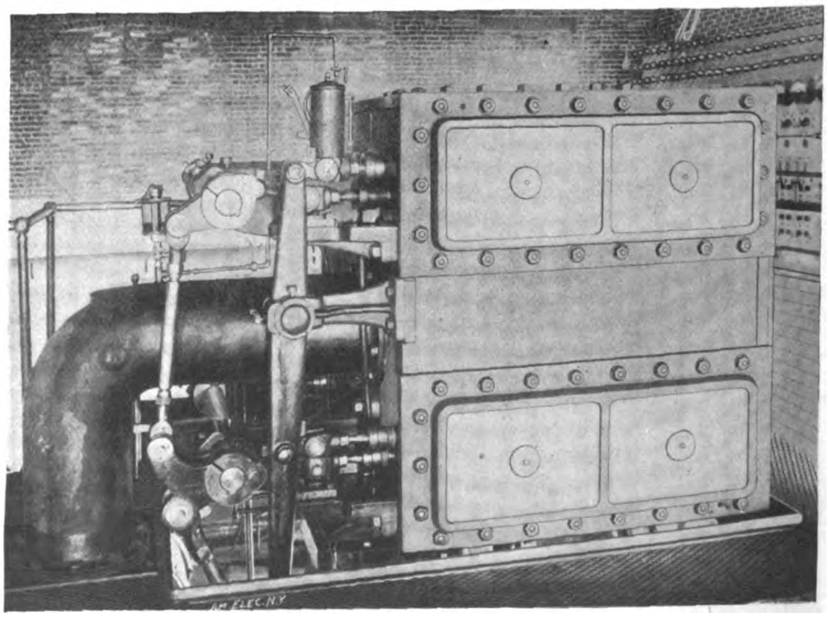

FIG. 6.—VALVE GEAR ON LOW PRESSURE CYLINDER.

The large engine was made by the McIntosh & Seymour Company, of Auburn, N. Y., and is an upright cross-compound with a 24-in. stroke. The high pressure cylinder is 16 ins. in diameter and the low pressure is 32 ins. The speed is 182 revolutions per minute. The high-pressure cylinder is steam jacketed, and a receiver of large capacity is placed between the high and low-pressure cylinders. The high-pressure cylinder has both heads jacketed, as well as the barrel; the low-pressure cylinder is not jacketed, the more efficient device of an intermediate receiver being provided. Fig. 5 displays a general view of this unit to good advantage. Fig. 6 shows a picture of the low-pressure cylinder and gives an idea of the arrangement of the valve gear. There are four valves to each cylinder, and the cut-off valves are worked by a separate eccentric, and both high and low-pressure cylinders are controlled by the governor.

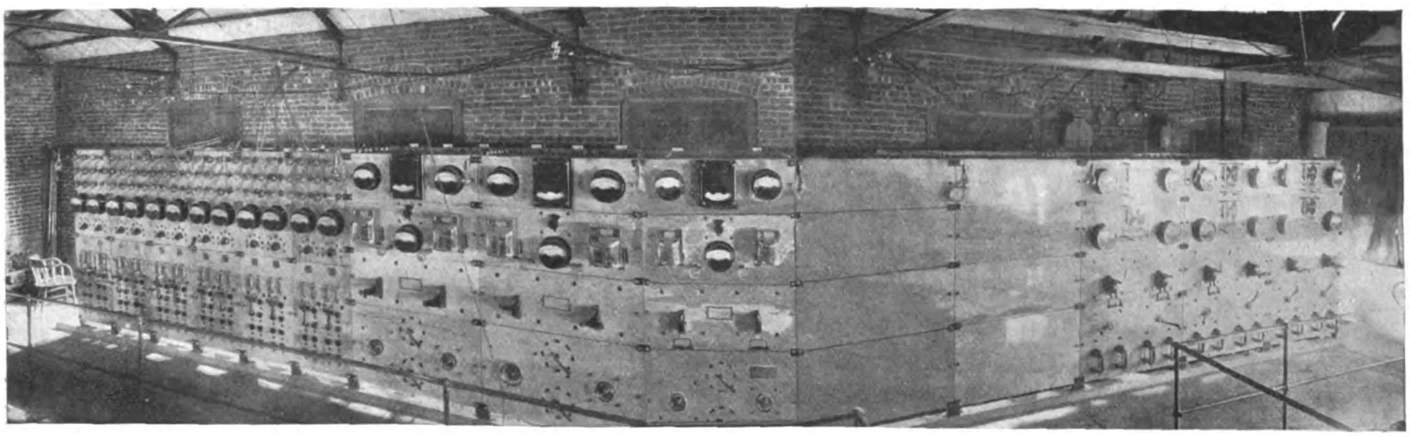

FIG. 7.—SWITCHBOARD.

The governor is of the regular McIntosh & Seymour type.

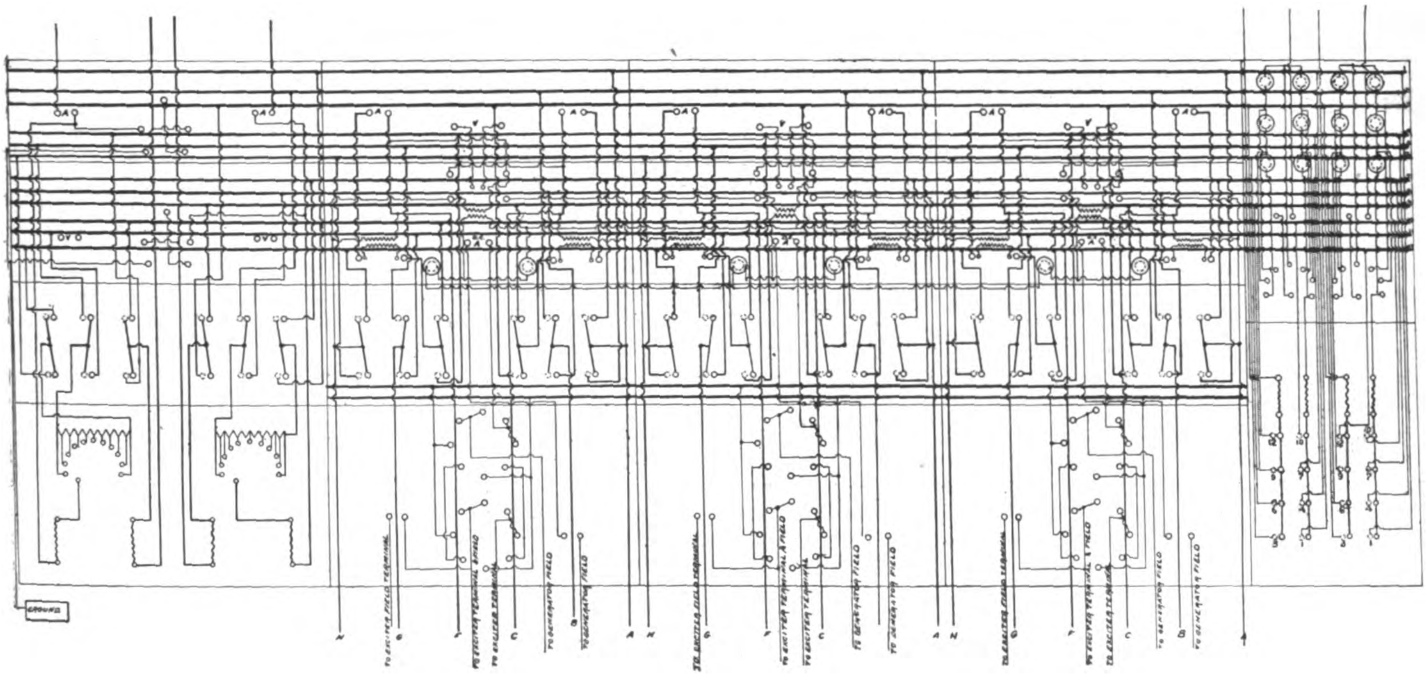

FIG. 8.—SWITCHBOARD CONNECTIONS.

The weight of the engine is 47 tons, of which 19,000 pounds is comprised in the flywheel, and as the inductor of the alternator has considerable flywheel capacity the motion of the engine is very steady. The shaft is 14 ins. in diameter at the armature hub and revolves in journals 11 ins. x 19 ins.

The engine is condensing, the exhaust being discharged into a Blake condenser. It has been found impossible to free the condenser water from oil sufficiently to permit of its use as a feed water, and hence the condenser water is discharged into the creek.

Before entering the condenser the steam passes through a feed water heater of the Wainwright type. The capacity of both the condenser and heater is 600 h.p. The heater, of course, has a certain condensing effect on the steam, and together with the condenser there is no difficulty in obtaining 24 ins. of vacuum continuously.

The smaller engines are those which were retained from the old station. One of these is a McIntosh & Seymour tandem compound running at 250 revolutions per minute. The cylinder dimensions are 13 x 19 x 15. The other is a little Ames engine, 11 x 10, operating at 320 revolutions per minute. Each of these is belted to a small S. K. C. generator.

The large generator is a beautiful piece of machinery. The rotating part has twenty-two poles on each half and is divided into four sections, any one of which can be removed in order to render the armature accessible. The halves of the inductor are secured to the shaft by means of stout bolts and keys. The generator can deliver its output, 350 k.w., in two-phase currents at a voltage of 2500 or 5000, according to the method of connection.

The smaller machines, which are shown in Figs. 3 and 4, are 150 and 50 k.w., respectively. At present the little 50-k.w. machine is sufficient for the day load. The 150-k.w. machine can deliver its output at 2500 or 5000 volts, but the 50-k.w. machine is only able to deliver current at the lesser of these voltages. All of the machines have the same frequency, 8000 cycles per minute, and can operate and be connected in multiple at the switchboard.

An interesting feature of this station is the exciters, and it is necessary to call attention to the fact that they are much too large for the work they are now doing, in order to dispel the idea that the alternators require any such current as the exciters are capable of delivering.

The exciting machines were in fact the two 12½-k.w. machines of the old station. The speed of these dynamos was reduced one-half, which proportionately diminished their voltage, and the field excitation was maintained the same as before by the simple device of connecting the four field coils two in multiple.

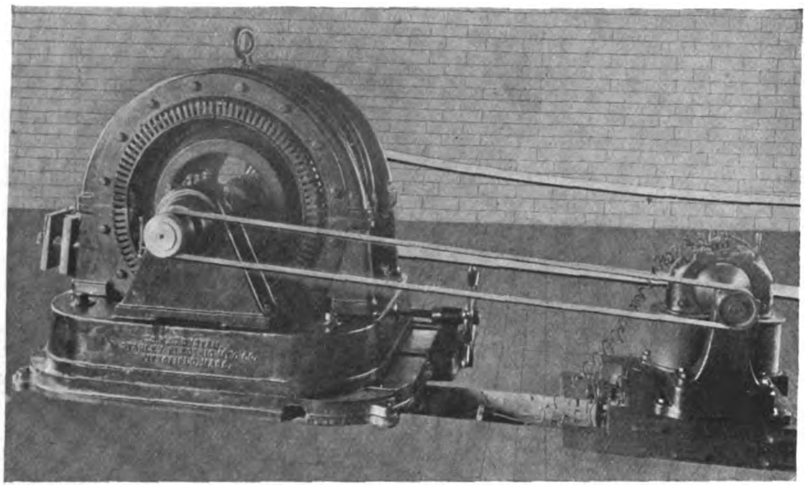

FIG. 9.—50-K.W. ALTERNATOR.

The switchboard is the subject of Fig. 7. This is installed on a balcony, and a bridge is provided connecting the balcony of the switchboard and that surrounding the cylinders of the large engine. The switchboard itself is a handsome construction of marble.

A word of explanation with regard to the illustration is necessary. The switchboard is a continuous construction, the panels being arranged in a straight line. It was, however, impossible to photograph it in one piece, and there was but one station from which it could be photographed, namely, the top of the engine cylinder, and therefore the pictures of the various parts are in three perspectives, and when matched together give the board the appearance of being bent around a corner.

It consists of generator panels, feeder panels and street lighting panels. The generator panels are provided each with a static voltmeter and with a suitable alternate current ammeter for each of the two phases. By means of suitable switches the machines are connected to separate bus bars, but may be connected to a common bus bar if necessary or desirable. A suitable transformer and synchronizing lamp is provided for switching the machine in multiple. Two panels in the middle of the switchboard are left blank, and are intended in the future to be equipped for the control of additional generators.

The service is divided into what is known as the commercial service and the street lighting service. The commercial service consists of a system of feeders, the voltage of each of which is independently controllable by means of a phase regulator. This consists, simply of a transformer with an adjustable secondary, manipulated by a handle on the front of the switchboard. Each circuit is provided with an ammeter on each phase and a static ground detector. The ammeters on this board were made by the Whitney Electrical Instrument Company, of Penacook, N. H., while the rest of the apparatus was made by the Stanley Electric Company, of Pittsfield, Pa. The switches are double throw devices and are manipulated by a rack rod, which meshes to a pinion, to which is fastened the operating handle. The jaws and contacts are on the back of the board. This prevents the possibility of a shock to the operator. The street lighting is on the series incandescent system, forty-eight lamps being placed on a single circuit. These circuits are used to balance the load on the two phases and are therefore adapted so that any circuit can be shifted on any phase of any dynamo. This arrangement is better understood by consulting the switch diagram shown in Fig. 8.

The street circuit is led to a suitable pair of copper bars, which are arranged in a vertical position and carry at intervals suitable contact sockets through which a rod may be thrust, and by engaging with a similar socket placed on a marble slab a few inches back of the main panel it will thus be connected to the bus bars. Two such rods are mounted in a hard rubber crosspiece carried on the end of an insulated handle, and one portion forces both rods in place and connects the circuit to the machine. This pair of rods may be inserted in any one of these plug holes, and as each street circuit is thus provided the load can be balanced very accurately.

The new system, with its higher voltage, is distributed over wires with a triple braid weatherproof covering mounted on deep groove double petticoat glass insulators. It is interesting to note that the old distributing system was bare copper, and that the copper displaced to make room for the new lines was sufficient to pay for the new distributing system with something to spare, and moreover the new system has a line loss of but 4 per cent, whereas the old system had a loss of 11 per cent. This plant supplies the street and house lighting of the following towns: Hackensack, Teaneck, Leonia, Ridgefield Park, Maywood, Arcola, River Edge, Oradell and New Milford, and further supplies current to the Englewood Lighting Company. This latter line is the longest circuit, being fully six miles in length. The eastern circuits proceed directly from the station and cross the river, which is a short distance away, by means of submarine cables. A cable house is to be installed with two or three extra cables, which can be brought into play in case one of the active cables should become disabled.

The motor service is at present very small, consisting of only ten motors. These are the two-phase Westinghouse type, and are used in small stores about the town which need power. There are also fifteen alternate current arc lamps. Arrangements are now being made, however, to increase the power demand and thereby provide a substantial day load for the station.

POSSIBILITIES IN ELECTROMAGNETS.

Electrical artisans and designers have for the most part been familiar with the performance of electromagnets on battery circuits. The application of the electromagnet on a large scale for heavy duty seems to be very limited. The power of a large electromagnet excited by suitable currents, which are now available almost anywhere in industrial localities, is very great indeed and very efficiently obtained. Electromagnets have been used to great advantage for handling steel beams and masses of iron in lieu of ropes and chains, but no one seems to have thought of applying the electromagnet to submarine hoisting, where the difficulty of applying ropes and chains is often very great.

Direct-connected motor driven machine tools are now conceded to be among the highest developments of the art, but there are many cases where rotary motion is transformed very expensively into reciprocating motion, and may be better accomplished by the simple application of an electromagnet. The trip and drop hammers used in our machine shops, and the punching press, offer excellent examples where the electromagnet might be profitably introduced, diminishing the first cost of installation without loss of efficiency. Mining stamps also represent a class of machinery which could be operated by large electromagnets at small expense.

The most popular objection to the magnet seems to be its lack of range. This can be largely overcome. There are plenty of mechanical devices that can transform a short pull of immense power into a moderate pull of longer range. The simple hydraulic device of different size pistons in the same connecting vessel suggests itself in this connection as being one very easy of application by the use of properly designed solenoids. Modern engineering finds no difficulty in constructing iron-clad electromagnets which are applicable to the severest service and will work in localities where a motor will fail utterly. Even if efficiency be somewhat lacking, simplicity will often be an advantage which will more than counterbalance.

For application to rapidly reciprocating tools, such as drills, cold chisels, beading machines and similar devices, there is a large field for the electromagnet. In such cases as these the difficulties have inhered in breaking devices and the elimination of the inductive arcs which occurred there, but this can now be overcome.

Electrical Equipment of the U. S. Cruiser "Newark."

BY E. W. COUNTISS.

The "Newark," one of the first of the famous White Squadron, has been recently overhauled and remodeled, and among the new fittings the electric plant is interesting, and this article is devoted to its description.

The electrical generating machinery consists of three direct-coupled sets. The prime movers are Armington & Sims two-cylinder engines of the inverted vertical type. The cylinders are 7 ins. in diameter, the stroke is 5 ins., and the speed is 400 r.p.m. The cranks are set at 180 degs. The governor is of the centrifugal type and placed on the end of the shaft, outside of the engine bed. The variation of cut-off is transmitted to the two valves—one for each cylinder—by means of a rocker arm and rods attached to the eccentrics. The steam chest and valves are placed between the cylinders. The connecting rods are fitted at each end to the crossheads and crank pins by straps, gibs and keys. The crank brasses are babbitted, while those for the crosshead pins are of gun metal without babbitt.

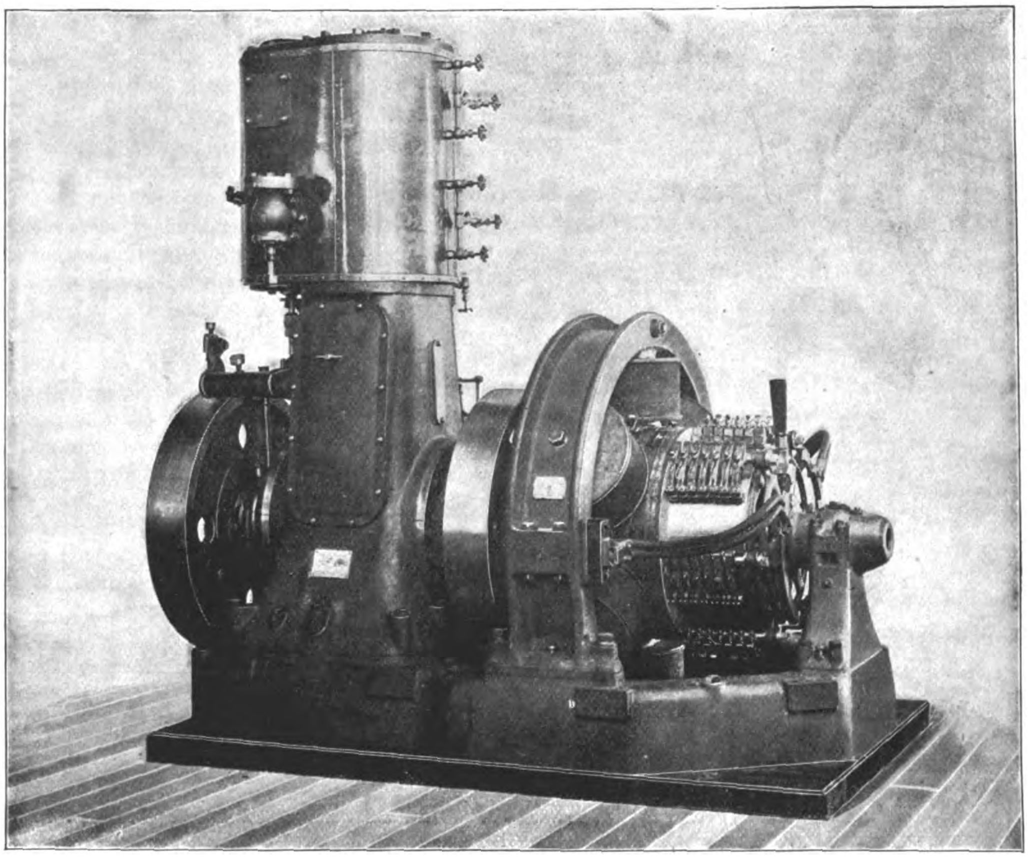

FIG. 1.—NEW GENERATING SET ON THE "NEWARK."

The steam piping is so arranged that the engines can be supplied from either the main or auxiliary boilers, while the exhaust can be turned into the main or auxiliary condensers, or both, and also into the atmosphere.

The steam pressure is adjusted to 80 lbs. by means of a reducing valve in the dynamo room. The pipe line also carries separators drained by steam traps. All drainage is trapped into the hot well.

To these engines are bolted the generators by means of solid couplings. They are three in number, made by the Thomson-Houston Co., of Lynn, Mass. They have four poles, are compound-wound, with cross-connected armatures, and are provided with two sets of brushes. The field frames are made up of Norway iron bars 4 ins. x 1 in., bolted together with cast iron pole pieces, six of these bars composing each field. The series coils consist of twelve turns of wire .128 in. in diameter, having a total resistance of .004 ohm.

Each shunt spool is wound with 800 turns of No. 10 B. & S. wire, having a total resistance when cold of 10 ohms.

The armatures are of the Paccanotti-Gramme ring type, each segment consisting of four turns of flat wire .125 in. x .320 in.

The commutators have seventy-two bars, each being 6⅜ ins. long, 1⅜ ins. deep, and 13-32 in. wide at the periphery. The armatures are 19¾ ins. in diameter; the air gap is 27-64 in.

This formed the original lighting plant; but owing to the installation of electric motors for ammunition hoists the plant was further increased by the addition of a 300-ampere generating set, made by the General Electric Company, of Schenectady, N. Y.

The engine of this latter set is an upright tandem compound, making 400 r.p.m. The cylinders, steam chests and housings are cast in one piece, the cylinders and crosshead guides being bored with one chucking. The stroke is 6 ins. Large bearing surfaces are one of the features of this engine. The bearings are cast iron with babbitted linings and oil grooves. The steam chest is so arranged that the steam pipe can be fitted to either side, as may be most convenient.

In each side of the housings there is a bonnet which can be removed for inspections and repairs to crank and crosshead bearings.

Instead of the usual individual oil cup for each bearing a large tank, holding about 5 gallons of oil, is placed overhead, and a ½-in. brass pipe led to the engine, where it connects to a distributer. Each bearing has its own oil pipe and by means of pet cocks the oil can be regulated to suit the requirements. The governor has few parts, but one weight and one spring, by which the throw of the eccentric is communicated to valves by means of a rocker arm. By adjusting the pivotal point and altering the tension of the spring a cut-off varying from 0 to ¾ can be obtained.

The dynamo is a six-pole compound-wound machine, with the field frame parted horizontally, so that the top half can be readily lifted off. Across the series winding a German silver shunt is placed for regulation, which is very close—within one-half volt from full load to no load.

There are six sets of carbon brushes, six brushes to a set, secured to an adjustable rocker arm.

The armature is an iron-clad drum, with formed coils, and has a massive commutator. The bearing shell at the commutator end is hollow and forms an oil reservoir, into which the oil ring dips. The journal proper runs in an iron sleeve with babbitted lining, such as is used on all General Electric generators.

The switchboard is of the standard U. S. Navy type for three generators. All four of the generating sets are connected to it in such a manner that any circuit can be used on any generator or any combination of them running in parallel. To accomplish this generators Nos. 1 and 3 were connected to the negative bar of the switchboard marked No. 1. The positive leg of No. 1 and No. 3 were each run through an ammeter on the switchboard and then connected together to No. 1 positive bus bar of the board. The equalizing leads from No. 1 and No. 3 were connected to the No. 1 equalizing switch. The positive and negative leads of No. 3 and No. 4 generators were then connected to No. 2 and No. 3 bars respectively, and the equalizing leads to their respective switch terminals. Switches were located between the generators and switchboards so that they could be cut out when not in use.

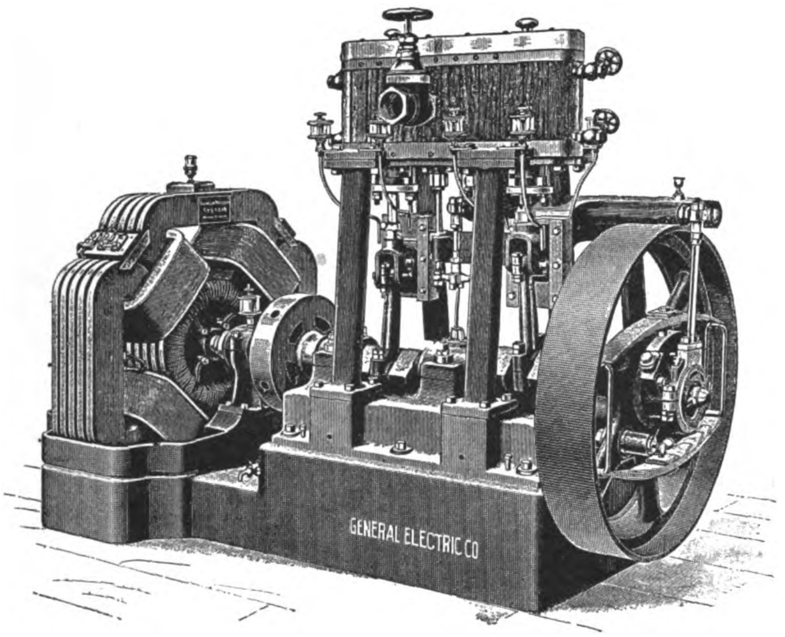

FIG. 2.—ONE OF THE OLD SETS.

Three voltmeters were used. No. 1 voltmeter was connected to generators No. 1 and No. 3 by means of double-pole double-throw knife switches, so that readings could be taken of each. No. 2 voltmeter was connected to generators No. 2 and No. 4 by the same means. No. 3 voltmeter was connected to each of the four searchlights by a single-throw four-point switch, so that the reading of the e.m.f. of the separate searchlights could be taken in the dynamo room.

The ammeters are of the Weston shunt type in metal cases and read to 400 amperes. The voltmeters are of the same make and read up to 125 volts. In the officers' quarters and where water-tight casing was not absolutely necessary the old moulding was replaced with new. But in the fire rooms, over the crank and crossheads in the engine rooms, in the coal bunkers, on the bridges, and spar deck, iron armored conduit was used, with special junction boxes inclosing the regular junction box fittings. Conduit was also used to carry the wires up the masts for the top and mast head lights, and for the guns in the fighting tops, as well as for the truck lights.

Standard fixtures were used throughout the ship. The old style of water-tight junction boxes were converted into the modern style by fitting them with new interiors and screw caps. All the old receptacles were discarded and modern appliances used in their places. Brackets for battle lanterns with hooks to hang the portables on were installed near the breech of each gun and elsewhere where needed, with the plug inserted in the receptacle ready to turn on the switch. Hooks were screwed in place upon which to hang portables. Racks were provided for lamps, both 16 and 32 c.p.

To expedite the handling of the ammunition for the 6-in. guns, which compose the main battery of the ship, the magazines and shell rooms were rearranged. To further add to the efficiency in this direction, electric motors were installed to hoist the shells to the gun deck. A vertical shaft of ½-in. steel plates was built for each magazine and shell room, with a partition which divided it into two compartments. At the top and bottom are shafts upon which are mounted sprockets over which endless chains are carried. To these chains are fastened carriers. Upon these the ammunition was placed and sent up to the guns. The bottom shaft was extended, and keyed to it was a gear wheel, which meshed into the gear wheel on the shaft of the motor. These motors, made by the General Electric Company, of Schenectady, N. Y., are iron-clad, shunt-wound machines, taking 35 amperes at 80 volts. They were connected to a starting panel, see Fig. 9, of polished black slate, located close to the motors, so that the attendant could control both the brake and the starting levers and switches. Brass armored conduit was used in the passing room to incase the wires, and brass junction boxes inserted in the mains to tap off to each panel. The mains are connected to the double-pole switch at the top left-hand corner of the panel. Through this switch current was carried to the fields. The switch at the top right-hand corner is for reversing. By properly connecting the armature leads the direction of the throw of the switch will control the direction of the hoist; that is, if the switch is thrown up the ammunition is hoisted, if downward, the ammunition is lowered. The small switch C is for speed regulation and D is the starting rheostat. E and F are electro-magnetic cutouts, which act in case of excessive flow of current. The motors are of 6 h.p.

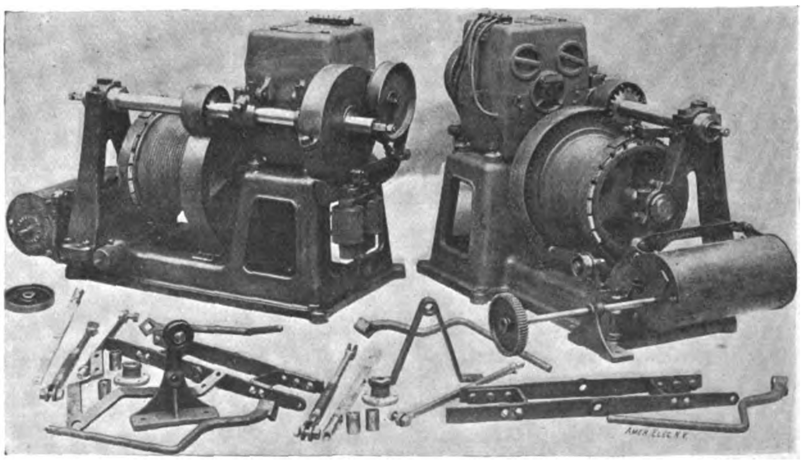

FIG. 3.—VIEWS OF THE AMMUNITION HOISTS.

The searchlights, four in number, are of the 24-in. inclined lamp type, having both hand and automatic feed. The upper or positive carbon is 1 in. x 12 ins., cored, and the lower or negative one ¾ in. x 7 ins., solid. These lamps were so well adjusted that there was no perceptible fluctuation of light during a four hours' run. The mirrors were of the Mangin type, 24 ins. in diameter, 1¾ ins. thick on the edge and ⅛ in. at the center. In the center of the mirror the amalgam was removed, leaving the clear glass for a peep hole, so that the position of the carbons could be seen. To protect the eyes from injury four colored glasses, two red and two blue, were placed in line with the peep hole, reducing the intensity of the ray. By means of hand wheels and beveled gearing the lamp could be focused from the side and back of the drum by altering the distance between the arc and the mirror. The front glass doors are made up of polished plain glass strips ¼ in. x 2 ins., set in a circular metal frame, with the edges ground true. A dispersing lens is provided, which is fitted over the plain front door to extend the beam laterally. This is composed of alternate plano-concave and plano-convex strips of glass fitted into a metal ring, the whole hung over the projecting lugs on the front of the projector drum.

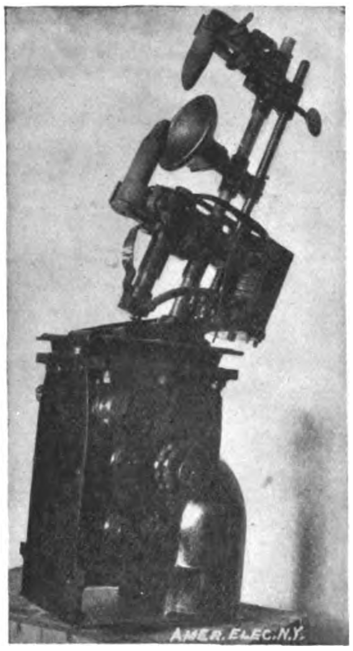

FIG. 4.—SEARCHLIGHT MECHANISM.

The drum is mounted and swung by trunnions on a fork secured to a pivoted base, to allow for directing the beam in any desired direction. On the bottom of the fork the wires are connected to spring plunger contacts through insulating stuffing tubes, with two rings secured to the pedestal. The leads from the switchboard connect to these rings. By this arrangement there is no fouling of the conductors and it gives perfect liberty of motion. The c.p. of each light is about 25,000. An adjustable resistance of German silver ribbon is inserted in the positive lead just after it leaves the switchboard. To get the best light this resistance is set so that the lamp burns at 45 volts and consumes 55 amperes at the lamp terminals.

The Ardois signal set is suspended from a gaff under the truck on the foretopmast. The cable and jackstays are then secured to eyebolts on the rail, and set up taut by turnbuckles. Every 4 ft. the cable and one jackstay are lashed to the topgallant backstay, to prevent swaying in a seaway or storm. These were illustrated in an article in the June number. The keyboard is situated on top of the chart house, so that the operator has an almost unobstructed view all around. The wires leading to the keyboard are led from the signal circuit in the chart house.

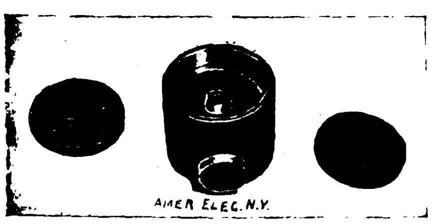

FIG. 5.—THERMOSTAT.

The truck lights are of about the same size and design as the Ardois lanterns, with the addition of a screw base, which fits into a metal cap. This cap is fitted over the topmast head and secured by through bolts. The lanterns have the upper lens red and the lower one white, each supplied with a 32-c.p. lamp. Short lengths of double conductor hemp portable wire are led from each half of the lantern to a receptacle situated in the top, into which is inserted a water-tight plug. Wires are carried up the masts in conduits to these receptacles from the bridge forward, where the pulsating switches are located. These switches are brass cases with outside levers, whereby the red or white half of the lantern can be burned at will. There is also a push button switch by which the lights can be pulsated as occasion requires for signaling purposes. These lights are situated on the fore and mainmasts, each mast having its own light and pulsating switch. Currents for these lights are also taken from the signal circuit.

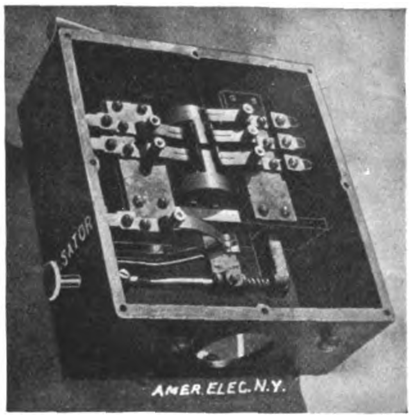

FIG. 6.—SIGNAL SWITCH FOR TRUCK LIGHTS.

An electric lighted binnacle is installed in the pilot house. The wires are carried up inside the base to two contact rings, upon which the top is secured. Plungers on the binnacle cover make contact with these rings, and current is conveyed to a miniature incandescent 80-volt lamp, obscured, except on the extreme bottom, to prevent the light from blinding the helmsman. A cage to protect and a switch to control the light are also provided.

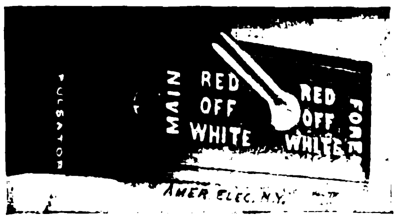

FIG. 8.—BOX FOR SIGNAL SWITCH.

An electric whistle operator, manufactured by the Signal & Control Company, of New York, was installed with the clock mechanism secured in the pilot house, with the necessary "at will" and "automatic" contact switches placed on the bridge.

Racks for holding the battle lanterns were placed at each gun and in the conning tower, upon which the lanterns are placed and the portable wire coiled up, with the plug inserted in its receptacle, so that if light is needed it is necessary only to turn on the switch, thus being always ready.

The bell and interior communicating systems are very complete, providing communication from the captain's and admiral's cabins, ward room, junior officers, warrant officers, to the various parts of the ship. There is, further, a speaking tube system and complete fire and water alarms. The batteries for the first five systems are placed in the pantries, while for the others they were placed in a large locker in the dynamo room. These batteries were of the Leclanche-Gonda type, placed in trays, with divisions between each cell, thus avoiding danger of breakage.

In the captain's and admiral's quarters are installed calls to the pantry and orderlies, from the cabin, staterooms, bath room and office. The wardroom calls are from the staterooms, bath room, lavatory, shower bath and mess tables. The executive officer has calls in addition to the yeoman, master-at-arms and ship's writer; the navigator to the dynamo room; the surgeon to the dispensary; the paymaster to the pay office; the chief engineer to the port and starboard engine rooms, and the engineer's yeoman.

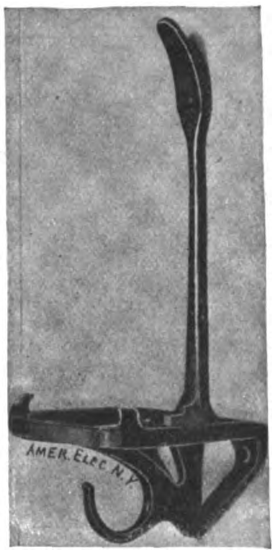

FIG. 7.—RACK FOR BATTLE LATTERN.

The voice tube system is the most extensive and embraces the calls and returns from the conning tower to the engine rooms—starboard and port—steering engine, powder division, central station and dynamo room, etc. The engine room communicates in this way to the chief engineer, fire rooms, dynamo room and steering engine, besides a multitude of calls to every part of the ship. In exposed places water-tight bells, buttons and annunciators are used. Where main trunk lines branch brass connection boxes are used, the wire made fast to terminals in metal boxes of various capacities.

Where joints are made a rosin core solder is used, as acids and salts are prohibited.

The general alarm gongs are seven in number, divided so as to reach the greatest area of space, so that everyone will be informed of the call. They are 12 ins. in diameter, single-stroke, mounted on a polished mahogany base, the whole secured to the bulkheads or other such support.

The contact maker is an inclosed water-tight brass case, by which these alarm gongs are made to strike.

The fire alarm system is composed of inclosed mercurial thermostats, secured to a hard rubber base and then screwed into a metal case with perforated lids, which allows the heat to reach the mercury and at the same time protects it from injury from lumps of coal. There are fifty-seven of these thermostats in the coal bunkers and store rooms.

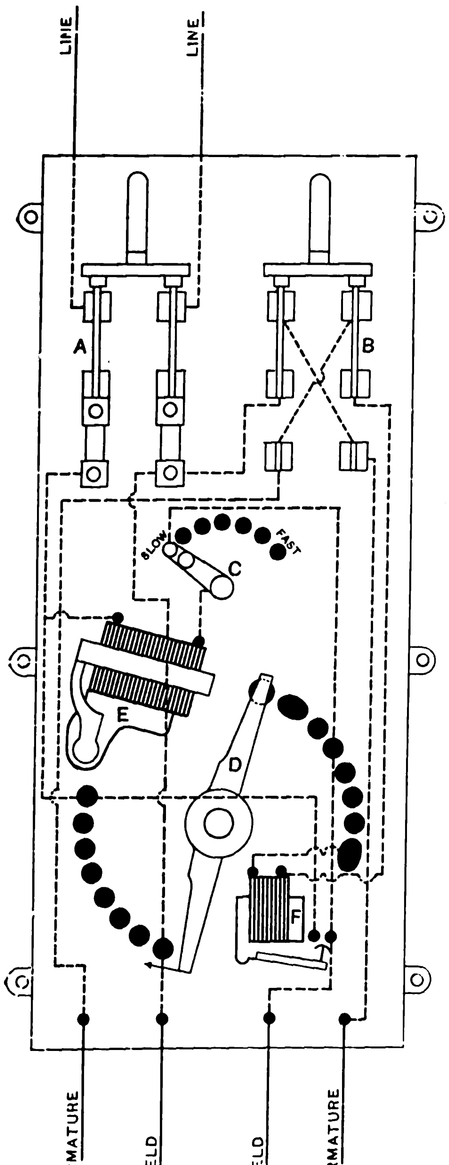

FIG. 9.—SWITCHBOARD FOR AMMUNITION HOIST.

The water alarms are six in number, placed forward and aft about 6 ins. from the outer sheathing, with double bottom.

These fire and water alarms lead to the same annunciator and are fed from the same battery, the annunciator being placed in the cabin constantly under the eye of the captain's orderly. Each drop has its own individual switch, so that in case of accidental short circuit on that line it can be cut out without interfering with the rest of the system.

In addition to the batteries a rotary transformer is supplied and placed on top of the battery locker to furnish current for the fire and water alarms, general alarm and voice tube systems. By means of double-pole double-throw switches it takes but an instant to change from one source of current to another. The transformer at the primary end receives current from the electric light mains at 80 volts, and delivers 20 volts at the other end. The type used is made by the Crocker-Wheeler Company.

Test of a Multi-Circuit Direct-Current Dynamo.

BY EDWARD J. MURPHY, JR., AND P. EDWIN VAN SAUN.

The demand for a direct-current dynamo capable of supplying to two or more circuits current at different voltages that are independent of each other is well appreciated. Such a machine offers the advantages that can be derived from two or more separate machines without the additional first cost expense för maintenance and floor space. The Rushmore multi-circuit direct-current dynamo is at present the only representative of this type of machine, and it is believed that the following article, which is descriptive of a test on one of these machines, will be of interest, as it contains information regarding what may be expected from this type of dynamo.

The manifold uses to which a machine of this character might be put are well known. It may, for example, supply current differing in voltage to the feeders of an incandescent lighting system, or it may furnish current at a given voltage to a lighting circuit on one side, while from the other current at a different voltage for charging storage batteries might be drawn. As a transformer for direct currents it opens up a new and interesting field for experiment. In this application current would be supplied to the circuit on one side, serving to drive the armature as a direct-current motor, and from the circuit on the opposite side current would be drawn at a voltage differing from that of the supply, and limited only by the speed and capacity of the machine.

In the design and arrangement of the mechanical features of the machine which formed the subject of this test the plan followed is similar to that pursued in the case of an ordinary multipolar single-circuit direct-current dynamo. The machine has four poles, each being provided with "form wound" field coils, each pair of which was connected as a shunt to the pair of leads from the brushes collecting the current between the corresponding poles.

The armature is of the drum four-path lap-wound type, but a Gramme ring winding might be substituted without interfering with the action of multi-circuit working. The current is drawn from the armature by four sets of brushes, placed so as to commutate between each pair of poles. Current for one circuit is taken from the right-hand side, while the remaining two brushes furnish a source of supply for the other circuit. Fig. 1 will assist in understanding these electrical connections.

In the ordinary multipolar dynamo the assumption has always been held to be correct that if two adjacent poles be excited to an equal strength the magnetic flux will tend to divide equally, producing a uniform magnetic field, which, acting on an armature of the drum or ring type, will produce an equal difference of potential between each pair of brushes of opposite sign.

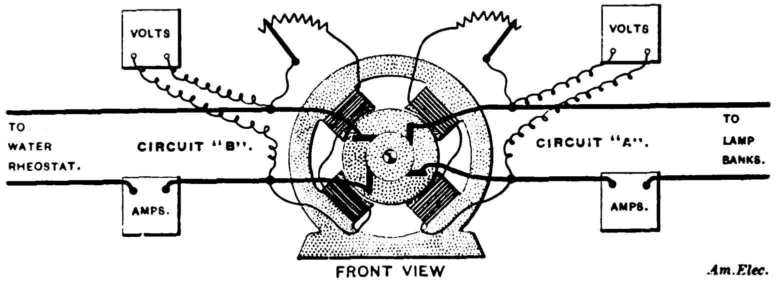

FIG. 1.—MULTI-CIRCUIT CONNECTIONS.

Experiments conducted some years ago by Mr. S. N. Rushmore on the multi-circuit principle have proved the above assumption to be erroneous, and in an arrangement similar to that just described the greater part of the magnetic flux tends to pass only between the magnetized poles, producing a difference in pressure between the brushes collecting on this side proportional to the excitation of the poles, while those on the opposite indicate scarcely any electric pressure except that due to the residual magnetism of the steel.

In this test, which was made at the Stevens Institute of Technology, the dynamo, which was of 20-k.w. capacity, was driven from a suitable source of power by means of the following device: A belt was led from the source of power to a pulley 15 ins. in diameter, placed upon a 2-in. counter-

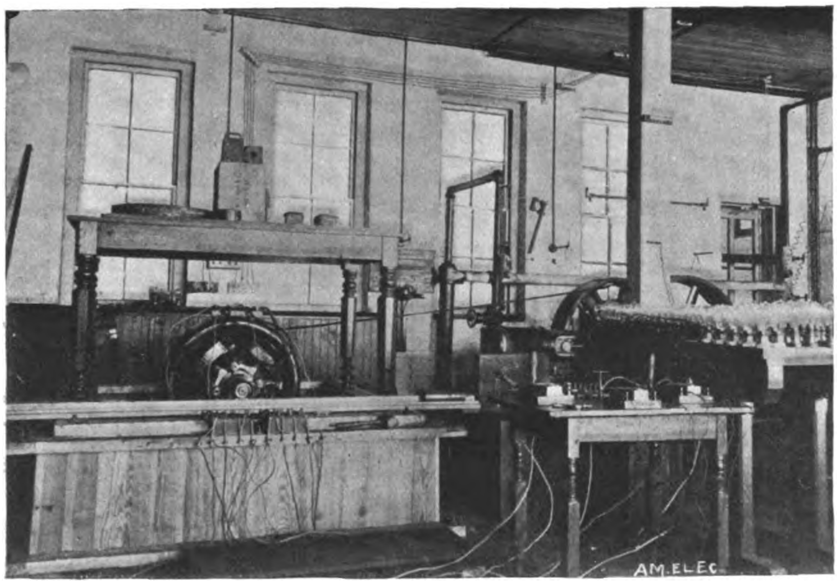

FIG. 2.—ARRANGEMENT OF APPARATUS.

shaft supported by two self-oiling hangers, placed one on each side of the pulley. Upon the end of this countershaft was keyed one-half of a flanged coupling, the other half being fastened to the dynamo shaft. The four bolts were removed from the coupling and in their place four steel pins were inserted to act as drivers. These pins were turned for a portion of their length to such a size as would insure a good driving fit in the holes of the coupling on the countershaft. The remaining length was turned to a size 1-64 in. less than that of the diameter of the holes in the coupling on the dynamo shaft, thereby affording a certain amount of clearance for the pins, and enabling the dynamo to move slightly without undue straining and binding. This was necessary because the Webb floating dynamometer was used, in which, as will be seen by the following description, the machine is likely to become slightly displaced until it is restored by adjusting the counterbalance weights. The dynamometer was one of the floating form devised by Prof. J. Burkitt Webb, of the Stevens Institute of Technology. In this device the dynamo is mounted upon a box or float, which is immersed in a suitable tank of water. The torque of the dynamo tends to tilt the float from a level position, and to restore it a sliding weight must be moved along a scale until a suitably arranged level indicates that the float is horizontal. From the position of the weight with reference to the zero position of the scale and the speed of the dynamo shaft, the h.p. transmitted can be calculated. To float a weight of this magnitude (some 1800 lbs.) it was calculated that a box 4 ft. 6 ins. x 4 ft. 7 ins. x 20 ins. deep was necessary. The tank in which the float was placed was of the same depth, but was 1 in. larger on each side than the inner box.

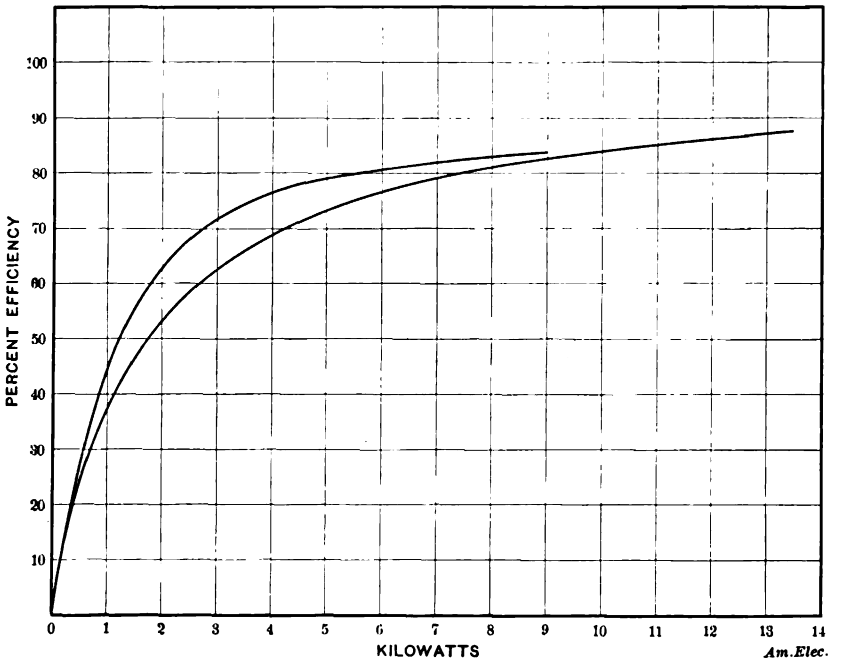

FIG. 3.—EFFICIENCY UNDER MULTI AND SINGLE CIRCUIT WORKING.

The dynamo was securely fastened to the floor of the float and the latter was immersed to about 18 ins. in depth by means of iron ballast placed upon the floor of the float; but it was found that this arrangement made the latter too stable to permit of the reading of small variations in the power. This difficulty was overcome by the expedient of placing a table 3 ft. high upon the float, and the ballast which had been previously fastened below was rigidly secured to the top of the table. This raised the center of gravity to a point nearer the meta-center and rendered the float much more unstable, and hence the dynamometer was more sensitive. The arrangement of the apparatus is depicted in Fig. 2, which shows the machine surrounded by its testing devices. The float was adjusted in a horizontal position by means of varying the position of the weights on the table, the final adjustments in the direction at right angles to the shaft being made by means of a brass clamp attached to the side of the table. The counterbalancing weight slid on a board on which was fastened four half-meter scales placed end to end, making a total length of 2 meters. This board extended in a direction at right angles to the shaft.

It is obvious that the h.p. transmitted is equal to $2 \pi lnw \div 33{,}000$, in which $n =$ number of r.p.m. of the dynamo shaft, l the distance in feet that the weights must be moved from their zero positions to bring the float to a level position, and w the magnitude of the weight used. It is easy to see that by properly adjusting the magnitude of w the meter scale may be made to read directly in foot-pounds, provided that the speed of the dynamo is maintained a certain constant quantity. For this purpose 1000 r.p.m. was chosen and a simple calculation, using the above formula, shows the necessary weight to be 9.7 lbs. In this case it was desirable to measure about 20 h.p. with the weight at the farthest position on the scale, and it was therefore necessary to double the size thus determined and use a pair of such weights instead of one. The power expressed in h.p. was, therefore, the scale reading multiplied by double the r.p.m. and divided by 33,000. This calculation allows for variations in speed.

The speed of the dynamo shaft was taken by a revolution counter, which could be started and stopped accurately on given intervals of time.

The current delivered to circuit B (see Fig. 1) was measured by a Weston direct reading ammeter. The currents in the other circuits were measured by Weston instruments used in connection with shunts. All of the instruments had been tested in the electrical laboratory at the Stevens Institute of Technology and found to be correct.

The current was led from the dynamo by means of wires which connected to binding posts placed along the side of the float. From these short pieces of wire dipped into mercury cups that had been suitably cut in pieces of paraffined wood fastened to the edge of the tank. This arrangement obviated any error that might arise due to the twisting or the springing of the wires, which would exercise a displacing influence on the float. The current in circuit A was absorbed by a series of lamp banks connected in parallel. Each bank consisted of ten 52-volt lamps arranged in five rows of two lamps each in series. In circuit B the current was absorbed by means of a wire resistance made by running a length of German silver wire upon a wooden frame and immersing it in an oil barrel filled with water. From previous experiments it was found that No. 20 B. & S. gage German silver wire would carry a current of 80 amperes for a period of 1¾ hours when arranged in this way. For measuring the voltage fine wires were led out from the binding posts, where the armature terminals were connected to a switch that could connect either pair of wires with the voltmeter at pleasure. The tests made comprised the following:

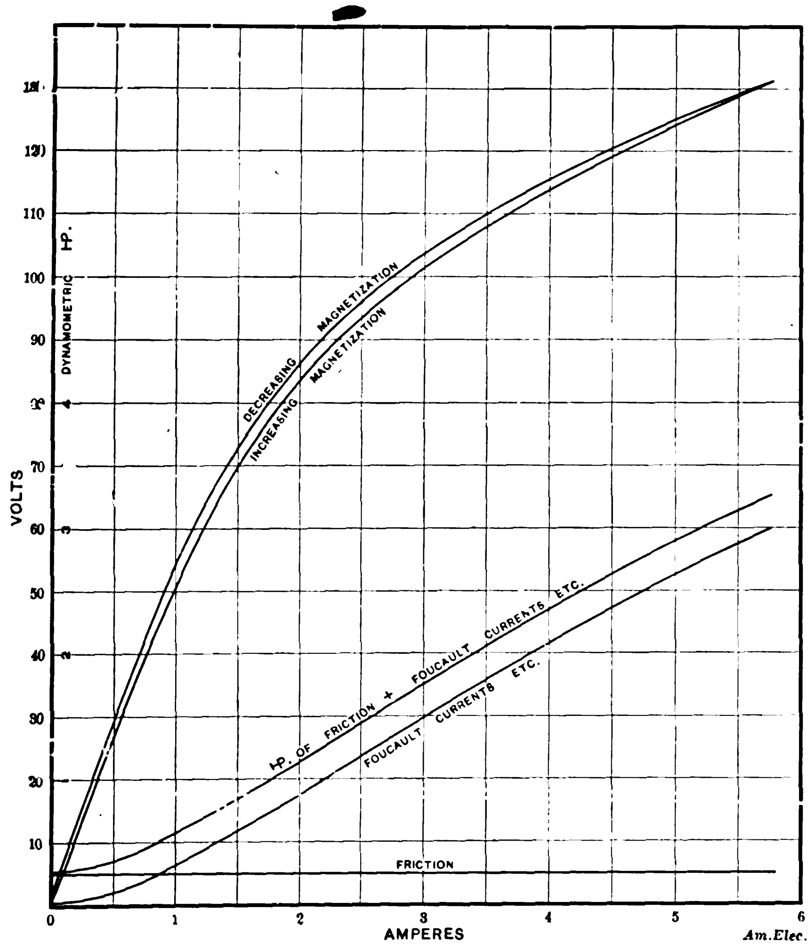

FIG. 4.—LOSS CURVES, ALL POLES MAGNETIZED.

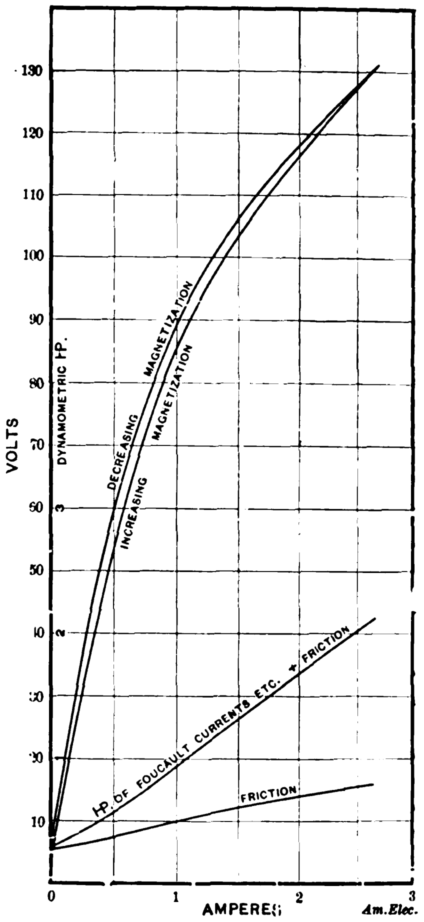

FIG. 5.—LOSS CURVES, OPPOSITE POLES MAGNETIZED.

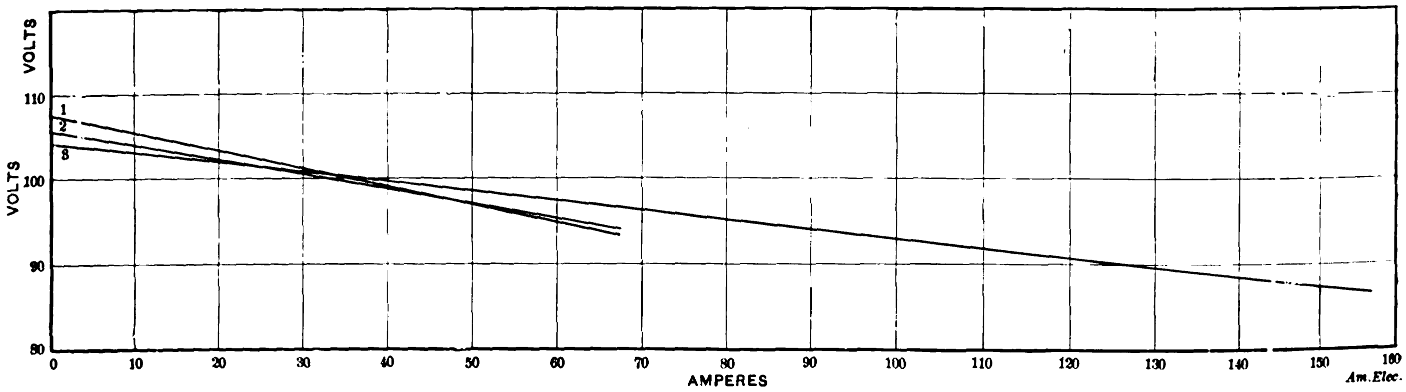

FIG. 6.—CHARACTERISTIC CURVES OF MULTI-CIRCUIT MACHINE.

A. The effect produced upon the voltage of circuit A by varying the voltage in circuit B without altering the external resistance in that circuit.

B. The effect produced upon the voltage of circuit A by keeping the current in circuit B constant, by varying the external resistance and reducing the voltage in that circuit from 110 to 0.

C. A determination of the efficiency of the dynamo when connected as a single-circuit multipolar machine at various loads up to the capacity of the machine.

D. A determination of the efficiency of the dynamo (when connected as a multi-circuit machine) circuit A only was closed and the load raised to a maximum output of 90 amperes.

E. The efficiency of the dynamo when connected for multi-circuit work under the conditions previously given for tests A and B, and also when the current in B is kept constantly at 50 amperes.

F. The amount of power consumed in friction by the bearings and brushes.

G. The power absorbed by the dynamo in Foucault currents, friction and iron losses under various conditions.

H. External characteristics under various conditions of operation.

The variation in the voltage of circuit A when the e.m.f. and current in circuit B are varied is shown in the following tables.

In these tables the results are the average of three readings taken at two-minute intervals. In table A the performance of the machine is shown when the e.m.f. and current in B are varied, the resistance being kept constant. In the case of table B it was endeavored to keep the current in B constant by varying the external resistance; the voltage was lowered in steps in circuit B. The results are interesting, as they show that circuit A is practically independent of circuit B, though from the description of the arrangement it could easily be conceived that the varying of the current and voltage of one circuit might materially affect the output of the other.

Am.Elec.

FIG. 7.—LOSS CURVES, ADJACENT POLES MAGNETIZED.

The results of the efficiency tests are best shown in the curves depicted in Fig. 3. The longer curve shows the efficiency of the machine connected as an ordinary single-circuit machine. The shorter curve shows the efficiency connected as a multi-circuit dynamo, current being drawn from circuit A only. It is believed that the iron losses of this particular machine were somewhat excessive, due to a defect in its construction noted beyond.

It is but just to the builder to say that this dynamo was an experimental machine and the performance cannot be used as a criterion on which to base the efficiency of similar machines now offered to the trade.

The results of the friction test can be summarized as follows: The power supplied was measured while no current was being drawn from the machine. The average power consumed by bearing and brush friction is equal to .268 h.p., and that consumed by hysteresis and Foucault currents and friction losses when the machine was independently excited to a potential of 100.3 volts across each pair of brushes was found to be equal to 1.75 h.p.

In subsequent tests the losses were eparated, the results being shown in Figs. 4, 5 and 6. In Fig. 4 the losses are shown with both pair of poles connected in parallel and independently excited. In Fig. 5 the same losses are shown with the cross poles independently excited, and in Fig. 7 with the adjacent poles independently excited. The loss due to eddy currents is believed to be somewhat greater than it should be, owing to the fact that the armature was notched with a dull milling cutter, which somewhat impaired the insulation between the individual laminæ.

The external characteristics of the machine were also investigated, the results being shown in Fig. 6. The longer line shows the relative values of current and voltage of the machine connected in ordinary single-circuit fashion. Line 2 shows the external characteristics when the load was divided between A and B, the load on B being constant, while that on A was varied from 0 to 70 amperes, and line 3 shows the external characteristics when current was drawn from circuit A only, circuit B remaining open. These lines are practically straight, although plotted from no less than eight different points in the case of the shorter line and ten different points in the case of the longer line. Each of these points was the average of their readings. The drop in voltage seems to be almost exactly proportional to the amount of current drawn from the machine. The conclusions to be drawn from the results of the tests are as follows:

The commercial efficiency of the machine when connected as a multipolar single-circuit dynamo at a load of 13½ k.w. is 87.1 per cent.

When connected as a multi-circuit dynamo at a load of 13.9 k.w., it is 85 per cent.

When connected for multi-circuit work having no load on circuit B and 6.4 k.w. on circuit A, the commercial efficiency is 81.9 per cent.

The h.p. absorbed in eddy currents and iron losses and friction with all the pole pieces excited is 1.8

The h.p. absorbed in the same losses with two adjacent poles magnetized is 1.23.

The increase of friction with the entire load on one circuit is .28 h.p.

The results of these tests seem to show that the multi-circuit machine is entirely commercial, and that it can be used in many places with great economy, and it seems safe to predict that the day of its introduction in practical work is not far distant.

Types of American Lightning Arresters.

BY HENRY R. RAYMOND.

It has occurred to me that the great dissimilarity in the appplication of similar principles involved in the design of lightning arresters would prove a subject of peculiar interest. The idea of a gap for the discharge to jump, and a preventing or curing arrangement to look after the ensuing rush of dynamo current, seems to have entered different minds from widely different directions, and I have endeavored to give as impartial a description of these differences as possible. It is not the intention of this paper to give any comparative values, and it is probable that what some of the devices lack in one respect they make up in others, and that some makes are peculiarly adapted to certain applications and service, while others are better adapted to other uses. I do not think it wise to attempt the employment of any one type of arrester for both direct and alternating currents.

It will be noticed that but one company recommends the installation of any great number of arresters at any one point, and that further advises a comparatively scattered distribution along pole lines. The more general practice seems to be in the installation of but one arrester for each wire where it enters buildings. It seems that, except for unusually severe conditions, it would hardly be necessary to bunch a number of arresters at any one point, but it is true beyond doubt that under no conditions of overhead operation should lines be protected by a single arrester at either extremity. The exact number and location should be determined for each individual case, no general directions being effectively applicable. The further use of coils of wire wound in series with the line to act as choking or impeding devices is also generally recommended. There are some conditions under which it is advisable to use these impedance coils, but there are others where it would be decidedly of negative value, and more under which little dependence might be placed upon them. In their place they are good, but I think that the general use of these coils is to be discouraged. It is too often the case that coils are placed in circuit, and so much dependence placed upon them that a thorough and intelligent arrester installation is neglected.

The Westinghouse Electric & Manufacturing Company put out an arrester that is self contained in all its action, and depends on no auxiliary devices to present a following arc of dynamo current. The discharging value depends upon the proximity of the electrodes, which are placed as close together and are as few as the designs of the arrester will allow: The non-arcing feature depends upon certain properties of the metals themselves. The total air gap is as small as the arc suppressing qualities of the metals will allow, and in order to prevent the passage of dynamo current the electrodes are made of a composition of certain metals as an alloy. The principal idea of the apparatus is to furnish, in as simple a form as possible, a minimum resistance to the static charge, and a non-arcing device per se.

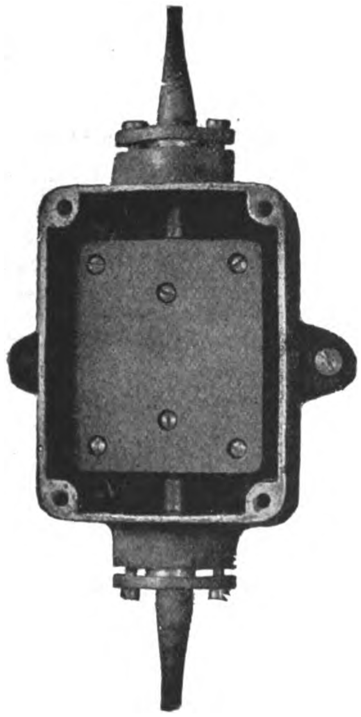

FIG. 1—RAILWAY LINE ARRESTER IN IRON BOX. WESTINGHOUSE COMPANY.

The entire dependence upon the non-arcing properties of the electrodes to prevent an arc from following the discharge, increases the necessary air space slightly, but does not do so to a prohibitive extent, and the potential necessary to start a spark across the gaps is less than with some types on the market.

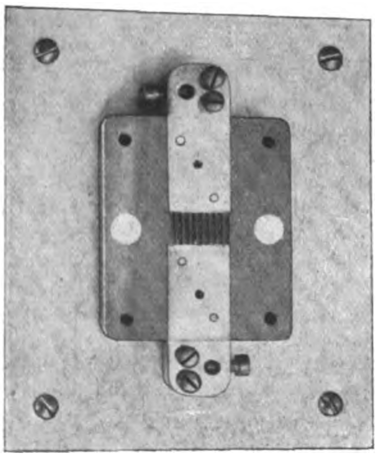

FIG. 2.—RAILWAY STATION ARRESTER. WESTINGHOUSE COMPANY.

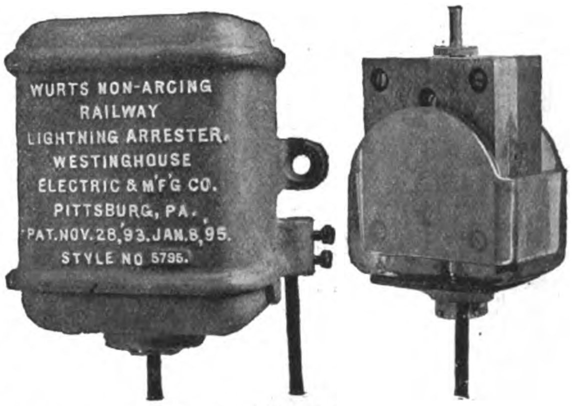
Naturally the applications of direct and alternating currents to electrical work demand separate treatment, and this branch of apparatus is not exempt from the general rule. Therefore their arresters are divided into two classes, both, however, based upon the same main principle. The direct current arresters consist of two blunt metal blocks, or "points," which are separated about ⅛ in. These are screwed to a wooden block so as to be flush with the same. The center of this block is slightly charred in little grooves running from the points of the dischargers. This charred wood offers a resistance of about 50,000 ohms, and serves simply as a surface over which the discharges may pass at a pressure much lower than would be required to bridge the gap alone. Another block of wood fastens over the one with metal dischargers, and fits so snugly that the non-oxidizing vapors are confined in the gap. The complete inclosure prevents the volatilization of the metal and the consequent arc. Fig. 1 shows the line type of this arrester in an iron box, with the gap cover still in place. Fig. 2 shows the station type with the gap and charred wood exposed. These types are made in single pole form only. The form of the iron box inclosing this type of arrester being subject to the action of water, should the upper packing become loose, a more effective form was designed, Fig. 3 and Fig. 4. This is modified only in the outer form, the case being an inverted iron box in which the arrester, setting in a glass cup, is inclosed. The ground connection is made directly to the iron case, the arrester being well insulated by the glass cup. In some localities where good grounding is uncertain it is advisable to use temporary but direct grounds, not depending on the gaps entirely. In order to make it a convenient proceeding the Westinghouse Company has produced an arrester, Fig. 5. which connects to the ground through a water resistance. This resistance is contained in a three sectioned tank lined with galvanized iron. A water pipe connection is made which constitutes the ground terminal as well as the means of supply. A small quantity of water is continually flow-



FIGS. 3 AND 4.—PERFECTED FORM RAILWAY LINE ARRESTER. WESTINGHOUSE COMPANY.

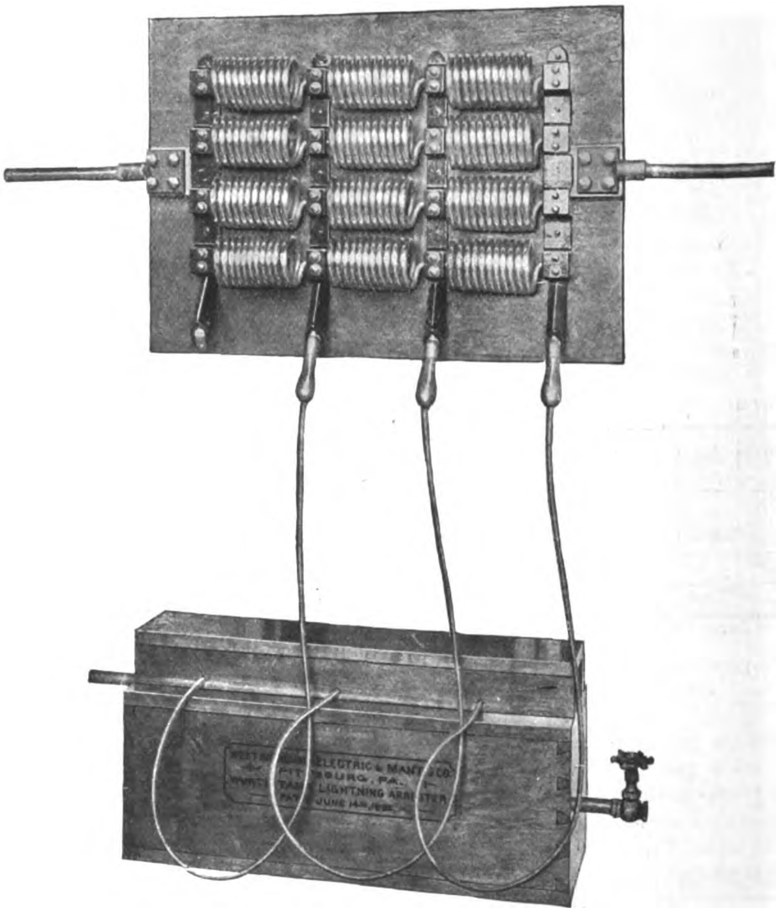


FIG. 5.—TANK ARRESTER, RAILWAY STATION. WESTINGHOUSE COMPANY.

ing from one tank to the other, in such a manner as to make a complete circulation and prevent the forming of salts. The line terminals are flat carbons, suspended in the middle of each compartment. Line connections are made by plugs and flexible cables leading to a choke coil board. The leakage under ordinary conditions is about 3 amps. The plug connections facilitate disconnecting during fair weather.

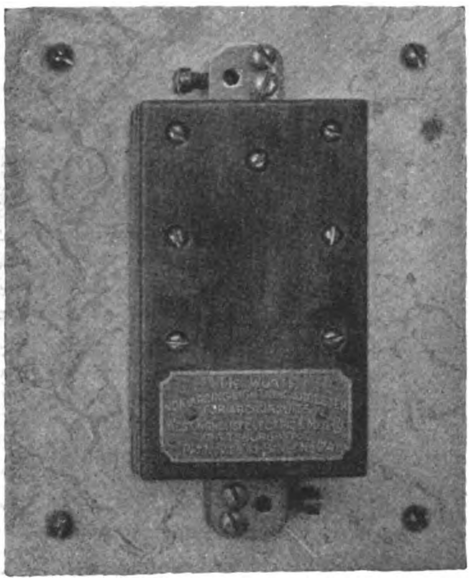

FIG. 6.—ARC ARRESTER, ARC CIRCUIT. WESTINGHOUSE COMPANY.

The arc circuit arrester is shown closed in Fig. 6. This device is practically identical with the 500-volt direct-current arresters shown in Figs. 1 and 2. As it is intended to be used on arc circuits at voltages up to 4000, provision is made for the increased pressure. The gap is not proportionally lengthened, because the current is small and limited.

The alternating current arresters are made likewise of "non-arcing metal," but differ in form, in the length of air space, and in the absence of any conducting material between gaps. In standard form, as represented in the cut shown herewith, they consist of seven cylinders separated 1-64 in. These cylinders are 1 in. in diameter and 3 ins. high. Their surfaces are knurled, possibly for looks, possibly for greater ease in turning them in order to expose different portions, but probably to introduce a number of minute points into the discharge path. The seven point, six gap arrester is designed to be used as a double pole device on 1000-volt circuits, and as a single pole one where the pressures are 2000 volts.

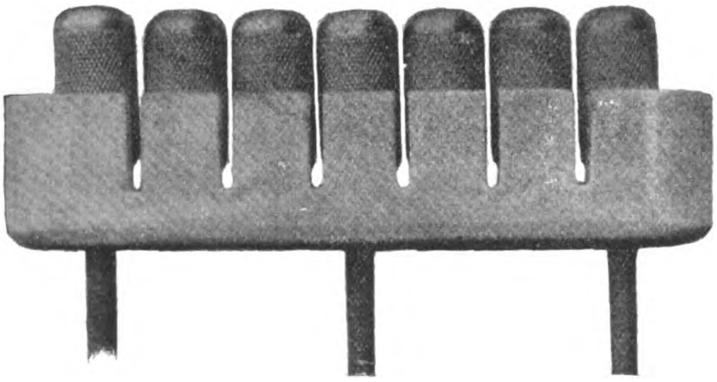

FIG. 7.—CYLINDERS ENCLOSED IN PORCELAIN. WESTINGHOUSE COMPANY.

These arresters in detail consist solely of the metal discharge cylinders and the porcelain or marble support for the same. In the form used for line work, Fig. 7 illustrates the method of holding the cylinders in place. The lower part is assembled by simply placing the dischargers in the hollows molded for them in the porcelain base. The top half slipped on and the arrester complete in an asbestos lined iron box is shown in Fig. 9. The station form, Fig. 8, is not inclosed, and instead of porcelain marble supports the dischargers. These are bolted axially to two marble slabs, which in turn are bolted to the base slab.

The manufacturers of these arresters claim that the method and location of the insallation of arresters is of importance equal to the effectiveness of the type, and it certainly is true that location is one of the vital points in any lightning protecting scheme. They claim that a "flash" of lightning and its kindred disturbances are not simple direct discharges to the earth, but that they are vibrations of enormous frequency and uncertainty of repetition. They state that the discharges do not come with any regularity, and are seldom in unison, believing that the oscillations of one discharge will be acted upon by those of the one preceding or following. Like waves of water, there will be presented both crests and troughs, and when the crests are at one point the resultant will be much higher than either, and that when a trough and crest are coincident the resultant will be a flat or level spot, one partially neutralizing the other. The general effect is supposed to find its analogue in the action of a choppy sea. It is further held that these "choppy" or "splashing" places may be and are very close together, and that they may pass along a line in this state of confusion. If a single arrester per line were the sole protection it is evident that its connection might be at one of the low spots, and that the potential at this point might be too low to bridge the gap, and also that the machine might be at the high point and break down with the resulting pressure. It would appear then that it were necessary to locate these nodal points and so arrange our system that an arrester would be at the crests and the machinery to be protected at the troughs. The claim is that the splashings are constantly shifting about, and that no definite location for their occurrence can be determined. On account, therefore, of this shifting of pressure peaks it is their custom to install such a number of arresters that one at least may always be at a point of high pressure; and to accomplish this they recommend the practice of banking them or placing them in compact groups in multiple on each line.

FIG. 9.—ALTERNATING ARRESTER IN IRON BOX FOR LINE USE. WESTINGHOUSE COMPANY.

It is common belief that coils of wire in the main line are of advantage in retarding the passage of a high frequency discharge, and this company generally advises the use of these coils in series with the line, so located that an arrester and coil will alt.rnate, as in Fig. 11, which shows one end of a 2000-volt 3-wire power transmission system with bank of arresters and choke coils. Figs. 13 to 17 represent a method they devised to economize on the number of arresters and still have the bank form providing for the selective paths. Each circle represents a coil, each rectangle a unit arrester. Fig. 13 shows four coils in series and one and one-half arresters to ground. Fig. 14, five coils in series and two and one-half arresters to ground. Fig. 15, six coils in series and four arresters to ground. Fig. 16, six coils in series and five arresters to ground. Fig. 17, six coils in series and seven arresters to ground. It will be noticed that in this way about 50 per cent of the installation is saved, and still no lessening of chances favoring the choppy sea idea. They make these forms of installations in a compact form styled type R, the entire combination being mounted in a hardwood crib or frame.

FIG. 12.—ARC ARRESTER, FORT WAYNE CORPORATION.

Any description of the "Wurts" apparatus which is manufactured by the Westinghouse Company would be incomplete without a mention of the peculiar properties of non-arcing metals and their discovery by Mr. Wurts. He conceived the idea that a device which, when the discharge was followed by dynamo current, instantly short-circuited the system and as quickly removed the short circuit, would effectually prevent the sustenance of the arc. He placed some carbon discharge points across the terminals of an alternator. This gap was 1-16 in. in length. In shunt with the same was a device which was to short circuit the system and at once open again. The current was thrown on and the test showed partial favorable results. It was found that the carbon dischargers would heat to such a degree that an arc would start again across the heated vapor and keep the affair in continuous operation. Trying to overcome this trouble by the use of metal instead of carbon, he found that some metals would interrupt the passage of current without the short circuiting device, and that others would melt like butter. Further investigation brought to light the fact that the composition of the metals was the leading factor, and that alloys of zinc and antimony were the most common possessing this property. The principal metals consist of zinc, cadmium, mercury, antimony and bismuth, and their alloys or amalgams. It was further found that the dischargers must be within a certain distance to exhibit this property, and preferably of such shape and position that any vapor would be held in the gap. The explanation is that the heat of the incipient arc volatilizes a small portion of the metal, and that the oxide so formed is non-conducting. This non-conducting vapor when confined between the terminals offers a barrier of so great a resistance to the arc that its maintenance is impossible.

The "Wood" arrester, manufactured by

the Fort Wayne Corporation, is one of the type depending upon mechanical movement to break any following arc. The arrester, Fig. 12, is for use on arc circuits. As is evident from the cut, the circuit is so arranged that both line and machine terminals connect to the lower part of the arrester. The ground path from thence consists of the two gaps, the lever and the upper contact, which is in direct connection with the ground wires. As shown in the cut the arm is "open." When in normal inactive condition, however, it hangs in a vertical position, so that the upper points of each gap stand directly over each of the lower terminals. When a discharge passes the described path, it is followed momentarily by the dynamo current. The magnet is connected across the upper gap, and the drop across this gap drives enough current through these coils to draw down the armature attached to the arm. This movement throws out the lower end of the arm, which draws out the arc to such an extent that it is at once broken.

ARMATURE WINDINGS AND CONNECTIONS.

TELESCOPE WINDINGS.

BY PROF. ARTHUR L. RICE.

In some dynamos, which are to be used for low voltage and for large currents, as, for instance, machines which are to furnish current for electro-plating purposes or for welding machines, it becomes a difficult matter to make the conductors and commutator bars sufficiently large to carry the current without dangerous heating. For such machines the telescope or multiple winding is adopted. In principle this consists of several separate windings, with the conductors and commutator bars of the several windings arranged side by side on the same armature, but not connected. The windings are then put in parallel by the brushes, which extend over as many bars as there are separate windings. Two windings in parallel are called a double winding, three a triple winding, and so on.

Three or four separate circuits are as many as will usually be necessary to carry the current safely; of course the fewer there are the less the complication of the armature. On the other hand, for large currents, the more wires used in parallel the smaller can be the wire, and a small wire winds on much more easily than a large one. Also, it is much easier to build up a mechanically good commutator if the bars have sides which are not too far from parallel than if they are quite decidedly wedge shaped. If few bars are used for large currents they must have large bearing surface, and that means that the commutator must be of large diameter or of considerable length, or else must be made of bars which are thick at the outside and thin at the inside edge. None of these conditions are good either from the standpoint of mechanical construction or from that of cost. It is better to use several bars in parallel, and the easiest way to do that is to use several windings on the armature.

Suppose that the case be taken of a four-pole machine to be wound as a four-circuit machine with a triple telescope winding; forty-eight conductors in two layers. There will be 48 ÷ 3 = 16 conductors in each winding; this makes eight coils, and therefore eight commutator bars will be needed per winding, or 8 × 3 = 24 bars in all. If this is to be a wave winding the pitch will be either; 16 = 4 × pitch + 4; 12 = 4 × pitch; pitch = 3; or 16 = 4 × pitch − 4; 20 = 4 × pitch; pitch = 5. Let 5 be taken as the pitch both front and back.

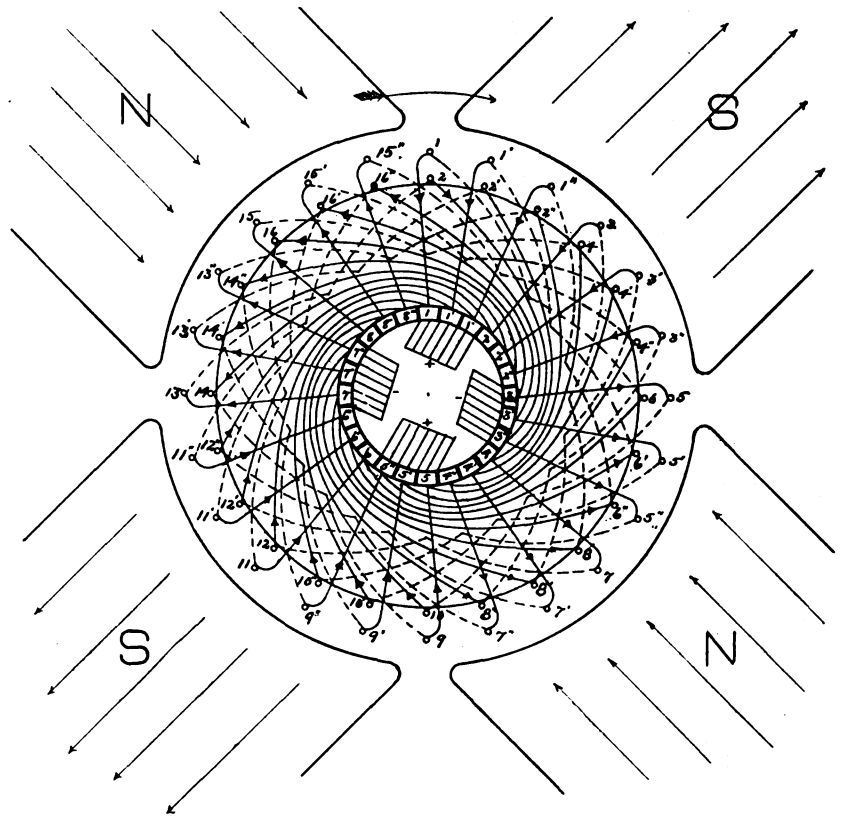

FIG. 1.—FOUR-POLE, FOUR-CIRCUIT, TRIPLE WAVE WINDING; DRUM ARMATURE.

Turning for a moment to Fig. 1, and starting at bar 1, every third conductor and every third bar will belong to one winding; i. e., those numbered 1, 2, 3, etc. The same will be true if 1′ be taken as the starting point, and 1′, 2′, 3′, etc., will be included in the second winding; the same is true for the third if the start be made at 1″.

For the first winding the connection is from:

Bar	1	to	Cond.	1	to	Cond.	6	to
"	6	"	"	11	"	"	16	"
"	3	"	"	5	"	"	10	"
"	8	"	"	15	"	"	4	"
"	6	"	"	9	"	"	14	"
"	2	"	"	3	"	"	8	"
"	7	"	"	13	"	"	2	"
"	4	"	"	7	"	"	12	"
"	1							

and a closed circuit has been formed. The directions of the e.m.fs. may be traced and the positions of the brushes determined as shown in Fig. 1.

If the second circuit be now considered, the connections will be:

Bar	1′	to	Cond.	1′	to	Cond.	6′	to
"	6′	"	"	11′	"	"	16′	"
"	3′	"	"	6′	"	"	10′	"
"	8′	"	"	15′	"	"	4′	"
"	5′	"	"	9′	"	"	14′	"
"	2′	"	"	3′	"	"	8′	"
"	7′	"	"	13′	"	"	2′	"
"	4′	"	"	7′	"	"	12′	"
"	1′							

and another closed circuit has been formed. The same process, starting at bar 1″ will result in the third closed circuit.

The three lie side by side on the armature and may be connected in parallel by brushes which join the three bars, 1, 1′, and 1″, so that there will be safely available three times the current which one winding could furnish, at the same voltage as would be given by the single winding.

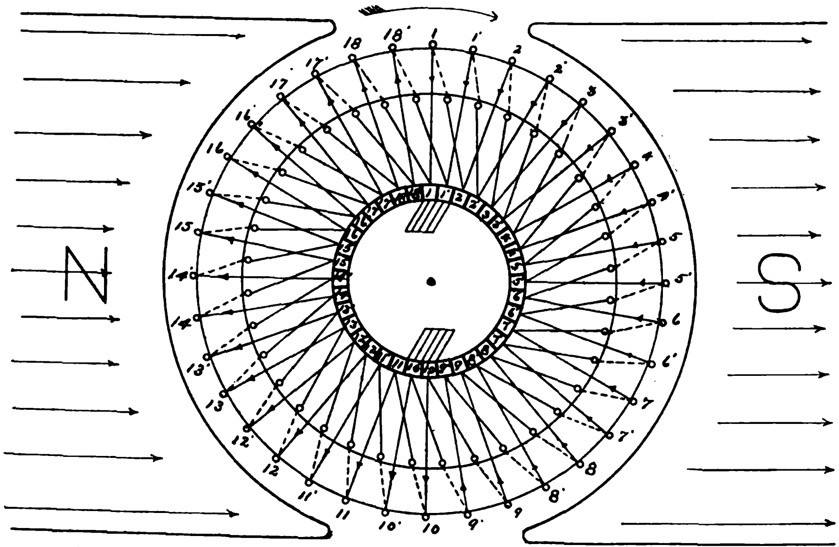

FIG. 2.—TWO-POLE, DOUBLE WINDING; GRAMME RING ARMATURE.

For another illustration, let there be taken a two-pole ring wound machine with thirty-six conductors in a double winding. Remember that, for a ring armature, the conductors are counted only on the outside of the core, and that a conductor stands for a coil. There will be $36 \div 2 = 18$ conductors or coils, and eighteen bars per winding, or thirty-six bars in all. Every other coil and bar will be part of one winding, and the alternate coils and bars parts of the other winding. Each coil will be connected to the ones in the same winding next it on each side through leads to the commutator.

Referring to Fig. 2, starting at bar 1, the connection goes to coil 1, then to bar 2, to coil 2 and so on around to bar 1. For the other winding, starting at bar 1′, the connection goes to coil 1′, then to bar 2′, then to coil 2′, and so on around to bar 1′ again, forming a second complete circuit. The two circuits are put in parallel by broad brushes covering at least two bars. From this winding there could be taken twice the current which would be available from a single winding, and at the same voltage as would be given by the single winding.

There is a limit to the application of this principle of telescope windings, which is indicated by the fact that the two windings of the second illustration do not occupy equivalent positions under the poles. It is still more noticeable in the first illustration, where the winding 1, 2, 3, etc., has quite a different position in relation to the poles from that of the winding 1″, 2″, 3″, etc. If the subdivision into parallel windings be carried very far, the difference in position and the inequality of the strength of the field at different points under the pole faces will result in the production of unequal e.m.fs. in the several parallel circuits, and there will be a tendency for current to flow from one to the other, causing bad sparking at the brushes. But, if there are not more than four circuits in parallel, and if the distance from a conductor of the first winding to the corresponding conductor of the last, i. e., 1 to 1″ in Fig. 1, be small, as compared to the width of the pole face, no serious trouble will ensue from the use of this form of winding.

◆

THE ELECTRIC SIREN.

In electrically propelled conveyances, such as cars, automobiles, locomotives or electric launches, there has always been a tendency, if some signal device akin to a whistle was desired, to provide a motor and air compressor for its operation. The noise produced by the device is not intended to delight the musical ear, but rather to act as a long-distance warning, and it seems strange that in this connection no one has thought of an electric siren built on the following plan:

It is a well-known fact that any magnet excited by alternating current emits a humming noise. If a thin sheet of iron be placed over it for immediate contact, the volume of sound will be a revelation, and if the iron sheet is mounted with a frame so as to form a diaphragm and the magnet be made sufficiently powerful and operated at a suitable frequency, a most piercing, penetrating noise is emitted, which can be heard for miles, and especially is this the case if the sound thus emitted is collected and transmitted by some device of the megaphone character. A very small rotary transformer will serve to supply the current to operate such an instrument, and would be immeasurably lighter than the electric compressor or equipment necessary to operate an equivalent whistle. The control would be accurate and easy and the pitch of the sound could be modulated, thus rendering a simple and more extensive signal code posible. The sound, it is true, would be weird and uncouth, but scarcely more so than that of modern steam calliopes, which are so popular on high-speed steam yachts owned by wealthy men.

It may be added that steam whistles of all kinds are enormously wasteful of power. For example, a prominent manufacturing company a few years ago reduced the size of the whistle on its works and shortened the time of blowing, because of the serious reduction of boiler pressure caused by operating the whistle for four minutes every morning. Applications have been made to the Government authorities for permission to shorten the length and reduce the frequency of the whistle blasts prescribed by law for foggy weather, because of the serious waste of steam.

When the expensive process of air compression is added to the already wasteful method of using the compressed fluid, it will be seen that the efficiency of the modern whistle in foot-pounds per sound unit, if such conception were possible, is very poor indeed.

The electric siren would always have the advantage of being less likely to get out of order, and water-logging would be an impossibility. It is not an infrequent occurrence for a pilot to be considerably embarrassed on account of being unable to make audible signals due to water in the whistle. For small work, to replace the familiar electric bell, the electric siren is an entirely feasible device. An ordinary telephone receiver attached across a 52-volt alternating circuit will quickly convince the experimenter of the noise-making possibilities of such apparatus. For signalling on board ship, where much depends on the working order of the calling device, such a system presents many advantages. There is no vibrator to get out of order, and the possibility of the failure of the instrument to respond to current is very remote. Shipboard signals are now operated by rotary transformers of direct-current type. Alternating rotary transformers are just as feasible.

Still another advantage of the electric siren is the ability to control it at great distances. The ordinary system of fire bells prevalent in many towns could be replaced by one of electric sirens, which would be controlled directly from current supplied by the local lighting company, without the use of relays or other devices likely to get out of order. The development of the device will be interesting, and the field for it, though not large, is undeniably existing.

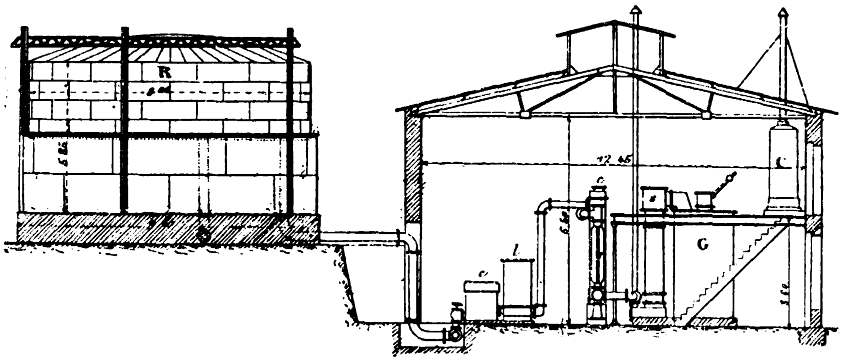
As a unique device for making a barbarous noise on the Fourth of July and similar patriotic occasions, an improvised electric siren has on several occasions eclipsed anything which has ever come to the writer's attention, but it does not seem either impossible or absurd to utilize its power to better advantage in useful fields.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Producer Gas in a Railway Power Station.—An exceedingly interesting installation, in which gas-engines supplied from producers are used, is described in "Le Génie Civil." The high price of coal at Lausanne (Switzerland), where this station is located, necessitated the most careful precautions against waste of fuel, and close consideration of various methods of saving. It was finally decided to use producers and gas engines, the plant having been erected under a strong guarantee that it would show a consumption of less than 1.375 lbs. of coal per h.p.-hour of actual output.

The installation comprises three Crossley two-cylinder gas engines of 130-h.p. each, direct connected to Thury dynamos giving 600 volts at 160 r.p.m. A cross section of the plant through the gas-generating and storing part is shown in the illustration. Two small boilers, C, furnish the necessary steam. The generators, G, are provided with a revolving sole-plate and have no grates. On the sole-plate a thick layer of cinders is laid, the mixed air and steam being injected into the middle of this mass and finding its way out through the fire, which is kindled directly on the top of the cinders. As combustion proceeds the fire burns upward, leaving an increasing thickness of cinders. Once an hour or so the sole-plate is rotated and some of the cinders discharged into an ash-pit, which is emptied about twice a week. The process is entirely continuous. The gas passes from the generator through a system of coolers, washers and purifiers to the gasholder, R, of about 175 cu. yds. capacity.



GAS PRODUCERS IN THE LAUSANNE STATION.

Water for cooling the engine cylinders is kept in a cistern on a nearby hillside, and after circulating around the cylinders is returned by means of a motor-driven pump, its cooling being effected by spraying as it enters the cistern. A battery of 300 cells of Pollok accumulators, of 700 ampere-hours' capacity, completes this admirably economical station.

The system worked comprises 25 cars running on 8.3 miles of track and what are said to be the heaviest grades and shortest curves on any European tramway, the former having a maximum of 11.3 per cent. The plant has been in successful operation for two years. During the first half of the current year the coal consumption is stated to have been 2.05 lbs. per k.w.-hour, this figure including all the coal burned in any part of the plant for any purpose.

Rates of Wages in France.—In a recent number of the "Revue des Transports Parisiens" is published a memorandum of the rates of wages to be paid laborers and workmen engaged upon the new Métropolitain, or underground railway, now being constructed in Paris. These rates are so much less than those commanded by the same labor in this country that they furnish an interesting comparison. The advertised rates are as follows: Foremen, for all classes of work, 17 cents per hour; laborers with pick, shovel or scraper, 12 cents per hour; rollers, hod-carriers, road levelers, rammers, messengers, helpers, etc., 11 cents; stone masons, bricklayers, cement mixers, pavers, 16 cents; second-class bricklayers and firemen, 12 cents; stone cutters, dressers, etc., 18 cents; shaft sinkers, miners and quarrymen, 15 cents; carpenters, glaziers and painters, 16 cents; smiths, horseshoers, wheelwrights, tinners, roofers, plumbers and enginemen, 15 cents; drivers, 10 cents. At night the wages for each of these classes are one and one-half times the rates above. One-horse carts, without driver, are hired at 18 cents per hour; two-horse carts, drays or wagons, at 32 cents, and three-horse vehicles at 46 cents. For men working at night or underground an allowance of 1 cent per hour is made for lights, which the men furnish.

In comparing these prices with American wages the most remarkable difference, after their generally low average, is the distribution of wages and trades. For example, an engineman there receives less than a carpenter and only 25 per cent more than a common laborer.

Magnetic Surveying for Iron Ores.—At a recent meeting of the Iron and Steel Institute at Stockholm, Prof. G. Nordenström read an important paper giving a description of the magnetic survey methods in use in the Swedish iron ore districts. An abstract appears in the (London) "Electrical Engineer." The most usual instruments are Thalén's magnetometer and Tiberg's inclinometer. The former is shown in plan in Fig. 1. It consists of an ordinary compass, similar to the old-fashioned surveyor's compass, provided with a scale graduated from zero to 90 degs. An arm, B, is attached at right angles to the diameter passing through the zero points of the circle, and on this a permanent magnet, C, is mounted so that its distance from the needle may be altered at will. The instrument is used either as a sine magnetometer or as a tangent instrument. For the latter the needle is placed at zero, after the instrument has been leveled and the magnet removed. Then the magnet is replaced and the angle of deviation is read. In using the sine method the needle is adjusted to zero with the magnet in place, and the deviation caused by the removal of the magnet is noted.

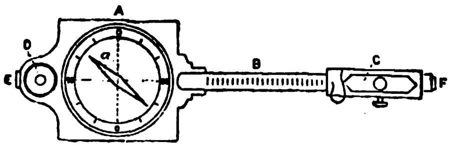


FIG. 1.—PLAN OF MAGNETOMETER.

The Tiberg inclinometer is simply a dipping needle, counterbalanced and provided with a permanent magnet similar to that just described, which compensates for the horizontal component of the magnetic field and allows only the vertical component to act.

To explore a field for ore the ground is staked off into squares about 10 meters (32 feet) on a side, and a reading is taken at every corner of every square with one or the other of the above instruments. If the magnetometer is used a plot of the ground is made and all the points of equal declination are connected together by curves, as shown by the heavy lines on the ideal map. These will be found to be arranged in two systems, grouped with more or less regu-

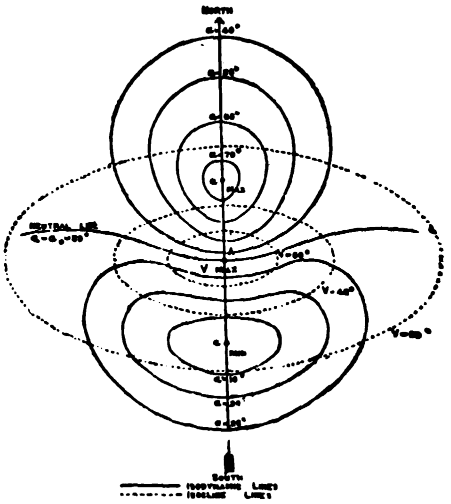

FIG. 2.—IDEAL MAP OF ORE-BEARING REGION.

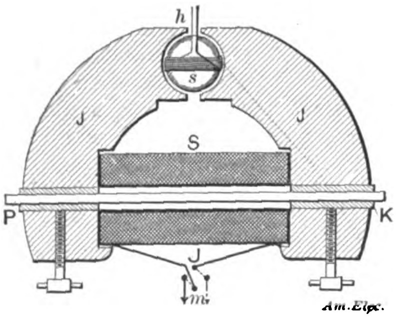
larity around two foci. One of these is the point of maximum declination, and is situated north of the main body of ore, the other being the point of least declination and situated either south of the main body of ore or just above it. Between the two groups of closed curves is one open curve, called the neutral line, and whenever certain conditions of the angular value of the minimum and mean deviations are satisfied the main body of ore is situated at the intersection of this line and the line connecting the maximum and minimum points.

With the inclinometer similar curves are plotted, shown on the map as dotted curves. These will be found to be grouped concentrically around a point below which is the greatest mass of the ore.

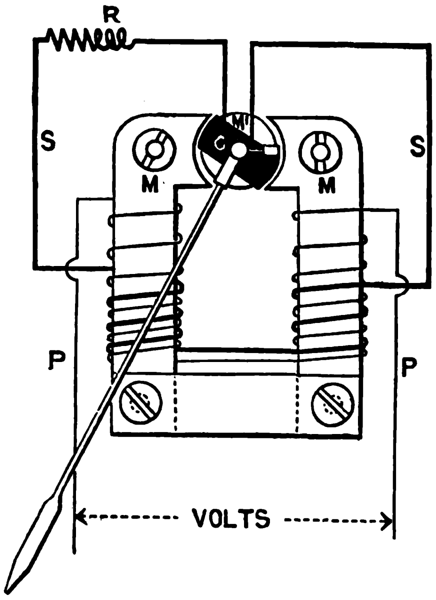
These methods are said to work as well in Southern latitudes as in Sweden. Of course this method of survey is only applicable to a magnetic ore, but as large quantities of magnetite are found in this country it is possible that the simple instruments described above may be found useful.

An Industrial Permeameter.—A new form of instrument for measuring the magnetic constants of samples of metal is described and illustrated in "L'Electricien." The principle of the instrument is similar to that formerly employed by M. Marcel Deprez, and consists in reversing the action of a Deprez-d'Arsonval galvanometer. The figure shows the instrument in plan. Between two stout polar pieces of iron, J J, is a movable coil of the d'Arsonval pattern, s, through which a constant small current is allowed to flow. Clamped securely between the polar pieces is the sample to be tested, P K, which consists of a bar of the metal carefully turned to size. This is surrounded by a magnetizing coil, S. On the polar pieces, J J, are wound also coils of a few turns, not shown in the illustration, which are used to compensate for the disturbing effect upon the magnetic circuit of the current in the movable coil. A coiled spring tends to maintain the needle attached to the moving coil at its zero position, and the deflections caused by currents of known intensities in this coil and the magnetizing winding, S, furnish the data from which the permeability of the specimen under test is calculated. The instrument is said to work very satisfactorily up to inductions as high as 20,000 gausses in the specimen.



INDUSTRIAL PERMEAMETER.

A New Alternating Current Voltmeter.—Mr. Arthur C. Heap describes, in the (London) "Electrical Review," a new form of alternating current ampere or voltmeter, designing to be free from errors due to wave form or periodicity. It consists of a magnetic circuit of laminated iron, as shown in the illustration, the yoke part being made removable so that the coils can be slipped on. In the space between the poles is a cylinder of laminated iron, leaving a small air gap on each side. In this space turns the pivoted coil, C. A winding of fine wire on the frame is connected with the source of current to be measured. Over this is wound a coil connected with the turning coil, C, and a resistance, R. The secondary current induced in the coils on the frame passes through the pivoted coil, which is thus caused to move in the field due to the primary turns. In order that the indications may be free from errors due to wave form and periodicity it is necessary that the magnetic leakage should be small and remain constant, hence the air gap is made as small as possible. The instrument is said to be remarkably constant and free from errors.



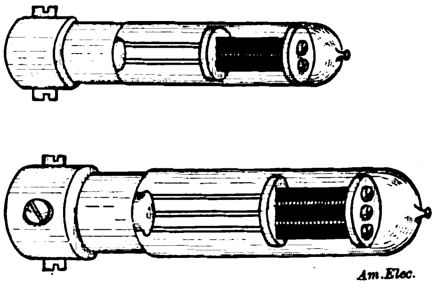
AN ALTERNATING CURRENT VOLTMETER.

Relative Costs of Conducting Wires.—In the (London) "Electrical Review" Mr. John B. C. Kershaw reviews the present comparative costs of copper, iron and aluminum conductors for equal electrical conductivity. He takes issue with recent publications on this subject, in which it is claimed that aluminum and copper for the same conductivity are about equal in cost, since this assumes the conductivity of the aluminum to be that of metal 100 per cent pure. Mr. Kershaw takes the present market prices as copper, 12.064 cents per pound; aluminum, 32.1914 cents per pound (the conductivity of the metal being taken as 0.59 that of copper, or that belonging to 99 per cent aluminum). Iron is taken at £3 12s. per long ton, or 0.783 cents per pound, and its conductivity at 16.4 per cent of that of copper. To the cost of iron is added 38 per cent for rolling. The following figures show the comparative costs, as calculated, for conductors of the same conductivity:

Aluminum, 99 per cent	375
Copper, electrolytic	278
Iron, rolling cost included	100

Vacuum-Tube Lamps.—Herr H. Ebert describes in "Wiedemann's Annalen" (abstracted in the "Electrician") some experiments upon the current consumption of vacuum-tubes. He used high-frequency alternating currents, not obtained in the usual way by the oscillating discharge of a condenser, but directly generated by a dynamo of special construction giving a frequency of about 1000 cycles per second. A step-up transformer was included in the circuit, the pressure at the terminals of the tubes being 1000 to 2000 volts. For a long discharge tube the following results were obtained: Continuous current: volts, 64; amperes, 1.81; watts, 116. Low pressure alternating current: volts, 33; amperes, 1.05; watts observed, 27; C^2R losses, 1.3; hysteresis loss, 1.0; phase displacement, 50 degs. 29 min. High-pressure alternating current: Volts, 2200; amperes, 0.01; C^2R losses, 1.4; consumption of tube, 20.6 watts. This tube gave a perfectly steady light of about 16 c.p. The actual watts consumed compare very favorably with the incandescent lamp, but not so the apparent watts.

Lightning Arresters for Feeble Currents.—The difficulty of properly protecting telephone, telegraph, and other lines using currents of small intensity against lightning has given rise to some very ingenious instruments, among which may be classed the two described in "L'Eclairage Electrique." In one of them the air-gaps are made between a pile of thin, flat carbon plates, separated by thin and narrow strips of mica. A considerable number of these plates are piled up, alternate carbon plates being connected to the line and to the earth. If both sides of a circuit are to be protected the earth plates alternate between those of opposite polarity. This arrangement is said to give excellent results on account of the large exposed surface of the carbon plates.



VACUUM LIGHTNING ARRESTER.

A more ingenious instrument is the vacuum arrester illustrated herewith. Two or three small carbon blocks with serrated edges, separated by a very small interval, are sealed up in a glass tube from which the air is partly exhausted. The well-known property of a partial vacuum for the conduction of high tension currents is utilized, the instrument allowing accumulated charges of high potential to leak off and silently discharging the line. Another glass tube containing a platinum wire of about No. 34 gage is connected in series with this arrester to act as a fuse in case of a cross with a line carrying heavy current at high tension.

The Influence of the Silent Discharge on Air.—The (London) "Electrical Review" abstracts and comments upon Messrs. Shenstone and Evans' paper on the results of their researches into the alteration of the chemical composition of air under the influence of the silent discharge, recently read before the Chemical Society. It appears that the formation of nitric peroxide as well as ozone has been for a long time well known. After describing a method adopted for the detection of this nitric peroxide in the presence of ozone, the authors seek to answer these questions: What is the highest yield of ozone that can be obtained from air under the most favorable conditions? At what stage is nitric peroxide first formed, and what is its subsequent history? What influence has moisture on the various phenomena under investigation? The conclusions are summarized as follows:

Oxygen, when diluted with nitrogen, furnishes a larger proportion of ozone than the pure gas, the proportion ozonized being as high as 98 per cent of the total oxygen present. If the process of ozonizing air is not carried too far nitric peroxide will not be formed. At a certain stage in the ozonizing process, depending upon the temperature and the amount of water vapor present, the nitric peroxide begins to appear. The presence of water vapor is highly favorable to the process of ozonization. As soon as the nitric peroxide appears the ozone rapidly disappears, it and the peroxide gas having a mutually destructive reaction. The destructive effect is not noticed at temperatures below the freezing point of water, except under the influence of the silent discharge. The potential difference used in these experiments was 13,000 volts. It was not found possible to say what proportion of nitric acid is formed by the action of the nitric peroxide upon the water present, but the authors seem to lean to the view that no appreciable quantity is generated.

Long Sparks.—M. Toepler describes in the "Journal de Physique" an arrangement by which he obtained sparks about 6 ft. long. Each terminal of a powerful Toepler influence machine is connected to one of the coatings of a battery of condensers, the other two coatings of the two batteries being connected through the primary of a high-frequency transformer. The secondary terminals of this are in contact with one side of a large glass plate, the other side of the plate being covered with tin amalgam. Sparks leap along the surface of the glass, some of them thus produced by the author being over 6 ft. long.

Alternating Current Heating Apparatus.—Some new types of electric heating and cooking apparatus are described, in "L'Eclairage Electrique," by M. R. B. Ritter, their peculiarity being that they are for use on alternating circuits only and that they utilize Foucault currents set up in heavy masses of metal or in the body of the utensil itself, and do not depend upon any C^2R heating of the conducting coils for their operation. Fig. 1 shows a cooking utensil in plan. Coils S S are wound on the laminated core M M, and the vessel, G, of massive iron, is placed in the polar opening. It is traversed by heavy currents and is also heated somewhat by hysteretic friction. The shields J J are inserted to protect the coils from excessive heating. A simple form of smoothing-iron is shown in Fig. 2. The base of the utensil is a solid iron casting, and on this rests the laminated core, E, carrying the coil, S. Copper rings, K K, contribute to the circulation of current in the apparatus. A very satisfactory form of water bath is shown in Fig. 3, the heat being produced in the heavy cast-iron rings surrounding the coil, S. In the case of this instrument and the smoothing-iron described above the insulation of the coil must be fireproof. In the utensil shown in Fig. 1 it need be only of ordinary material and the wire may be made, in all cases, much larger and less delicate than in apparatus working on the usual principle under commercial voltages.

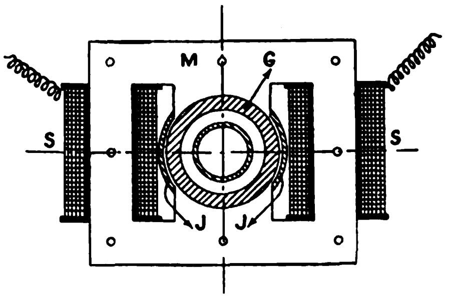


FIG. 1.—ELECTRIC COOKING UTENSIL.

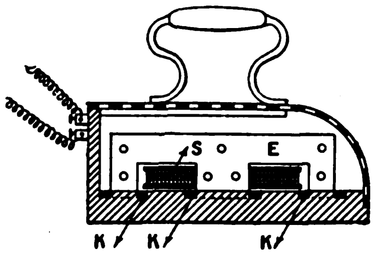

FIG. 2.—ELECTRIC SMOOTHING IRON.

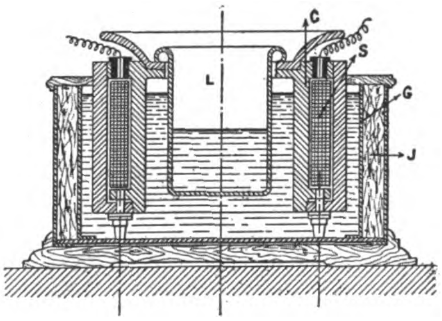

FIG. 3.—ELECTRIC WATER BATH.

The New Telephone Exchange in Paris.—Mr. Mervyn O'Gorman describes, in "Lightning," the new La Villette telephone exchange in Paris. Situated in a trade center, it is the busiest exchange in the city. The exchange is arranged to handle 9000 subscribers and is trunked to all the other exchanges and sub-exchanges in the city. The Adhémar multiple board is used, consisting of jacks in parallel, without test keys, and with indicators that are automatically reset. Each jack consists of two springs for the line circuit and one ring for the test circuit. The plug has three corresponding parts and is attached to a three-conductor flexible cord. The calling and disconnection signals are placed on the upper part of the board behind glass, which protects them from dust and moisture. The arrangement is such that when a jack is plugged the corresponding calling drop disappears and its coil is cut out from the line. This effectually prevents weakening of the talking current by bridging through the drop and also cross-talk due to the mutual inductive actions of the drop coils, which are very close together. The test circuit used to see if a line called for is in use is entirely local, being completely disconnected from the talking circuit, so that there can be no interference with the conversation or "listening in" by the attendant. On the trunking lines to the other exchanges an automatic indicator is used, multiplied at each section of the board and showing the operator which of the various circuits is in use. By this means there is no loss of time in testing the trunk circuits to see which one is free when a connection to another exchange is desired.

Electrical Canal Towage.—The (London) "Electrical Review," in a long editorial on electric haulage in connection with canals, calls attention to some facts that seem equally pertinent to American conditions. The lack of any system of trunk-line canals, the popular interest in railways at the time of their first development, and the fact that the canal interests fell into the hands of railway managers, all contributed as factors to the decay of the British canal system. There is no reason why heavy freight may not be transported cheaply by canal if some reasonable and economical system of towing is adopted. The Thwaite system, now being exploited in Great Britain, consists of an "electric horse," or truck, running on a tramway or aerial structure on the tow path and hauling the boat with a tow line in the time-honored manner. The striking advantage of this method of transporting goods is that there are no grades on a canal. There is no necessity for a motor of large power, as canal speeds can never be high and but a few h.p. are needed to move a great weight of freight. With the electric motor the problem of attendance is solved. The horse requires a driver, but the motor may be controlled from the boat.

The problem of electric canal navigation is an important and promising field for study. While we have not, in this country, the vast network of canals that is a feature of the countries along the North Sea and the British Isles, we have important systems which have, like those in England, fallen into disuse and are too often allowed to go to pieces for lack of proper repair. A system of cheap electric towage would make the canal again a factor of prime industrial importance.

A Long Underground Telegraph Cable.—The following details of what is said to be the longest underground telegraph cable are taken from the "Mechanical Engineer." The cable is now being laid between London and Birmingham, the distance being 105 miles. It consists of 76 copper wires, each insulated with brown paper. The cable is lead encased, its finished diameter being 2½ ins., and is drawn into a 3-in. iron pipe laid about 2½ ft. below the surface of the ground. Sections 450 ft. long are made up, connection between the conductors being made by a small piece of copper tubing fitting neatly over the ends of the wire, which are soldered fast in place in it. At intervals of 5 miles the cable is brought up into a testing box mounted on a cast-iron pillar. These pillars also contain apparatus for pumping chemically dried air into the cable to dry out any moisture that might enter through an imperfection in the lead casing.

It is a pity that some of the main telegraph lines between our great cities are not laid in this substantial fashion. It is safe to say that no "blizzard" will ever interfere with the working of the magnificent line described above.

The Largest Induction Motor.—There was recently completed at Baden what the "Mechanical Engineer" says is the largest induction motor in the world. The machine weighs 27 tons, runs at 544 r.p.m. under full load at 2500 volts and 46 cycles, has ten poles, and gives 1000 brake h.p. The stationary part is the usual ring, mounted upon slide frames. The rotor has its shaft hollowed out at one end for the connectors to pass out to the starting collector rings. Heavy end plates closing the motor can be moved out along tracks to expose the interior for cleaning or repair. The motor will be used to operate a large centrifugal pump to be installed in the municipal pumping plant of the city of Geneva.

The Concourse of Automobiles at Paris.—In the early part of the past summer there was held in Paris a concourse of automobile vehicles under the auspices of the Automobile Club of that city. The various vehicles were given an elaborate series of tests of all sorts and the report of the commission having in charge the experiments has just appeared and been published at length in "Le Génie Civil." It is probably the most important contribution to the literature of motor vehicles, and contains much of interest to electricians. The electric vehicles exhibited bore away the palm, not only for speed and ease of control, but as well for long radius of action and good hill-climbing qualities. The data of the accumulators used goes to show that the French manufacturers are producing storage batteries of excellent performance. The constants of a vehicle of medium class are as follows: The vehicle was a closed coupé seating normally two persons and a driver. Its weight was 3894 lbs., including passengers, of which 81.6 per cent was the weight of the vehicle and accumulators. The batteries were of a seventeen-plate type, the rubber cells being about 5 ins. x 6 ins. x 12 ins. over all, and the forty-four cells carried weighing 1005 lbs. Speeds on level streets ranged from 4.8 to 15.2 miles per hour. On an 8.2 per cent grade the speed was 3.6 miles per hour. The current used in charging the batteries was 300 watt-hours per mile run. This vehicle made a run of 63.55 miles in the streets of Paris over a route containing grades up to 8 per cent with one charge of its batteries.

The Exposition of 1900.—"L'Electricien" publishes the general rules for the installation and exhibition of generating sets, the following being a short summary:

Electricity will be generated by direct-coupled sets only, no belted or other indirectly driven machines being allowed in the generating plant. The administration will consider exhibits of sets or of dynamos and engines separately. Steam will be furnished at a pressure of 142 lbs. (within 10 per cent variation) in the main steam pipes. Electric current must be delivered by the exhibitor at a proper switchboard, which he must supply, at 125, 250 or 500 volts if direct current, or 2200 volts at 50 cycles per second, if single-phase alternating current, Polyphase currents, the same frequency and tension (presumably in each phase). Exhibitors must send in their plans for acceptance by the administration, and must conform to certain rules to insure public safety. The space required is indicated by the administration and furnished free to the exhibitor, who builds his own foundations. At the close of the exposition these foundations may be left in place or removed, at the option of the exhibitor. Exhibitors of engines must make attachments to the steam mains at their own expense, a valve to be provided in each tap near the main header. All the piping for hot and cold water is to be provided by the exhibitor and laid in the conduits provided for it. The general system of conduits is free, but branch conduits to the set are to be built at the expense of the exhibitor. There are special rules concerning the minutiæ of joints, packing, etc. Current is to be delivered at a switchboard containing all proper switches and indi ating apparatus, of designs approved by the administration. Should the latter require it meters are to be provided. The administration buys the current at the terminals of the board from the exhibitor. Those showing alternating and polyphase machinery must provide the necessary transformers for the utilization of the currents supplied by them at places desired by the administration. The sets are to be operated from April 15 to November 5, or 205 days, though the administration may decide to increase or decrease this period by thirty days. Each set will be operated about seven hours per day under a schedule to be promulgated, but exhibitors must be always ready to give the administration the use of their total output.

Water and steam are furnished free to exhibitors, who will also be allowed a sum to partly remunerate them for the expense of construction and a further payment proportional to the number of working hours and normal output of the exhibit. These sums are estimated on the basis of $2.80 per h.p. for sets of less than 1000 h.p.; $1.70 per h.p. up to 1500 h.p., and for larger sets $1.25 per h.p., these payments being intended to go toward the cost of installation. The h.p.-hour rate is: For the first 1000 h.p., 0.3 cent.; for the next 500 h.p., 0.13 cent; for further power, 0.1 cent. At least 500 hours of operation are guaranteed exhibitors. Work is to be begun upon each exhibit by October 15, 1899, and finished before March 15, 1900, when the administration will make tests of all the installations. Failure to be ready at the date fixed is penalized, the dilatory exhibitor having his concession described above reduced, while a delay of a month beyond the opening day renders the exhibit liable to be taken out. Of the total power desired one-half will be generated by apparatus of French manufacture, the other half by exhibitors from other countries. The total appropriated for the payment of the installation costs of the latter is $34,000.

Coherer Action.—Dr. R. Malagoli describes in "L'Elettricitá," some interesting and curious researches into the "coherer action" of powdered metals exposed to electric waves. Arons had already observed that when metallic powders in the field of a microscope are subjected to the action of electric waves minute sparks appear between the particles, but this observation has not been sustained until Dr. Malagoli's work. He made use of a photographic method, covering a narrow space on a photographic plate between two fixed electrodes of sheet metal with a thin layer of powdered metal. A discharge in the neighborhood was followed by the appearance on the plate of dottings that looked like photographs of bacteria—chains and rows of dots. This the author attributes to exceedingly minute sparks leaping from particle to particle of the metal under the influence of the electric waves. He concludes that the drop of resistance in a coherer is always accompanied by this interstitial sparking.

ELECTRICAL WORK DONE FOR SAMPSON'S FLEET BY THE "VULCAN."

When the United States repair ship "Vulcan" was fitted out at the Boston Navy Yard early in June last, it was expected that the electrical installations on board modern men-of-war would be among the very first to make requisitions for repairs. The work was thoroughly anticipated. Every provision was made to meet possible exigencies of the situation off Santiago. Skilled electrical machinists were among her picked crew. Testing instruments and all kinds of electrical stores for marine installations were taken along.

Before the battle of Santiago, and after, electrical work and repairs were executed for the "New York": two searchlights were replaced by new ones, the telephone system was tested for grounds and breaks, armatures of common fan motors were rewound and tested, and other motors were tested for grounds. The only other ship in the engagement for which the "Vulcan" afterward made electrical repairs was the "Indiana," whose small blower motors were overhauled and the armatures of two or them rewound.

Two vessels of the auxiliary fleet, the "Potomac" and the "Manning," called for minor electrical work and repairs to their signal and side lights, electric bells, rewiring of deck distribution and general overhauling of the electrical machinery.

The dynamo fields of the "Vesuvius" were very carefully tested and found to be without fault. When the "Maria Teresa" was brought to Guantanamo Bay for general overhauling by the "Vulcan's" force, previous to being taken north, the dynamos were thoroughly examined and found to be everywhere grounded. No attempt was made to repair them.

◆

HOW DYNAMOS ARE SOLD.

There is, perhaps, no commercial business so susceptible to ingenious twisting of facts as that which has for its object the sale of electrical apparatus, and this may be well illustrated by the common practice of a good dynamo salesman. Let us suppose, for instance, that we have a capitalist who wishes to install in his office building a 500-light dynamo. Relying on his own business shrewdness, which has stood him in stead for many years, he writes to a number of dynamo builders, and is soon surrounded by their agents, who are anxiously bidding to secure the contract. The various prices are submitted, each agent bidding on the nearest size which he manufactures. If the quality of the machines are equal in every case, the bids will be very close indeed, and in a measure proportional to the size of the machines. The capitalist will review the bids carefully and then talk with each of the representatives upon the merits of the machines in order to make a decision.

The lowest bidder does not need to argue very eloquently. He has the initial advantage, but it is not an infrequent occurrence that the highest bidder can readily carry off the palm. The shrewd agent will soon see that his price is high and will admit as much to his prospective purchaser, but will say: "These other gentlemen are bidding on machines which will carry 500 lights and no more. The machine that I propose to supply you is specially designed to carry an overload of some 50 per cent for four or five hours. The conditions of your load might be such that you will find this an extremely valuable feature. We rate our machines very liberally and allow ample margin for contingencies; for this reason we think we justly ask better prices."

The prospective purchaser will take this matter very much to heart, and the chances are strongly in favor of his buying a 600-light machine disguised under the name of a 500-light machine able to carry overloads. If the agent had said that his machine would carry 600 lights, the buyer would have said, "I do not want 600 lights, 500 lights is ample," but the idea of getting added capacity for practically the same money is most attractive.

Again, we have the case of the purchaser who has pretentions to electrical knowledge. In no case is the old proverb, "A little learning is a dangerous thing," more forcibly illustrated. The chances are ten to one the agent knows about as much of electricity as the purchaser, and the way they exchange high-flown technical terms to their mutual mystification is amusing in the extreme. To illustrate an actual case in point may be mentioned an instance where a certain man had been considering the relative merits of several bids for a dynamo machine for his factory. Some of the agents had been talking knowingly of losses, efficiency, rise of temperature, hysteresis, and other matters relative to the performance of a dynamo. The purchaser gathered that these various quantities were desirable qualities, arguing to himself if these were not such the agents would not have mentioned them, or more probably obtaining his idea from inference rather than argument. When the next bidder appeared and asked for an audience, he proceeded to talk of temperature rise, hysteresis and like matters. The agent likewise, at once inferred that these things were much to be desired in a dynamo. He was of German extraction and he communed within himself, "If Thomas Huston and Edison haf hystersis in their dynamos ve must haf some too." He succeeded, however, in arguing so well that he closed the contract, one of the inducements being that he should write to his firm and stipulate particularly that in the dynamo to fill this order there should be an exceptional amount of hysteresis.

Again, we are told of a case which seems hardly worthy of credence, but is said to be an actual fact, that of two bidders, one making a proposition on an iron machine and the other submitting a price on a machine with a cast steel frame, the former secured the contract, arguing that his machine was the heavier by some 400 pounds, and therefore more substantially built, and was not starved of iron or copper, and there was plenty of material there to stand the load, etc., etc.

A good agent will make talking points out of nothing, advantages out of disadvantages, and virtues out of necessity, and will carry off a contract at a high price, while a man of mediocre business ability with a better machine and scrupulously careful of what he says, will fail to secure the order.

Capitalists do not seem to appreciate cautious, conservative opinions. They must be superlative or they are adverse. Truly said the great showman: "The American public likes to be fooled," and the capitalist most of all. He will not invest his money unless the facts are highly colored, even to misrepresentation.

AMERICAN ELECTRIC RAILWAY APPARATUS ABROAD.

If the advertising columns of our foreign contemporaries is a criterion we have reason to be very much flattered with the commercial success of American electric railway apparatus in England and elsewhere. In the current number of a prominent foreign publication devoted to electric railway interests, some 80 per cent of the advertisements by actual count either exploit American railway specialties distributed through agencies, or are due to local manufacturers who are producing under American patents. Less than 20 per cent of the insertions are entirely free from advertising American railway goods. This speaks more eloquently for American manufacture than any published statement.

It is not surprising, however, that this would be the case in the electric railway field, in which America is the admitted pioneer. We cannot expect a progressive people to begin where their predecessors began, but rather where they are at present. Any newly incorporated industry could not in common prudence do otherwise, and it cannot be expected that foreign countries will continue to use our electric railway apparatus unless we progress, and, what is more, progress faster than they do.

◆

ACCURACY AND PERMANENCY IN SWITCHBOARD INSTRUMENTS.

Modifications of the electrodynamometer have ever been popular in electrical meters, but for some reason it is not so largely used in switchboard work as its great advantage would lead one to expect, preference being seemingly given to types containing permanent magnets or moving iron. For switchboard work a pair of dynamometer coils, with gravity for the restoring force, seems absolutely ideal. There is nothing to change. The same instrument can be used for both alternating and direct currents. It can be manufactured as a voltmeter, ammeter or wattmeter. By the use of air dampers it can be made practically dead beat, and by the ingenious placing of the counterbalance or the employment of several weights successively brought into play, the scale may be made with practically uniform scale divisions. Once calibrated it becomes a standard. Indeed, many standards claim their excellence on account of their employment of this principle. It may further be made very delicate and it is not an expensive construction. Properly constructed there is not a single objection to be recorded against it. An instrument maker properly employing this principle need only excel in workmanship and detail to largely control the market in switchboard instruments.

The Steam Turbine and the Uni-Polar Dynamo.

The simplicity of the uni-polar dynamo has led many electricians to investigate the possibility of its commercialization. Indeed, this has been so persistently attempted and the problem has seemed so insurmountable that it has become a sort of electrical measles and is closely analogous in its effects upon the engineering fraternity to perpetual motion, its mechanical prototype. The electrical ignis fatuus, however, has the redeeming feature that it is always to a certain extent operative, and the problem is rather to increase its operative efficiency than to demonstrate its possibility.

The current carrying capacity of the unipolar dynamo is enormous. The problem is to increase the voltage, and there are but two ways in which this may be done, the first, that of making a very intense field, and the second, that of increasing the speed. The steam turbine seems to offer unparalleled opportunities in accomplishing the desired result by increasing speed. A 30-h.p. turbine running at 30,000 r.p.m. is a practical possibility, and direct-coupled to a uni-polar disc could produce measurable voltages and current capacity within the limits of the power of the turbine. If we have a disc some 80 ins. in diameter, the effective area which can be fluxed is some 35 sq. ins., through which it ought not to be difficult to thread 35,000 lines of force. If we run such a disc at 30,000 r.p.m. we shall have an effective voltage of 1.75, which is perfectly adaptable for some kinds of plating work. If we increase the diameter of the disc to such dimensions as we can without endangering it from a mechanical standpoint we may raise this voltage to 15 or 20 volts, and by connecting two such machines in series we may attain a voltage of 40 or 50, which is useful for many purposes. If electrical power can be obtained from such simple and cheap apparatus in such quantities, commercial uses will be quickly found for it.

Small Polyphase Stations.

In small country towns, where stations of a few hundred kilowatts capacity will supply the entire demand for electric lighting and power, it is a question whether single or multiphase apparatus is the best suited. In the polyphase station we have the advantage of the possibility of carrying a power load in the day time, but it has been argued by those who favor single-phase machinery that in small stations the motor load will be so minute as to be a positive disadvantage, compelling moderately large generators to run lightly loaded, and that the disadvantage which the necessity of balancing polyphase circuits entails will render the installation of such machinery in such cases very poor engineering.

Where a station is supposed to supply continuous service there is no question that the bigger the load the better, and if the station load were small with the motors, it would be smaller still without them. The problem of balancing the circuits can be very easily solved if the latter are properly planned. Elsewhere in this paper we describe a small installation in which the load in the different circuits can be balanced within an ampere by the simple device of shifting the street circuits from phase to phase, as the conditions may require.

It must not be expected that a good day load will come to any station because it is able to supply it. It must be actively canvassed for and frequently created. There is much missionary work to be done among manufacturers and users of power who are not aware of the advantages to be gained from the use of electric motors. New industries can be induced to locate near power stations if enticing rates are made. Interurban railways frequently thread through towns in which small power stations are operating, and the chances of erecting a small rotary transformer substation to feed nearby sections of the trolley system are almost always exceedingly good; in short, a day load can be acquired if the generating machinery is such as to permit it. If the problem is simply that of meeting an existing load carried on existing circuits, it is undoubtedly true that single-phase machinery would be best, but electric light managers who are content to let their conditions of load remain the same cannot be even called conservative, but are better described by terms which savor strongly of indolence or indifference. The wide-awake progressive manager who is alive to the interests he represents will use polyphase machinery, and by acute and resourceful management and energetic executive ability will create a day load for it. This will make the multiphase station the larger dividend earner in almost every case.

The Candle Power of Lamps for Decorative Purposes.

Incandescent lamps are now very largely used for decorative purposes, particularly for electric signs in the theater district of New York City. In such a case as this efficiency is not particularly to be sought after, for the object of the lamp is not so much to give light to surrounding objects as by its own luminosity to assist in tracing out the name or advertising sentiment so that it will appear brilliantly illuminated at a distance of many hundred yards. It is a fact that if letters of the sign are closely made and brilliantly lighted, that the sign will be less legible than if the lamps were burned at a lower candle-power, for the same reason that the true size and shape of an incandescent lamp filament can be best distinguished when burned at dull red heat. The eye is dazzled by more brilliant light. The outcome of this reasoning seems to be that a sign lamp must be burned at a considerably lower efficiency than one intended for ordinary illuminating purposes, partly because the signs will use less current, and partly because the lamp will be of double or possibly triple life. The true commercial efficiency of the sign lamp cannot be measured in watts per candle-power, for its object is to attract attention rather than to illuminate.

Thickness of Insulation of Magnet Wire.

The rule is given that in shunt magnets the strength of magnetization depends upon the gage of the wire, its specific resistance and the average length of turn, and this latter quantity varies but little with a slight increase of bobbin in diameter and none at all when the bobbin is lengthened along its axis. It is usually assumed that great accuracy is not essential in winding shunt bobbins where there is a single magnetic circuit or where the bobbins are not connected in series. The thickness of the insulation, however, has a great deal to do with the average length of turn. It is a common expedient among makers if the magnetism of a certain coil is not sufficient to rewind with a wire of the same gage and thinner insulation; thus if the same number of turns are retained, and the same gage of wire is used, with equal voltages a single silk covered wire will give a much stronger magnet than a double cotton-covered wire, for the simple reason that there is less copper in the coil and the average turn is reduced. It is a fact that many winders know nothing whatever of electricity, though they may be excellent artisans of their class, and the curious ideas that some of them have are surprising. In this case winders have been known to hold the opinion that the increased power was due to the silk cover, which allowed less electricity to escape than the cheaper cotton covering.

Power Distribution to Long Distance Railroads.

The great problem that must be solved if electricity is to supplant steam on trunk lines is the distribution of power. The polyphase current and the high-tension line, together with the rotary transformer, can take care of ten, twenty, or perhaps fifty miles without trouble, but greater distances than these begin to approach the limits of successful transmission. A multiplicity of power stations will, of course, solve the problem, but at great attendant expense. The policy of stockholders of steam roads has very frequently been such as to direct investment in channels not exactly akin to railroading, such as the acquisition of coal mines, or the traffic in grain or other commodities which are largely transported by freight. It does not seem too much to suppose, therefore, that the projector of an electric trunk line would hesitate very long at investing in an enterprise involving the sale and distribution of electric power in the various localities through which the railroad passes.

If a railroad is to be remunerative, it must pass through the principal towns that lie between its termini, even at the expense of a considerable divergence from the straight line connecting them. In each of these towns there is a market for more or less power, and in the principal ones could be installed a power house of sufficient dimensions to take care of a section of the railroad, to distribute to sub-stations at intermediate distances and to supply electric current for power, light and the propulsion of the local electric railroad system. It is the large station which reduces the cost per k.w.-hour. Large engines and boilers and large generating units reduce attendance and repair and increase efficiency. The alternate current system enables the introduction of an installation to supply all kinds of service.

Consider the problem of an interurban road 100 miles in length, passing through six or eight small towns of, say, about five or ten thousand inhabitants, and three or four large ones, of from fifty to one hundred thousand inhabitants. Two stations with an appropriate number of sub-stations would be sufficient to equip this road electrically. These stations should be located in or near the larger cities and the sub-stations distributed in the smaller ones. The power house would generate high-tension alternate currents for distribution to the sub-stations, 750-volt current for the trunk line, 500-volt current for the local street railway systems, and 110 to 220-volt alternating current for power and light. This service would be duplicated in so far as possible in the sub-stations, the idea being to secure for the station a diversified load and a very even load curve. The commercial advantages of this arrangement are apparent. The enormous station generates the power very economically, and the competition of the local light and power companies can be carried to so low a figure as to compel consolidation. In small towns in which the rotary transformer sub-stations were located, power and light could be supplied at a profit in quantities so small that an ordinary lighting plant could not possibly subsist on the income. Short street railways could be installed in the smaller towns and be made to pay. In this way the sub-stations which, if they depended for their load on the trunk line alone, would run idly for long periods, would have a paying load at all times, thus doing away with the principal commercial objection, that of a multiplicity of lightly loaded stations.

The gigantic dimensions of such an enterprise, applied to a large trunk line, are appalling, not so much on account of the enormous size of the stations as on account of the fact that such a combination of capital would be a trust of immense power, and also because, however improbable the development of such an enterprise may be, it is not impossible, and would tend to disturb the social conditions in the country to an even greater extent than they are at present in these times of strikes and trades unions.

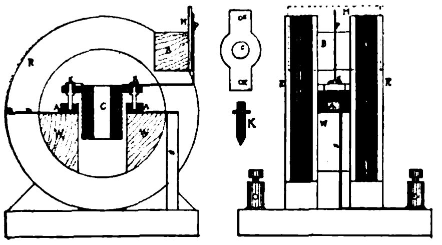
Should the Dynamo Frame Be Grounded or Insulated?

It is a much discussed question between American and English engineers as to whether it is advisable to insulate a dynamo frame from the earth or to thoroughly ground it. With machines whose maximum voltage does not exceed 125 it makes little difference, in the case of isolated plants. Where the output of the machine is distributed over outdoor wiring, the danger of destruction by lightning is greatly enhanced by grounding a dynamo. A high voltage machine with a grounded frame increases the danger of burn-outs in case of a ground somewhere on the line, but if the machine is additionally insulated this danger may be practically eliminated. Indeed, in some three-phase machinery connected on the Y plan it has been suggested and even practiced to connect the wire from the common junction of the winding to the ground. If this is done there would certainly be no added danger in grounding the field frames themselves. On the other hand, the element of safety to attendants, if taken into consideration, forms the basis for a strong argument in favor of grounding the machine frame. It is obvious that if this is done the danger of shock to the attendant is very much reduced, because the ground on which he stands is of the same potential as the machine frame which he has occasion to handle. If the welfare of the machine only is to be considered, by all means it should be insulated as well as possible from its foundation, but if safety for the attendants is the desideratum, the winding of the machine should be better insulated and the field frame itself securely grounded.

SIMPLE VOLT-, AMPERE-, AND WATTMETERS.

BY CHARLES T. CHILD.

The instrument shown in Figs. 1 and 2 belongs to the moving coil type and is adapted to either alternating or direct currents. On a wooden base are mounted two wooden rings, R R, about 6 ins. in diameter, upon which are wound about 20 turns of No. 10 wire. The blocks W and W carry on their upper surfaces small copper cups, A and A_1, which are soldered to the copper strips m and n and so connected that the current circulating in the coils R R includes in its circuit the two cups and the coil C, which is suspended between them. This coil is wound on a thin hardwood frame of the shape shown in the drawings, the upper of the two small drawings showing its upper surface. The coil has 20 turns of No. 10 wire, its ends being soldered to the copper pins K K. One of these is shown on a larger scale in the small drawings. At their bottoms they are filed into knife-edges, so that when they are placed in the copper cups, A and A_1, the coil C rocks on them. The bottoms of the copper cups are slightly hollowed to keep these knife-edges in place at the center, and the whole system is balanced so that it rocks very easily on the knife edges. The cups A and A_1 are filled about half full of mercury, on the top of which is placed a drop of kerosene, or, better, of a mixture of about 4 parts of kerosene and 1 of alcohol in which is dissolved 5 per cent of cyanide of potash. This preserves the mercury surface from oxidation and also relieves the surface tension. A pointer, P, is attached to the rocking coil and plays in front of a scale as shown. The instrument should be covered with a bell-glass, or a wooden box having a glass front, to keep out dust and air currents.



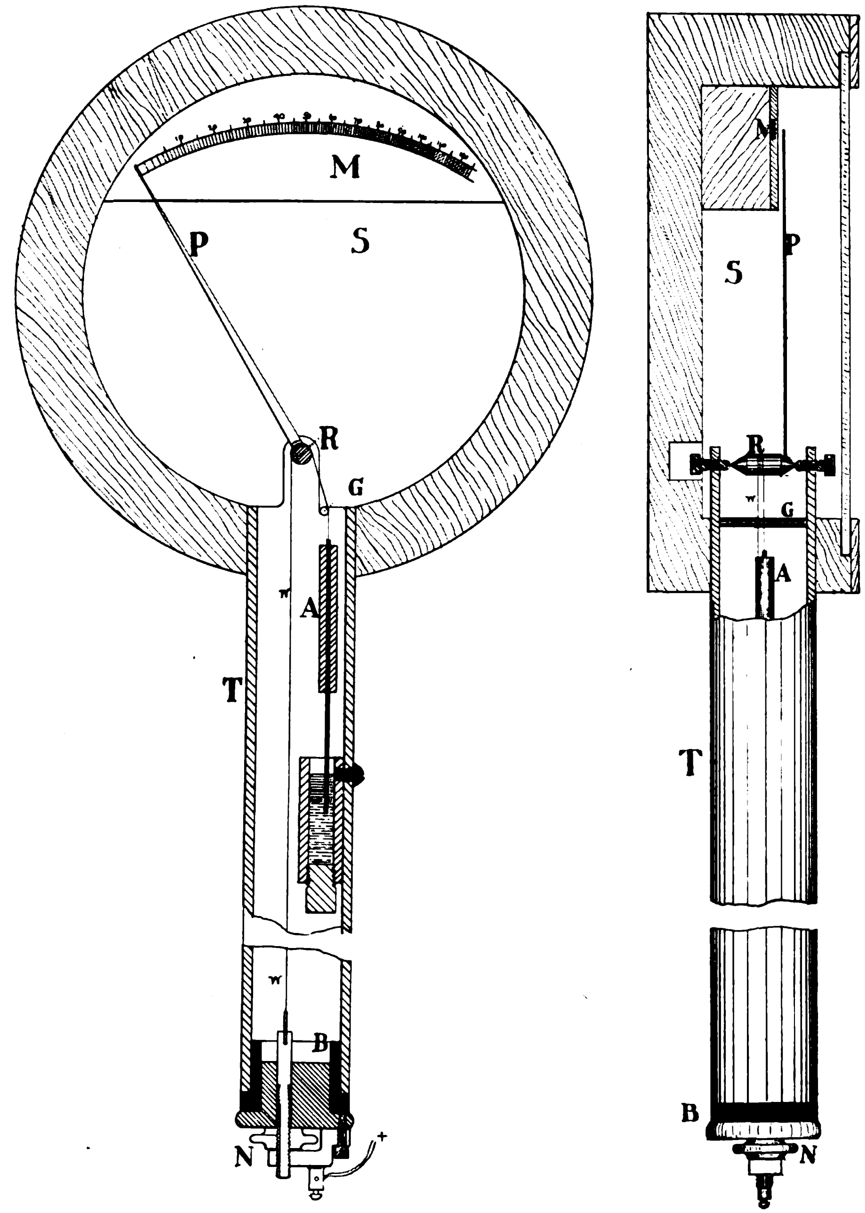
FIGS. 1 AND 2.—ALTERNATING AMMETER.

While this is by no means an ideal instrument it is a satisfactory one for many purposes. It should be mounted on a shelf on a wall or in some other place where it will not be disturbed or subject to vibrations, and it should be taken down and cleaned occasionally. The nearer the knife-edges come to the center of gravity of the suspended system the more sensitive the instrument will be. It is advisable to make the coil, C, as light as possible, and for this reason aluminum wire should be used in place of copper for winding it if this can be obtained. This instrument is not "dead beat," but it has a fairly constant scale through a range of about 30 degs., which is a great advantage.

For alternating current work the "hot-wire" instruments possess some important advantages, among them that of not affecting the circuit in any way, as the coil instruments do by their self-induction. The instrument next to be described is somewhat similar to the Cardew hot-wire voltmeter, and, while rather delicate, is an excellent instrument in careful hands.

The principle upon which it depends is the expansion of a small wire heated by the current to be measured. A wooden box, 8 ins. in diameter, is turned to form the head of the instrument, and to this is attached as shown a piece of iron gas-pipe, T, 1¼ ins. inside diameter and about 3 ft. long. At the bottom of this pipe (the instrument is intended to be attached to a wall with the wooden box part uppermost) is a brass plug, insulated from the pipe by an insulating bushing, B, and carrying a threaded rod and nut, N. This threaded rod is grooved, a small pin engaging in the groove so that when the nut, N, is turned the rod is screwed in or out, but does not turn around. There should not be the least lost motion about this fitting, as the motion of the threaded rod must be accurate and exact. In the upper extremity of the threaded rod is soldered a small bit of copper wire split at its upper end. This is to clamp the platinum wire, w, whose expansion is recorded by the instrument.

At the upper end of the tube, T, is arranged a small drum, R, having coned ends resting in the screws as shown, or the screws may be pointed and the drum coned out for their reception. The drum should be not more than 3-16 in. in diameter, and is best made of steel. It is shown relatively too large in the illustrations. Around this drum the platinum wire, w, is wrapped two or three times, the surface of the drum being first enameled with a mixture of finely powdered asbestos and water-glass (soda silicate) painted on and dried with gentle heat. It is not absolutely necessary to enamel the surface, but it is well to do so, as this prevents any current from flowing through the cone bearings of the drum and heating them.



FIGS. 3 AND 4.—HOT WIRE AMMETER.

In the tube, T, is secured a small piece of ½-in. iron pipe, closed at the bottom with a plug, and partly filled with mercury. The platinum wire, after passing around the drum, is deflected by the glass rod, G, so that the wire attached to the weight, A, suspended from the platinum wire, dips in the mercury. This wire should be of copper and the weight should be of lead or brass, its weight depending upon the size of the platinum wire, but enough to keep it taut. For a No. 38 platinum wire the weight should be about 1½ ozs.

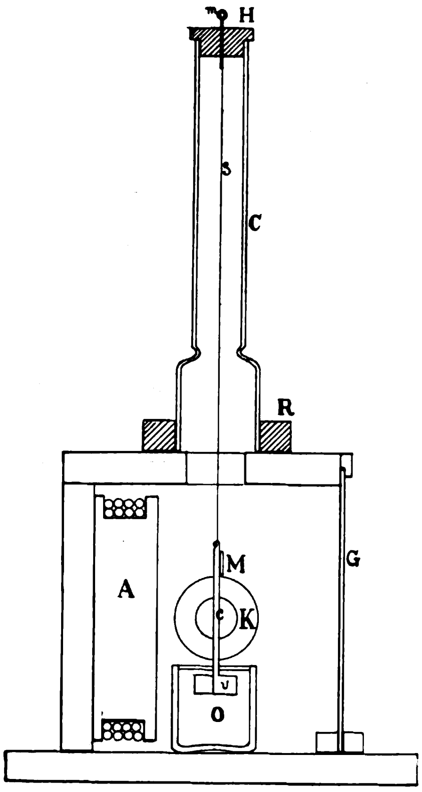


FIG. 5.—SIDE ELEVATION, WATTMETER.

A resistance is absolutely necessary with this type of voltmeter, and the otherwise empty space, S, will contain it comfortably. For voltages up to 150 a resistance of about 4000 ohms should be used and the platinum wire should be about No. 38 or 40. The resistance can be wound on a wooden spool and is best of German silver wire, about No. 32, preferably not smaller.

As the expansion of the iron pipe and the platinum wire are not the same, the daily changes of temperature, the stretch of the fine wire, etc., will make the zero point somewhat uncertain. For this reason the nut, N, and its adjuncts are provided, so that the needle can always be adjusted to zero before the reading is made. The instrument is quite sensitive, absolutely dead-beat, and entirely unaffected by external magnetism. The best way to increase its accuracy without making it more delicate is to lengthen the pipe, T, but this has practical disadvantages. It should be mounted by means of wooden cleats against a wall and left there. Care should be taken in winding the resistance coil not to make it inductive, as this will vitiate the accuracy of the instrument and introduce complications in the circuit. To wind the resistance non-inductively two wires should be wound at once on the spool, and then connected together so that the current circulates in different directions through each.

A sensitive and excellent wattmeter may be very simply made as follows: On a wooden base build up with brass screws or glue a wooden box, as shown in Figs. 5 and 6, about 7 ins. x 8 ins., and 7½ ins. high, having a glass front, G. Against the back of this box is mounted a wooden spool, A, carrying a coil of a few turns of coarse wire. For currents up to about 20 amperes No. 8 wire and 8 or 10 turns are advisable. In the center of the top of the box is cut a hole, and mounted above this in a wooden ring, R, is an ordinary glass lamp-chimney of the shape shown (such as is used with "student lamps"). In the top of this is a plug, H, fitting so that it can be turned with the fingers, and carrying two wires, m, n, fitting rather tightly in the fibre or wooden plug. If wood is used it should be boiled in paraffine, as the voltage measured is in full force between the two pins, m and n. These pins should be 1½ in. apart, and should be split at the bottom so that the two thin suspension wires, S and S, may be pinched in the split part.

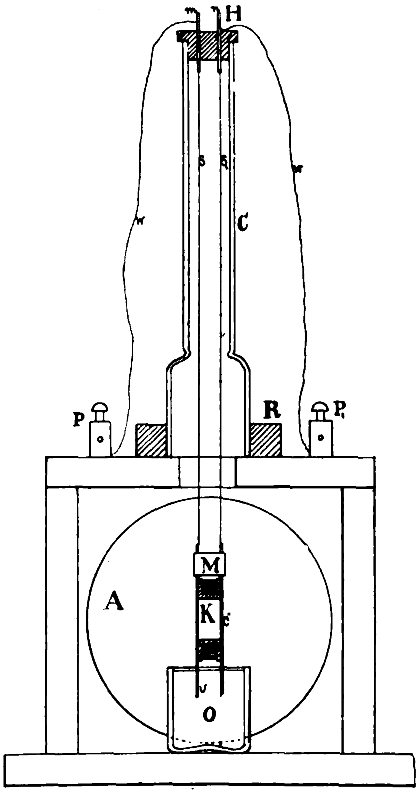

FIG. 6.—END ELEVATION, WATTMETER.

Suspended from these two wires is the coil of fine wire, K. This is wound on a fibre spool, 2 ins. outside diameter, 1 in. inside diameter and having a space for the winding ½ in. wide measured along the axis of the spool. It should be as thin as possible to reduce its weight, and should contain about 300 turns of No. 32 wire. In winding this the greatest care should be used to insulate it thoroughly, and the wire should be copiously shellacked and the coil thoroughly baked after completion. The ends of this coil are connected to the two thin sheet copper or aluminum strips, c, which are shellacked to the sides of the spool. At the lower end of each of these strips is a vane or projection, v, the two being arranged to point in opposite directions. These are intended to dip into kerosene oil contained in the cup, O, and to dampen the swinging of the suspended coil. Across the two strips, c, is fastened with gummy shellac a small mirror, M, best made by silvering the surface of a bit of glass such as is used for microscope slide covers, though a piece of ordinary thin looking-glass will answer. The two suspension wires, which should be of exactly equal length, are fastened to the strips, c, with small drops of solder. These suspension wires should be of copper, not larger than No. 36 gauge and preferably smaller. It is not necessary to remove the insulation from them.

Two binding posts, P and P₁, are provided for attaching the fine wires, w, leading from the pins m and n. To these posts are connected the terminals from the two sides of the circuit to be measured, while the main current is led through the coil A. The deflections of the swinging coil are read off by means of a lamp and scale, a simple and excellent arrangement for this purpose having been described by Mr. J. M. Hobart in "The American Electrician" for February, 1898, in an article entitled "A Sensitive Mirror Galvanometer." For small deflections the scale readings are proportional to the watts. This instrument is equally good for alternating and direct current work, and in careful hands is surprisingly accurate. It is quite good enough for incandescent lamp measurements.

Of course, a resistance must be used in series with the fine coil, the amount being proportional to the voltage of the circuit. Up to 150 volts, using No. 32 wire on the coil, the resistance should be about 2500 ohms, and it should be wound non-inductively as described above. If very accurate determinations are to be made the self-induction of the fine wire circuit may be compensated by a condenser consisting of a glass plate with a strip of tin-foil on each side, but this is an unnecessary refinement for ordinary work.

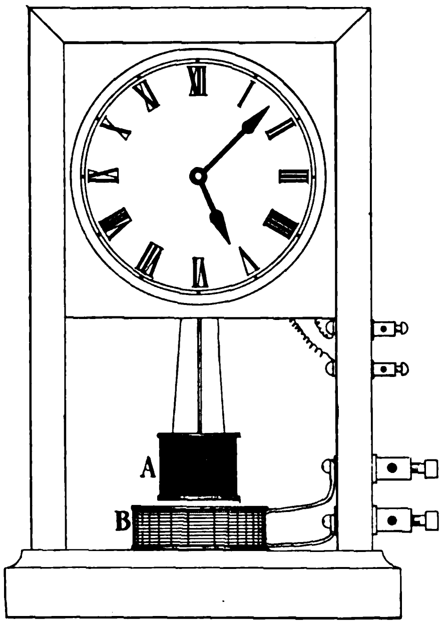

FIG. 7.—RECORDING WATTMETER.

A watt-hour meter may be made from any pendulum clock, a good one being, of course, preferable. The arrangement is shown in Fig. 7. The bob of the pendulum is replaced by a fine wire coil of many turns, small wires being led up to points near the center of motion of the pendulum and thence to the binding posts on the case. Below the pendulum and as near it as possible is a coarse wire coil, B. The main current flows through this while the fine wire swinging coil is bridged across the circuit. The clock is first adjusted carefully to keep correct time with no current in the coils. The mutual attraction between the coils causes either an acceleration or retardation of the rate of the clock in proportion to the watts passing, and all that is necessary is to know the constant of the apparatus and note the gain or loss of the clock. Up to a gain or loss of about 3 minutes per hour this meter is very accurate. Of course, to get the constant it is necessary to calibrate the meter by working it for several hours on a known load. It is equally applicable to direct or alternating currents.

On a constant pressure supply system, direct current, the swinging coil may be replaced by a bar magnet, and the instrument then becomes a coulomb-hour meter, or, if the voltage is constant, a watt-hour meter. The well known Aron meter, much used in England, is constructed on this principle.

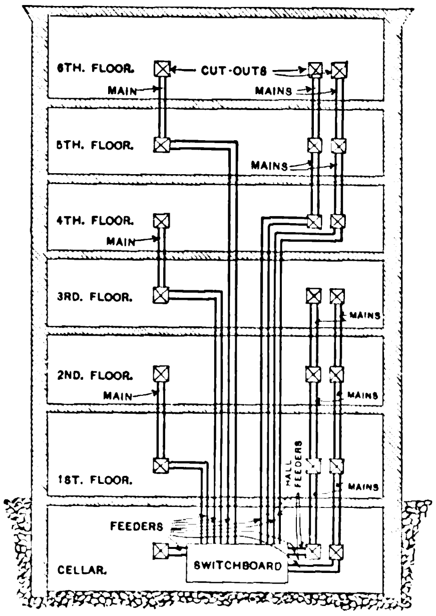
INTERIOR WIRING.

BY CHARLES E. KNOX.

FEEDERS AND MAINS.

The control of hall or night lights from the main switchboard is one of the most important points to be considered in the arrangement of the feeder system.

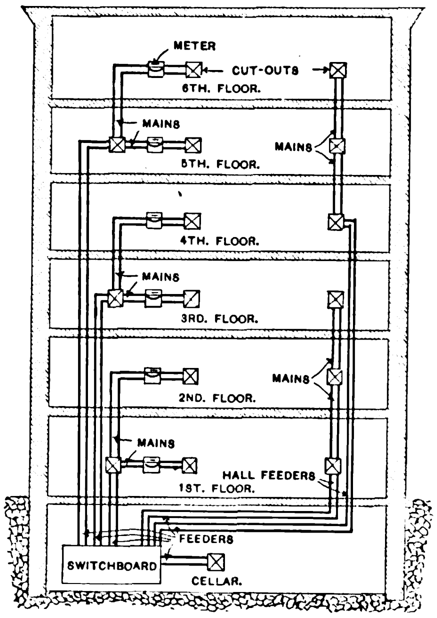


Am.Elec.

FIG. 1.—ARRANGEMENT WITH SEPARATE HALL FEEDERS.

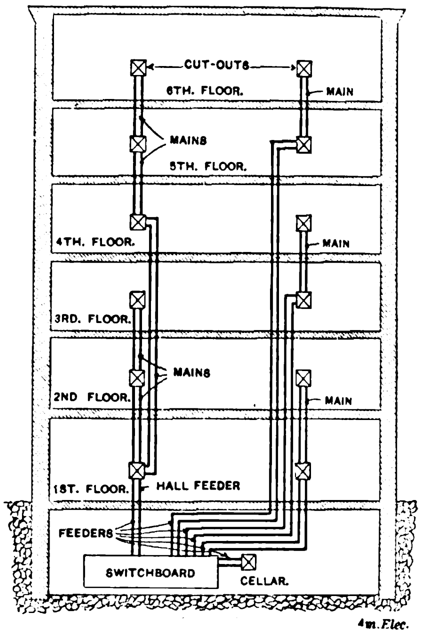
In a private dwelling house it would hardly pay to have a separate feeder for the hall lights, as these lights are generally few in number and could readily be controlled by a few local switches, more readily, in fact, than by a feeder switch at the main switchboard. It may not be necessary even in a hotel, where there are attendants continually passing through the hall who could control the lights, either by local switches or by switches at the distributing center. It is questionable, however, whether it would be as economical to allow the average hotel attendant to use his judgment in putting on the hall lights, as it would to have them turned on at the proper times by the switchboard operator.

In the majority of public buildings, however, the advantages of having separate feeders for the hall lights are so obvious that the problem is generally not whether there shall be separate feeders for the hall lights or not, but whether there shall be one or two sets of hall feeders. By having two sets of feeders for the hall lights, local switches for them may be dispensed with and they may be controlled entirely by the main switchboard. Of course, having two sets of hall feeders increases the cost of the wiring installation and makes the system more complex, but its possibilities for saving current are considerable. In a large building having long corridors, one set of hall feeders would not be sufficient unless the lights were also controlled locally at each floor. During a large part of the day some light may be needed in the hall, but a small portion of the whole number would be ample. With but one set of feeders it would be necessary for the electrician to close the hall feeder switches and then to go through the halls and turn those lights off which were not needed; when it became time for all the lights to be turned on, it would be necessary for him to make a second trip to turn them on again. By having two sets of feeders, one set supplying, say, one-third of the hall lights, and the other set supplying the remaining two-thirds, this control would be entirely from the switchboard and would undoubtedly result in a saving of current. The lights controlled by the feeder supplying one-third of the whole number would also serve for an all-night circuit (for a watchman) in case this was necessary. Where there are two sets of hall lights thus controlled, the wiring of the outlets should be such as to give a uniform distribution of light when either set of lights were burning. Fig. 2 shows a typical case of a business building with two sets of hall feeders. This arrangement very nearly corresponds (on a smaller scale) to the arrangement of the feeder system in a New York City building. As a rule, a saving of current would usually result from having two sets of hall feeders in a building over five or six stories, having more than six or eight hall lights on a floor.



Am.Elec.

FIG. 2.—ARRANGEMENT WHERE TENANTS ARE SEPARATELY METERED.



Am.Elec.

FIG. 3.—ARRANGEMENT FOR FACTORY BUILDINGS.

Where a building receives its current supply from an outside source, the tenants paying for the current consumed (as measured by a meter), a separate feeder for the hall lights is indispensable, as the hall lights of course should be paid for by the owner of the building. Fig. 3 shows an arrangement of feeders in such a building, where each floor or loft may be rented to a separate tenant. It will be noted that here the meters are located on each floor instead of at the switchboard. Where a building is not of sufficient size to require a separate feeder for each floor, this is a much more economical arrangement than having them placed on the switchboard, as two or more floors may be fed by the same feeder. It is sometimes a difficult matter to find a suitable place to locate the meters on the various floors, but it has the advantage that the tenant can take his own meter readings as a check on the lighting company's inspector.

Fig. 4 is an example of a factory building where a watchman is employed to make the "rounds" of the building at certain periods. Of course, light must be left on the stairs and hallways for this purpose, but it is required nowhere else. By having a separate feeder for the halls, the current may be cut off from the lofts at the switchboard, thus saving any current consumed by lamps that may have been left lighted by the employees when leaving the building.

3. Maximum number of lights should be controlled by one feeder.

"Mark Twain" says he believes it is the best plan to put all your eggs in one basket and then "watch that basket." This would not be a good maxim to adopt in arranging your feeder system.

It very frequently happens that an engineer will be caught with one machine running almost up to its maximum capacity when a sudden rapidly rising load is seen to be coming on. Now if all the lights are supplied through a few heavy feeders, he may have to take his chances on getting a second machine running and up to voltage before his circuit breaker throws out or a fuse blows. If, however, there are more feeders supplying fewer lights, he might be able to select one or two that might be cut off the board if necessary until he got another machine "up to voltage." Then, again, a short circuit might occur which would go past the fuses in the main distributing boards and throw the feeder circuit breaker out or blow its fuse. The greater the number of lights on this feeder the greater would be the "area of disturbance."

It would be impossible to give any rule as to the limit in the number of lights that it is best to supply through one feeder, as this will vary under different circumstances. The total number of lights in the building, the available space for the switchboard, the method of control desired, and the cost, would all tend to influence this consideration.

4. Best maximum limit for the size of feeder conductors.

Two variables influence the size of the feeder conductors, the number of lights supplied and the loss allowed.

As a rule, when the number of lights is the only factor determining the size of the wire, i. e., when the distance is so short that the loss desired would call for a smaller size of wire than the current carrying capacity would allow, it is best to limit the number of lights to the neighborhood of 400 (about 190 amperes). One reason for this is that this load is the limit allowed for a 4/0 B. & S. wire, which is the largest size of wire that can readily be installed in an inch and one-quarter conduit, and when the use of a larger size of conduit may conveniently be avoided it is well to do so. Where the conduits are to be run concealed under the floors, it is generally difficult to find suitable runs for larger sizes than this.

Also for the reasons noted under the previous heading (maximum number of lights that should be controlled by one feeder) this number of lights would tend to be a limit.

Where, however, the number of lights is not alone the determining factor, but where the loss also has to be considered (which is true in the great majority of cases), we frequently have to use larger sizes of wire for the feeders.

5. Portion of total loss allowed in the feeders and mains.

As stated in a previous article, the loss usually allowed in the branch circuits is one volt. Where the total loss (from the switchboard to the lamp) is four volts, this leaves three volts to be distributed between the feeders and the mains. Where the total loss is three volts, two volts is divided between the feeders and mains. In any case, it is best to allow most of this loss in the feeders, as this tends to minimize the difference in voltage between lamps supplied by the same feeder. As a rule, the best results are obtained by having two-thirds of the remaining loss in the feeder, and one-third in the mains. In the case of four volts total loss, this would mean two volts loss in the feeders and one in the mains and one in the branch circuits. Where the total loss was three volts there would be a volt and one-third in the feeders, two-thirds of a volt in the mains, and one in the branch circuit. Where the total loss was more or less the same ratio might hold good.

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

PROTECTIVE DEVICES.

Another device somewhat similar to this, but adapted to open the circuit instead of connecting it with the ground, is shown in Figs. 1, 2, 3, 4 and 5. This is an invention of Mr. F. R. McBerty of the Western Electric Company, Chicago. The construction of the coil itself is best illustrated in Fig. 12, in which b is a small hollow rivet of conducting material, upon which the coil a of German silver wire is wound. One end of this coil is attached to the shank of the rivet, as shown, and the other end to a metallic plug or button f. The hook c is soldered into the hollow rivet b, and the whole is inclosed in a hard rubber bushing d, as is clearly shown in Fig. 13. A hard rubber plug e is forced into the cavity in the bushing after the rivet has been put in place, and this serves to insulate the head of the rivet from the metallic plug f. A forked standard g is mounted, as shown in Figs. 9, 10 and 11, so as to form a support for the heat coil when in place. A leaf spring i, insulated from the support, forms one terminal of the line and presses firmly against the plug f. The hook c of the heat coil is engaged by a spring l, which is held thereby under a considerable tension. This spring forms the terminal of the instrument wire, so that the circuit from the line passes through the spring i, the plug f, the coil a, the hook c, and the spring l to the instrument. When a current of sufficient strength to melt the solder passes through the coil, the plug c is pulled out and the spring l is thus allowed to assume its normal position. This produces a wide opening in the line, so as to prevent arcing across the gap.

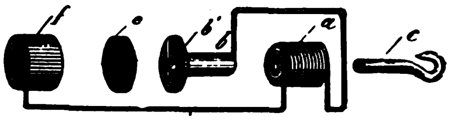


FIG. 4.—DETAIL OF MCBERTY'S ARRESTER.

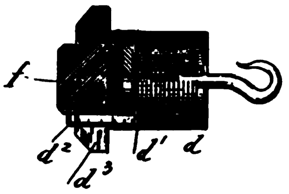

FIG. 5.—DETAIL OF MCBERTY'S ARRESTER.

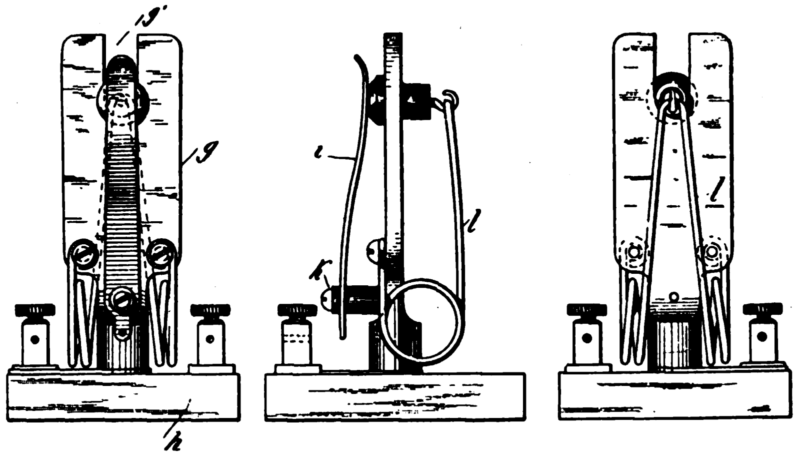

FIGS. 1, 2 AND 3.—MCBERTY'S THERMAL ARRESTER.

Heat coils may be so adjusted as to be operated by extremely small currents, and they show great uniformity in their operation. By varying the length of the resistance wire or its size, they may be made to respond to a given current in almost any length of time desired. The times of operation for coils constructed in the same manner will not vary over 1 per cent from each other. These coils are usually adjusted to act when subjected to a current of one-quarter ampere for thirty seconds; they are, however, sometimes adjusted for currents as low as .15 ampere. In later coils about 30 ins. of No. 31 B. & S. German silver wire is used. Heat coils of types similar to these are now built in several different forms and are generally combined with carbon arresters. In protecting switchboards, it is of the utmost

Eng Soc. Library

importance that arresters be provided for each side of each drop and, as economy of space is a very important item in telephone exchanges, it becomes necessary to arrange them in as compact a manner as possible. Fig. 14 shows combined carbon arresters and heat coils mounted on long strips of iron for this purpose. The principles of operation are the same as those already described, although the structural details are somewhat different. The line wire enters at spring D and thence passes to spring F, through the heat coil B to the spring G and thence to the switchboard wire through terminal E. The spring F rests in a groove of the carbon block A, which is separated from a similar block by a small strip of mica, shown in detail at the right-hand portion of this figure. This second block rests on a ground plate. An added feature of protection is provided by inserting in one of these carbon blocks a small drop of fusible metal. If an arc occurs between the two blocks, this metal will melt, thus establishing a perfect connection between the two, and grounding the line. In case, however, a smaller current comes in over the line, it operates the heat coil and allows the central rod, which is of metal, in this case, to press the light spring attached to the lower side of F into connection with the ground plate. The other side of the line is connected to the other side of the switchboard coil in the same manner; the line entering at the terminal C, passes by means of an insulated bolt through the iron frame on which the apparatus is placed, to and through the corresponding heat coil on the lower side of the plate. It passes to the switchboard wire by the terminal E.

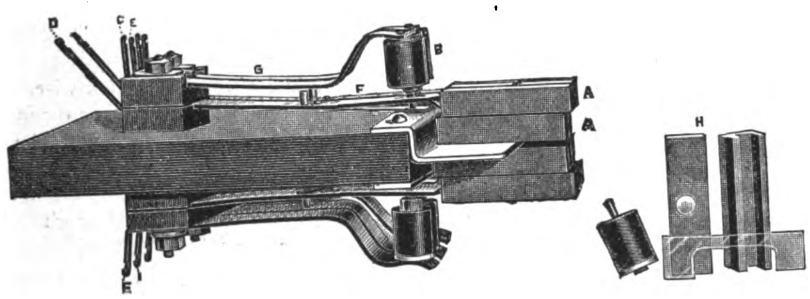

FIG. 6.—COMBINED CARBON AND HEAT COIL ARRESTER.

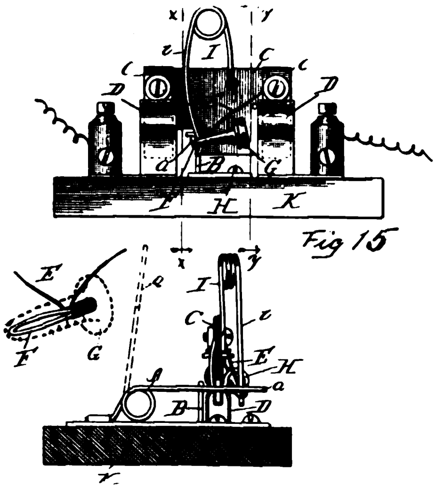

FIG. 7.—ROLFE THERMAL ARRESTER.

Still another type of arrester which is coming into increasing use among the independent companies is that shown in Figs. 15 and 16. In this, which is the invention of Mr. C. A. Rolfe, of Chicago, the two binding posts which are connected respectively to the clips D and D', form the terminals of the line wire, and of the wire leading to the instrument to be protected. On an insulating strip C, usually of fibre, are provided the metal ends c, which are adapted to be held firmly between the clips D and D'. A fine wire coil E of German silver is connected between the metal end pieces c, being attached thereto by small screws and washers. The coil E is imbedded in a mass G of some easily fusible substance resembling plumbers' wax; the smaller portion of which extends through an eye H on the plate C. Said eye is arranged to support G and to provide a stop against which the head of the button is normally held by the tension of a spring I, secured to the upper portion of the plate C, as shown. A is a coiled spring mounted upon the base K, and provided with an arm a, which may be held by a catch B. The relative position of the springs I and A are such that, if the spring I is released, it will strike the arm a of the spring A and cause it to disengage the catch B. The spring A will then, in its attempt to rise, as indicated in the dotted portion of Fig. 16, strike the under side of the plate C and lift it entirely out of the clips D and D'. As the coil E forms a part of the circuit, a current in excess of that which it is adapted to carry will develop enough heat to melt the wax, and this will allow the head of the coil to pull through the ring H. This in itself usually breaks the wire E, and thereby opens the circuit; but, as an additional protection, the spring A gives a violent kick, which is sufficient to throw the entire plate C and its mechanism high into the air. This affords a very effective break between the line terminals, so much so, that it is almost impossible for an arc to form. This arrester is sometimes termed the grasshopper cut-out, on account of its peculiar action.

◆

A SERIES ARC HINT.

Station managers are now placing as many series arc lamps on their lines as the insulation will stand. In long street lines, such as boulevards and the like, two machines, one at either end of the line, with an equal number of lamps on each connecting leg, will cut the maximum voltage in two.

STEAM ENGINE PISTONS.

BY JAMES F. HOBART, M. E.

The earliest form of piston was undoubtedly a piece of iron with a groove turned in the edge and filled with rope or twine, in much the same manner that the boy of today makes tight the plunger of a squirt gun by winding twine around it.

An improvement was soon found necessary, and the piston head was made in two pieces, one part being so arranged that it could be screwed down on the packing, as the latter wore out, in much the same manner as far as screwing down is concerned as the gland on a valve stem is screwed home when the packing lets steam leak past it.

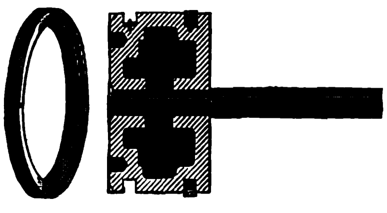

FIG. 1.—PLAIN SNAP RING PISTON.

For many years fibrous packing was used with never ceasing annoyance from leakage. Finally some person to whom no monument has yet been erected made a ring packing and the problem was solved.

Fig. 1 shows a structure of this kind. It is hollow to secure ample wearing surface without excessive weight to cause needless friction. The rings are made eccentric and are fitted with dowel pins in the grooves to prevent the rotation of the rings upon the piston. The rod and head are forced together, the former being shouldered and riveted on either side of the piston head, so there is no danger of its coming off through the loosening of bolts, etc.

The two holes in top end of piston are for the purpose of screwing the rod into the crosshead, a wrench being furnished to fit them.

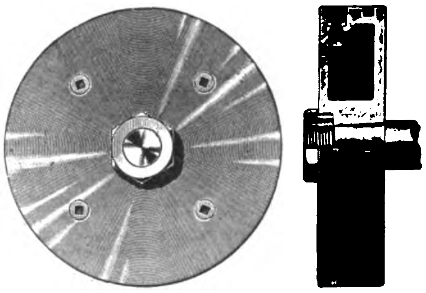

FIG. 2.—SOLID PISTON RINGS, SPRING ADJUSTED.

Fig. 2 shows another form of one-piece, or "solid" piston, for all that it is cast hollow, and the four plugs noticed in the end elevation are for closing the cavity so as to prevent the ingress of steam or water.

The peculiarity of this piston is in the manner of adjusting the rings. Instead of being sprung into the grooves in the piston, the rings are cut into sections and a spring placed between the ends of each adjacent section. The engraving plainly shows the manner in which the rings are forced out by the spiral springs which bear against the oval connecting pieces.

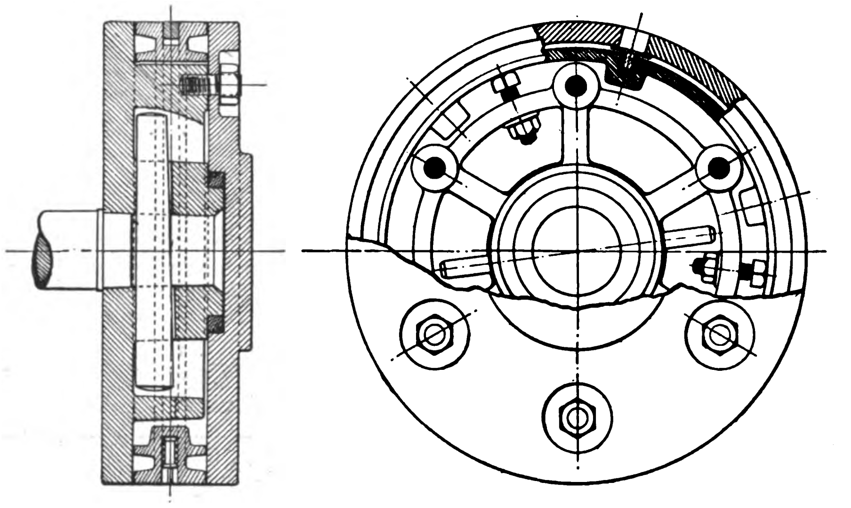

FIG. 3.—SPRING EXPANDED RINGS, WITH SCREW ADJUSTMENT.

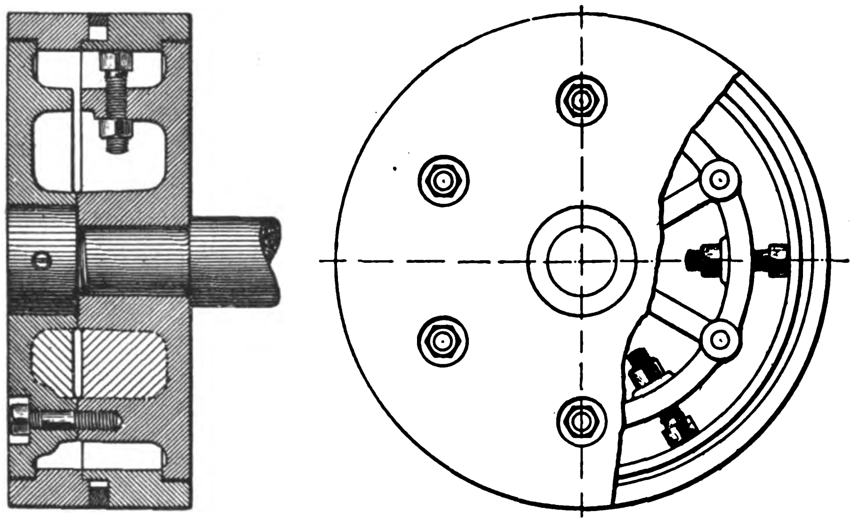

FIG. 4.—DOUBLE BULL RING PISTON.

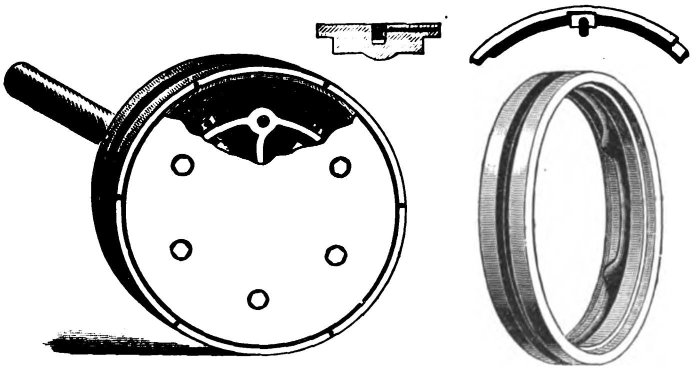

FIG. 5.—BABBITT & HARRIS PISTON PACKING.

Another similar form of piston, shown by Fig. 3, also has the spiral spring ring expansion, in addition to which the ring itself is placed in another ring, which is adjustable by means of screws inside the piston, so that the latter may be centered inside of the cylinder. These rings are made steam-tight by means of bronze "keepers" and the coiled springs are of German silver. The head is pressed on to the rod, which is riveted and keyed, thus making it impossible for the head to come off accidentally.

A somewhat similar form is illustrated by Fig. 4, but here the front or head end of the piston is flush, and needs very little clearance room. The rod is forced into the body of the piston, then a nut is screwed on and dowelled, after which the follower is put on and bolted. There is also a screw adjustment for centering the piston in the cylinder. This piston is made with only one packing ring, for the reason that its builders do not believe in two rings. It will be noted that in this piston the steam ring does not need to be sprung into its place, as by taking off the follower and one-half of the bull-ring, the rings can be slipped in or taken out at will. This is a point to be appreciated by those who have "monkeyed" with a stiff ring and a screw driver, even to the point of profanity.

Fig. 5 shows another form of single ring piston packing, but with a sectional ring automatically expanded by German silver springs. The three cuts in engraving No. 5, show clearly the manner in which the rings are placed in a loose one-piece bull-ring, which has centering adjustments.

A somewhat similar construction, but with two rings instead of one, is the subject of Fig. 6. Here the coiled spring is used, and the rings are made sectional, the springs being placed under the ends of the spring sections. This piston is fastened to the rod by jam nuts, which are let through the follower and bear directly against the body of the piston, through which the rod has been forced. It will be noticed that this piston has its edges chamfered off where it comes opposite the ports. The reason is obvious, but it necessitates placing the piston in a certain position at all times, and if it be rotated by accident or design steam cannot enter freely until after the commencement of the stroke. Several times a card showing very bad initial pressure has been traced to this cause.

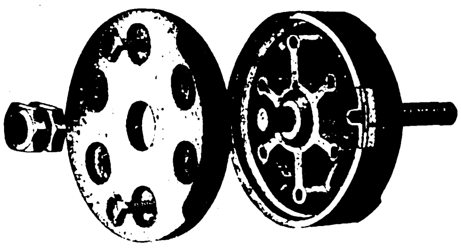

FIG. 6.—DOUBLE PACKING RINGS.

◆

Lessons in Practical Electricity

HOW TO DESIGN A DYNAMO.

In the last three articles we succeeded in determining, approximately, the dimensions of a 100-light dynamo. We must now go over our calculations with a view to accurately determining the size of the field coils and the wire with which they shall be wound.

The duty of shunt bobbins is to provide a field which will produce in the armature a voltage equal to the voltage of consumption; that is to say, the voltage at the lamp socket and other translating devices. The duty of the series bobbin is to generate additional voltage to make up for the drop in the armature at full load, the loss in the lines, and the loss of voltage due to armature reaction. The first two of these latter quantities can be accurately calculated, the third only approximately.

The shunt bobbin being the simplest will be taken up first. It should produce a flux of force sufficient to make the armature generate 110 volts, and with an armature carrying 168 conductors and revolving at 1500 r.p.m. it must force through it 2,619,046 useful lines. If further we assume a loss in leakage of ~~60 per cent,~~ as we have assumed, the amount forced through the

61.6

field frame must be ~~60 per cent~~ 1.6 more, or 4,190,474 lines.

To find the necessary ampere turns to force a given number of lines through a given mass of metal, air or other material, we must multiply that number of lines by the length of the path through which they are to be forced and divide that result by the area of the path and by the permeability of the substance at that density of magnetization. If these dimensions were measured in centimeters, the product obtained would be the magneto-motive force in gilberts. To reduce it to ampere turns it must be divided by 4π divided by 10, but as in this case we are not using metric measures, we must multiply by a suitable constant to reduce to English measures and .3132 is such a constant. The formula then becomes:

$$\text{Ampere turns} = \frac{\text{N} l \,.3132}{a\mu}$$

where N equals the number of lines of force, l the length of the path, a its area, and μ its permeability.

We will first apply the formula to the case of the field magnet. The length may be taken as that of a line drawn through the center of magnetic space from gap to gap, as shown in Fig. 1, and such a line will be found to be 28.06 ins. long. This determines l. N we know to be equal to 4.190474; a we have determined by the field core is 5 ins. x 11 ins. and has an area of 55 ins. It remains to find μ.

The permeability of iron or steel is very different with different compositions and varies especially in the case of steel. Indeed, so great is this variation that it has frequently been customary to cast a small slug of steel or iron on the main casting, which is broken off and its permeability determined and assumed to be the same as that of the main casting. This is probably the most accurate method, provided that the slug is not cast too thin, thereby becoming much harder than the rest of the casting. Where founders have succeeded in turning out a uniform product, resource may be had to permeability curves. In such a curve the permeability is plotted as abscissæ, and the density in square inches or square centimeters as the case may be, is plotted as ordinates, and in this way the permeability at any given density can be readily pricked off. Such a curve is shown in Fig. 2. Often the curve is plotted in what is known as a saturation curve, in which the magnetization force is plotted as abscissæ and the resulting induction or lines of force per unit of area as ordinates. Permeability is equal to magnetizing force divided by the induction, and hence if we select a point on such a curve as this at the induction at which we wish to measure the permeability and divide the induction by the magnetizing force, we shall have the quantity we require. Such curves as this have the advantage that no matter in what units they are plotted, they can be used with either the English or metric system, for permeability itself is independent of units of measure. We will consider the curve shown in Fig. 2 as a fair representative of the steel of which we are going to make the field magnet. The maximum lines of force in the field frame we have previously found to be nearly 4,950,000, which gives a density of 90,000 lines per square inch, and from the curve we find the permeability at this density is 920. We now have all the quantities in the formula and can at once compute the number of ampere turns as 726. This gives the necessary ampere turns to force the flux through the field magnet.

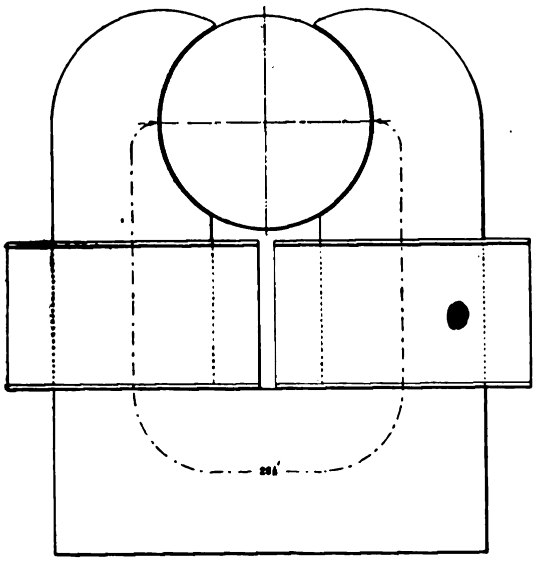

FIG. 1.—SHOWING LENGTH OF PATH IN FIELD MAGNET.

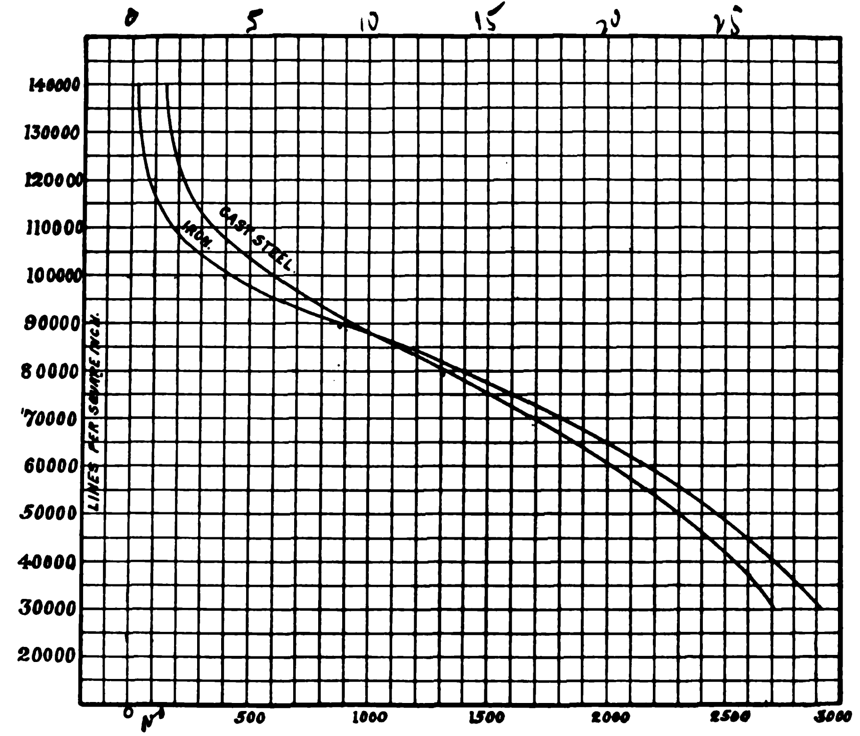

Fig 2

PERMEABILITY CURVES OF IRON AND STEEL.

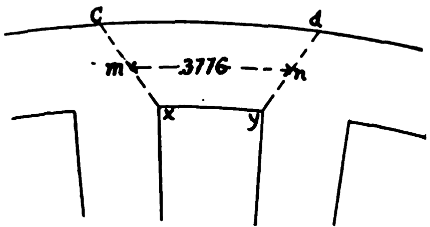

FIG. 3.—METHOD OF DETERMINING AREA OF GAP SPACE.

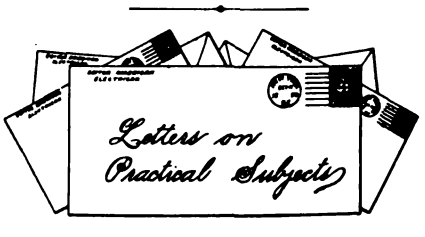
The next question is that of the gap space. The pole piece covers fourteen teeth in the armature and an area of at least 15 per cent additional should be allowed for fringing, to take account of the fact that the lines spread out in pyramidal form in passing from tooth to pole piece. To determine this quantity more accurately we may draw a section of the polar surface, together with several teeth, as shown in Fig. 3, and lay off the lines c x and d y, the points c and d being opposite the middle of the slots. Then measure the arc mn and this will be the proper width to use in computing the effective area that a single tooth contributes to the gap space. This will be found to be .3776 in., and multiplied by the length of the tooth and by the number of teeth covered by a pole piece we have the full area of the gap space, which is found to be 58.15 ins.: The length of the gap space is equal to twice the clearance, because there are two gap spaces, or .1 in. The permeability of the gap space is 1, for it is of air which has the same permeability at all densities. Applying the formula we find that the number of ampere turns necessary to force the flux through the gap space is 1410.



Handling Rotary Transformers.

To the Editor of American Electrician:

Sir: Possibly a great many indifferently designed and constructed electrical devices are coaxed into doing good work by unceasing care and skillful attention on the part of the attendants, but, on the other hand, how many good machines are ruined or severely damaged by careless handling and nonsensical "expert" work?

A case in point: Some new rotary transformers had just been set up temporarily to supply current during building operations. The transformers were located in a rough board shed, with no floor except the earth, with a few boards thrown around the machines. Naturally, the dust from the dry earth flew everywhere and made it bad for the transformer rings. The middle ring especially seemed to feel the dirt more than the others. The transformers were of the General Electric style, type T C, form A, class 4-100-750. I believe the middle ring does about all the work of starting the motor; at any rate, it seemed to cut worse than the rest.

The attendant had no vaseline, but he prepared a strip of cloth, folded it thick, and kept it saturated with oil. The rings were wiped off every few minutes with the greasy rag, all copper dust being thus removed as fast as formed. But the rings persisted in cutting, until one day, the night man chanced to come in early, and the attendant asked him to find a chance to sandpaper the rings that night after the load was off.

"Why," said the night man, "I sandpaper those rings every night," and then it came out that the night man had been in the habit of holding sandpaper and a block against the rings, with the brushes running in place, every time he came in at night, thus removing all traces of the cutting which the day man had not been able to stop, and making everything ready for another day's cutting by leaving the copper and sandpaper dust between the rings and the brushes after the sandpapering operation was finished.

It so happened that the machine was not run much after the night man got there, so he had just time to fill the brushes with sand, and then shut down until morning. It did not require much time for the day man to very forcibly lay down the law to the night runner, and it is safe to say that no more sandpaper dust will be found in those rotary transformer rings or brushes. The night man was directed to throw off all the brushes, after shutting down, to clean them and the rings thoroughly, then to wrap a long strip of emery cloth, or sandpaper, around the ring. The sandpaper was to pass about half way around, then the tangent ends were to be held in the hands and pulled back and forth, the armature being partly revolved while the sandpapering was progressing.

In this manner the roughness would all be smoothed off, and the brushes would not be made a catch receptacle for silex rock, or other abrasive material that might be made into sandpaper. I can add that this treatment thoroughly cured the cutting of the transformer commutator rings, and that similar management might do a good deal toward improving the running condition of many other electrical machines.

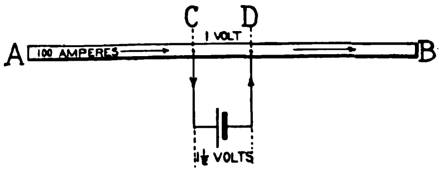
Jno. J. Holden.

Pittsburg, Pa.

An Electrical Paradox.

To the Editor of American Electrician:

Sir: In the accompanying diagram some very ludicrous conclusions may be drawn from apparently logical grounds. AB represents a feeder of, say, an electric railway system, carrying 1000 amps. The little distance DC represents a length of this feeder around which the drop of potential is 1 volt. If we apply an e.m.f. of 1½ volts to these terminals opposed in direction to the direction of the current we shall reverse the latter, stopping the main current altogether, because it is presumably impossible to have two currents flowing in opposite directions in the same wire. If this is true for the position shown we can reduce the distance CD to a smaller amount and apply a lesser voltage and the same result will still hold. If all this is true, we can take any battery, however small, and connect in this way with a sufficiently short section of a feeder carrying a powerful current and stop the latter altogether. The much mooted question of current in the Brooklyn Bridge cables could thus be very easily solved by the proper application of a few cells of dry battery. The conclusion savors so much of the impossible that, in spite of the apparently logical premises it cannot be credited; and it has been my experience that the would-be solvers of this problem are either compelled to make astonishing assumptions or quickly argue themselves into difficulties in endeavoring to evade the issue. I submit it on its merits to your readers.



AN ELECTRICAL PARADOX.

C. D. Blake.

ELECTRICAL CATECHISM.

247. What is the difference between a voltmeter and an ammeter?

An ammeter measures current, while a voltmeter measures pressure (or e.m.f.). As actually constructed, most voltmeters are simply special forms of ammeters. From Ohm's law, the current through a given circuit equals the pressure at its terminals divided by its resistance; if a high resistance is connected in series with a sensitive ammeter that will measure very small currents, then the current passing through the circuit is directly proportional to the pressure or voltage at its terminals, and the instrument may be calibrated to read volts.

248. What is meant by calibrating an instrument?

Calibration refers to the construction of the scale of the instrument, or to the determination of the value of different positions on the scale. For example, suppose that an instrument has a resistance of 10,000 ohms and that 0.001 ampere (or 1 milli-ampere) causes the pointer to move to a point say 1 in. from the zero or starting point. The pressure necessary to send 0.001 ampere through 10,000 ohms is 10 volts, since $E = C \times R$. That point on the scale might be marked either as 0.001 ampere or as 10 volts. In a similar way, the value of every other point on the scale might be determined. If the current values are marked on the scale, we say that the instrument is calibrated to read amperes or milli-amperes; while if the scale were marked to show the pressure at the terminals of the instrument necessary to give the same readings, we would say that it was calibrated to read volts.

249. Why does a voltmeter have a high resistance?

For the sake both of economy and of accuracy. By making the galvanometer very sensitive, less current is required to operate it, and as a result more resistance is needed to keep the current down to that required. Some voltmeters take so much current that they soon become heated to a dangerous degree if left in circuit continuously, and therefore the switch or push-button should be left open except when the instrument is in actual use. Even if the instrument does not become so hot as to endanger its insulation, its resistance changes as it becomes warm; this allows less and less current to pass through the instrument and it then indicates a lower voltage than that actually at its terminals.

250. Why does a voltmeter with low resistance get a poor reputation even if the switch is closed only when in actual use?

A voltmeter with low resistance takes considerable current. If the circuit whose voltage is being measured has comparatively high resistance, the additional current taken by the voltmeter may cause an appreciably greater drop on the line, so that the voltage at the point tested may be considerably lower when the voltmeter is in circuit.

251. Why are the division marks omitted in the lower parts of the scales of many instruments?

Some instruments are intended for use with currents or pressures that vary only through narrow limits, and the scale is marked only on those parts to save expense. Other instruments are not accurate for small readings and so the scales are not calibrated below a point where the instrument becomes unreliable.

252. Why are such instruments not reliable for small readings?

Partly because the friction of the moving parts is relatively great, and partly because many instruments depend upon the attraction or repulsion of soft iron cores, which is not constant for small currents at different times on account of hysteresis.

Queries and Answers.

Criticisms and extensions of the answers given in these columns will be welcomed. Windings for amateur motors and dynamos cannot be supplied, as the designs rarely justify the labor required for the calculation. The complete series of designs of small machines now being published in this journal will usually furnish data for other small machines, if intelligently applied. The privilege of this department only extends to subscribers, and queries must be accompanied by name and address to secure attention.

Can a polyphase generator be made self-exciting without the use of a D. C. commutator?

No. There must be a rectifier of some device which is closely akin to a direct commutator used in connection with the machine.

I have described a bipolar armature in which the brushes cover three segments on the commutator. I understand that the proper amount is one and one-half segments. Will the arrangement I have described cause the armature to heat excessively? G. R. R.

The arrangement you describe will make the commutation imperfect and probably cause the armature and more especially the commutator to heat more than they should.

When a common wire or common ground return is used for telephone, telegraph or trolley systems, do the different currents pass each other, thereby creating the condition of currents in opposite direction in the same conductor? H. H.

It is impossible for the current in a conductor to have two different values at the same time. It may grow greater or smaller or reverse in direction, according to the algebraic sum of various currents supplied to it. The best conception of a ground return is to consider it a reservoir of electricity from which current is delivered to and drawn from a single circuit in equal amounts. A good analogy in hydraulics would be that of a long line of pipe connecting two points in the same great body of water and through which current was forced by means of a pump.

Is there any rule to calculate the voltage between any two wires on a three-wire phase or three-phase system, when the voltage of the generator is known? M. T. K.

On the three-phase three-wire system the voltage between any two of the wires is equal to that at which the generator is rated. On the three-phase four-wire system the voltage between any of the three output wires and the fourth wire is equal to the line voltage divided by the square root of three. With the two-phase three-wire system the voltage between any wire and the common return is the rated generator voltage. The voltage between the two output wires is equal to the generator voltage multiplied by the square root of two. If independently wound on the four-wire plan the voltage between two wires of the same phase is the rated generator voltage, and between two wires of different phase is zero. With the two-phase four-wire system connected on the star plan the voltage between two wires of different phase is equal to one-half the generator voltage multiplied by the square root of two.

What method is used in determining when a storage battery is fully charged?

There are several methods of determining the amount of charge in a battery. The specific gravity of the electrolyte in the cell as measured by the hydrometer, is one of the best. The voltage of the cell is also an indication of the amount of charge it contains. To apply both of these methods intelligently it is necessary to know the kind of cell and the original density of the electrolyte used. A good way is to take the cell in a discharged condition and supply it with its rated capacity in ampere hours. At the close of that time note the specific gravity of the electrolyte by a hydrometer and the voltage by a low reading voltmeter. These readings will be criterions on which future observations can be based.

Please explain the action of the Thompson recording wattmeter. How is the speed kept proportional to the load? A. T. B.

The motor, for such it is, is wound without iron either in armature or field. Its back e.m.f. is, therefore, negligible. The armature is connected directly across the mains. The field is in series with the mains. The current in the armature is almost directly proportional to the impressed voltage, because the back e.m.f. is so slight. The current in the fields is, of course, proportional to the main current and the watts, which is the product of the two, are therefore proportional to the torque of the motor and the motor is given a load by means of the magnet and disc beneath it of such quality that its speed is always proportional to its torque and, therefore, to the watts in the main circuit, and if properly calibrated it will read in watt hours. In some cases the back e.m.f. of the motor is too great to be neglected, rendering current in the armature smaller than it should be for accuracy. In such cases a small field coil placed in series with the armature would increase the torque the proper amount.

1. What is the best method of spiraling two 3-phase lines on the same pole, working in parallel, to avoid mutual and static effects?

2. Would two barb wires arranged on separate cross-arms above be recommended as lightning protectors?

3. If a telephone 3 ft. below lower arm and with 12 ins. between centers is run, how often should it be spiraled or crossed?

4. In a step-up-step-down system using low tension machines and high tension line service, should the frame of the generators be insulated from the foundation?

5. What is the current in each leg of a Δ and Y winding? E. T. B.

1. Avoid placing wires carrying currents in the same phase adjacent to each other. Spiral the line once about every 5 miles. Be sure to have an even number of complete rotations.

2. Yes. Provided the barb wires are well grounded. In such a case, however, one wire is usually supposed to be sufficient.

3. The line should be crossed about once to a mile, and in addition at every place where the alternate current line above it crosses. Of the total length which underruns the power circuits half should be in one transposition and half in the other.

4. There is less danger from lightning for the machine if it is insulated from the foundation.

5. In the Y winding, the current in each leg is the same as the current in the line it feeds. In each leg of the Δ winding it is equal to the line current divided by the square root of 3.

How can four messages be sent over one wire at the same time by use of the Quad instrument?—R. L. C.

Two different types of instruments are used and two different types of transmitting keys. One instrument responds to a variable strength of current, but not to reversals; the other responds to reversals, but not to a variable strength of current. One key is arranged to vary the strength of the current; the other to signal by means of reversing the current. It is obvious that none of the keys and instruments mentioned will interfere with each other, and consequently that two messages can be sent over the same wire at the same time by these two principles.

In addition the services of both the intermittent and reversing systems can be developed by means of what is known as the differential principle. This is illustrated in the accompanying figure. The magnet is provided with two coils. The signaling current splits and goes around each coil of the home instrument in opposite directions, and therefore does not affect it. It enters the distant relay by only one coil, and therefore does operate that instrument if the key of the distant instrument is on the back stop. If the key of the distant instrument is on neither stop, the signaling current goes through both coils of the instrument; but, as it will be noticed, in such a direction as to have the coils assist each other in making the signal audible although the current has in this case to pass through an artificial line to the ground the double ampere turns on the receiving instrument enables the feebler current to do the work. If the distant key is on the front stop, the current in the line is neutralized by the opposition of the two batteries, but the current in the local circuit is not neutralized, because it has a free path independent of the other battery and the signal works despite the fact that the sending current was interfered with. This differential principle is combined with the one recited in the first paragraph, thus making the Quad svstem a possibility.

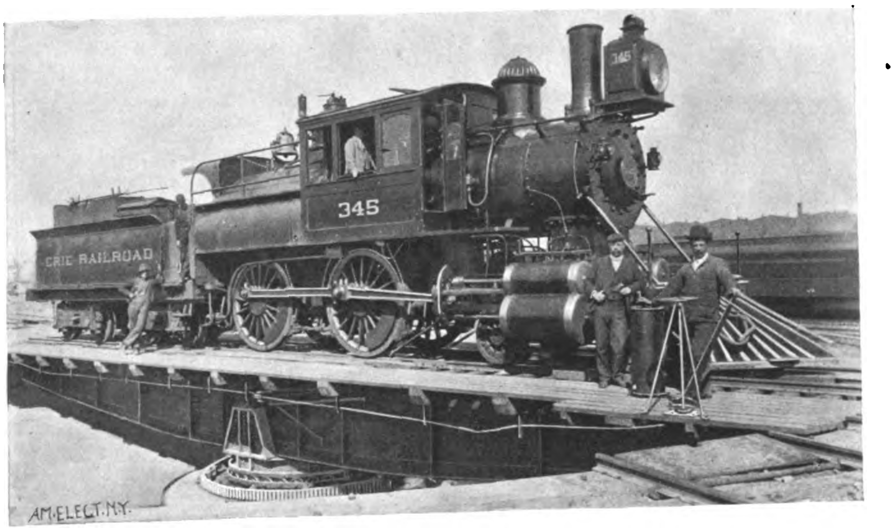
What acids are used in frosting glass, and how long must the glass be left in the solution?

The fumes of hydrofluoric acid are used for frosting glass. The parts that are to remain clear should be covered with wax and the design traced upon them. The hydrofluoric acid fumes may be generated by pouring sulphuric acid upon fluorspar spread evenly in a leaden tray. The prepared glass may be laid over the top of the tray and the latter slightly warmed. The etching or frosting is not very satisfactory, as it is not sufficiently opaque. The best results are obtained with a sand blast, in which a continuous stream of sand is blown against the glass to be frosted, by means of compressed air.

New Apparatus and Appliances

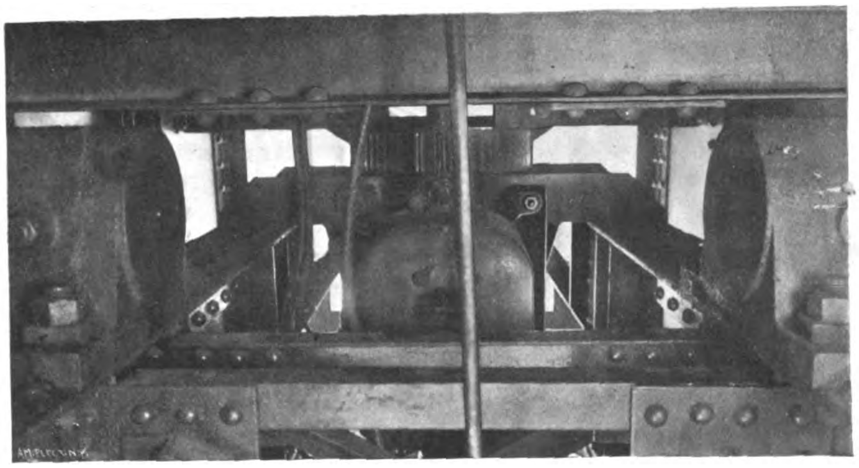
AN ELECTRIC TURNTABLE.

The Erie Railroad Company has installed an improvement in its yards in Jersey City in the shape of a new turntable driven by electricity. Although electric turntables are not new, the particular application of electricity to this one is interesting, as it involves several new features. The turntable itself is quite different from the average device for turning locomotives. It consists of a sort of a swinging drawbridge. There are two longitudinal girders which support the table platform which rest upon equalizing drums, and the entire weight rests on a set of rollers as in drawbridge practice. A pit track is provided at the outer ends of the girders, which are free to tilt down on trunnions until their end wheels rest thereon. The great problem in this drawbridge was to install the motor in such a position that the alignment would be unaffected by any motion of the table and the gears be kept properly in mesh. The motor was therefore placed upon the circular base between the girders, and is independent of any motion of the table. The power is transmitted by a double reduction system of gears, connected to a 15-h.p. series-wound motor built on the enclosed plan. The motor may be partly seen in the illustration. The upper end of the armature shaft carries a pinion which drives a gear, and the latter in turn drives a second pinion which meshes in the circle of teeth on the pier. The table is equipped with a controller at each end, and provided with reversing mechanism so that the direction of motion may be controlled. It is desirable for the operator to be directly over the end of the table, so he can see for himself when the rails are perfectly in line, and the electrical controller permits this. The current to operate this drawbridge is taken from the 500-volt power circuit of the Jersey City Electric Light Company, and is brought to a pole near the turntable and from thence the wires run underground through a cast-iron pipe to the centre of the table, where they are brought up through the vertical steel tube forming the central pivot. At the top of the table the conductors are connected to collector rings, from whence the various other wires pass to the controllers. On the pole are placed the protective devices and switches, consisting of one M. M. circuit breaker, a 75-ampere double-pole switch and two M. D. magnetic blow-out lightning arresters.



THE TURNTABLE IN ACTION.

The power required to turn the table is very small, and in practice the current is cut off after the table is turned through 35 or 40 degs., its own momentum serving to carry it the balance of the distance. The motion of the table is controlled by a band brake acting on a friction wheel, which is of sufficient dimensions to insure rapid and powerful action. The table turns from 175 to 225 engines per day and largely eliminates the congestion of traffic that has hitherto obtained in the Jersey City yards.



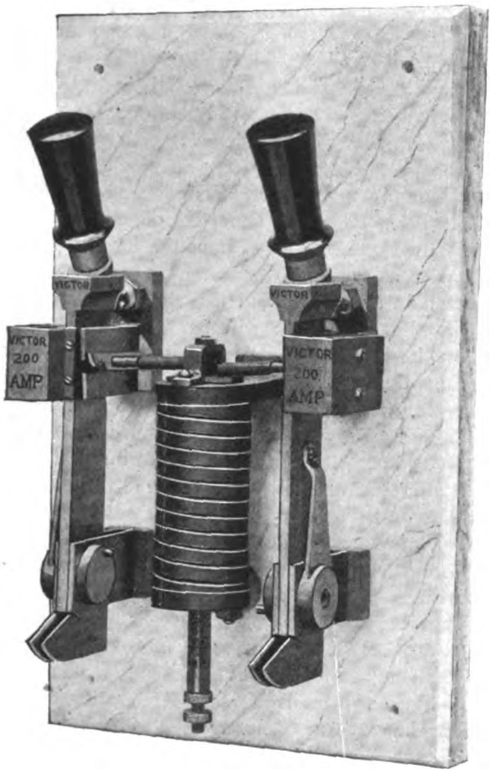
VIEW OF THE DRIVING MOTOR.

The economy of the new system has been estimated to save $270 per month, but even if no saving were made the convenience and rapidity of the electric turntable in preventing the accumulating of locomotives waiting to be turned, justifies the expenditure.

The table was built by the New Jersey Steel & Iron Company of Trenton, N. J., and designed by Mr. Mason R. Strong, assistant engineer of the Erie Railroad Company, under the direction of Mr. Charles W. Buchholz, chief engineer, and the complete electric equipment was furnished by the General Electric Company.

A NEW CIRCUIT BREAKER.

The circuit breaker illustrated in the accompanying cut has many unique features. It is a double-pole device, having two blades which can fly out independently or simultaneously. The advantage of this arrangement is that a short circuit cannot be thrown on the line without the interposition of a breaking device. One blade is thrown in at a time, and if a short circuit exists the first blade will be thrown out when the last is thrown in. The two cannot be thrown in at once, except by deliberate intent. Each blade has a separate latch and catch which acts on a roller principle, reducing the friction to a minimum. The hinged joint at the base of the blades carries on its pivot a nut which is connected by an arm to the blade itself. The closing of the blade compresses the clips of the hinge posts and improves the contact. It can be adjusted to any desired degree, and can be set to a pressure of 1000 lbs. to the square inch if necessary. This makes the hinge posts even a better electrical joint than an independent jack-knife contact. The circuit breaker is equipped with a new style carbon break of liberal capacity, and so adjusted that the copper contacts separate over an inch before the carbons, which therefore take the entire arc. This effectually prevents burning of the clips. The solenoid is wound with two coils. They are formed of bare copper and are carefully insulated between turns. The outer surface of the coil is turned and polished and presents a very fine appearance. The conducting parts of the circuit breaker are calculated on a basis of 750 amperes to the square inch. The range of adjustment of this instrument is from 100 to 400 amperes, and the normal capacity is 200 amperes. This circuit breaker is also made with under-load attachment. It is carefully calibrated and said to as reliable as any ampere meter on the market. Its installation on the switchboard is very convenient. Seven holes are all that are required to hold the circuit breaker in place on the board. These instruments have been used with great satisfaction on some of the largest installations in New York City. They are manufactured by F. A. LaRoche & Company, of New York City, and are known as the "Victor" circuit breakers.



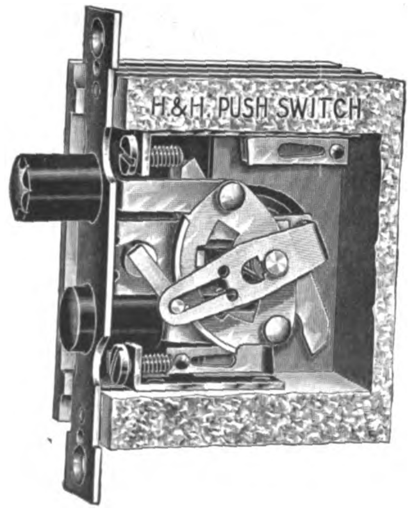
AN AUTOMATIC CIRCUIT BREAKER.

A NEW PUSH SWITCH.

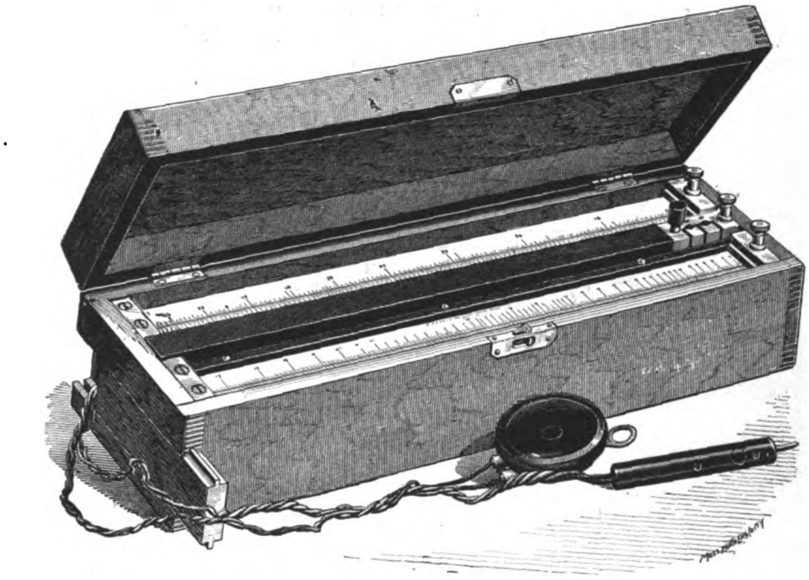
The accompanying illustration shows a new push switch which, it is claimed, is particularly desirable for use in hotels, public buildings and private houses, on account of the great ease with which it can be operated. Contractors, electrical engineers and others, who have had experience in installing push switches, know that there have been many complaints regarding them, and that a large percentage have been replaced, because they stuck or worked hard. No such difficulty will be experienced in using this particular switch. The switch is encased in a single piece of porcelain, strong and substantial, and the contacts are of the "knife switch" form. The switch plates are thoroughly insulated from the mechanism, the action is quick and positive, the break long and the carrying capacity ample. The wiring is done from the front, and all holes in the procelain which would tend to weaken it are done away with. It is stated that half the time usually required for wiring a switch is saved by the method used in the switch herewith described. The following sets forth the result of a test of this switch recently made by a large central station: "The switch tested was a double-pole Push Hart 'H. & H.' switch encased in porcelain, except the front, which was of plain nickel, and rubber push buttons, one marked to indicate light. The action of the switch was quick and positive, breaking the circuit in four places. The switch was designed for 220 volts and 10 amperes. The test consisted of making and breaking a circuit as follows:

1500 times at 115 volts and 15 amperes.
1500 " " 230 " " 15 "
200 " " 230 " " 20 "

The switch worked perfectly free and no undue heating or arcing was observed. At the end the switch was taken apart for examination and was found in good order, hardly showing that it had been used. No disastrous effect of arcing could be observed." These switches are at present made in double-pole, single-pole and three-way types. by the Hart & Hegeman Manufacturing Company, 52 High Street, Hartford, Conn.



PUSH SWITCH.



A DIRECT READING OHMMETER.

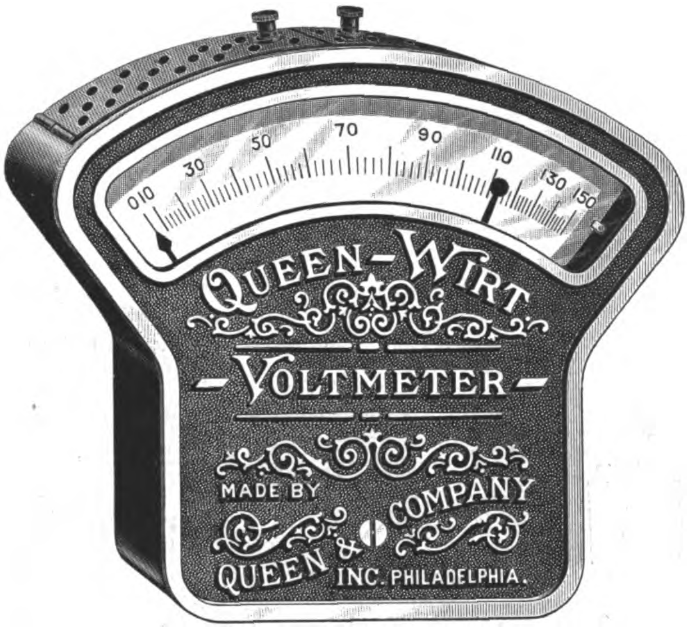
A DIRECT READING OHMMETER.

A new device for measuring resistance has been placed on the market and is depicted in the accompanying cut. It is, strictly speaking, a commercialized slide wire bridge. A wire is stretched over a scale which is divided into two parts, making the entire scale some 30 ins. long. The resistance to be measured is to be connected across the two further binding posts. A telephone is used as the detector, and a hard rubber stylus provided with a battery key is held in the hand and is touched at various points along the slide wire until a point is reached where no sound is heard in the receiver, when the resistance in ohms may be read off directly from the scale beneath.

The scale is lettered in three colors and there are three plug holes in one end of the bridge colored to correspond, and it is obvious that when the plug is placed in a hole the scale of the corresponding color responds. The resistance is connected directly across two of the binding posts, the third being provided so that other cells can be used in case the cells in the box should become exhausted and it be not convenient to renew them at once. The claims the manufacturers make for this instrument are its rapidity of operation, simplicity, adaptability to be used in any position and in dynamo rooms where strong magnetic fields are prevalent, and its cheapness. Notwithstanding the low figure at which it is sold it is thoroughly well made, being finished in polished mahogany with polished hard rubber trimmings, and accurately finished lacquered brass connecting blocks. It carries its own battery, is complete in itself and is always ready for use, and is as easily applied to a circuit as a voltmeter. It is particularly useful in running down faults on telephone switchboards, dynamos, field coils and all constructions which use electromagnets or resistances of any kind. It has just been placed upon the market by the American Electric Specialty Company of New York City.

AN ILLUMINATED DIAL SWITCHBOARD METER.

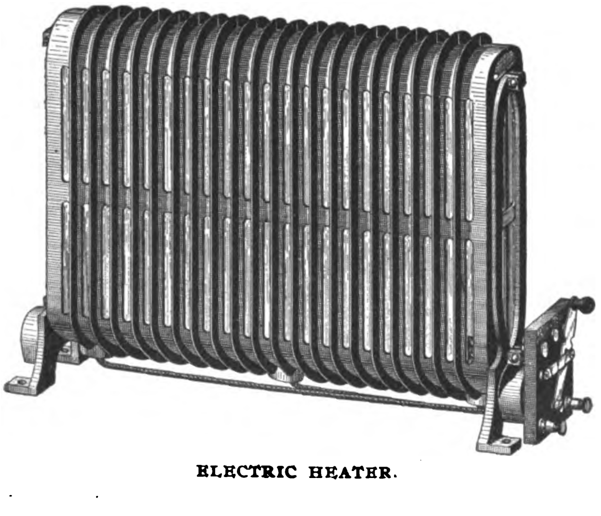
The accompanying illustration represents a new instrument which has recently been introduced on the market and is beginning to find favor in switchboard practice. It is of the illuminated dial type, the dial being illuminated by means of incandescent lamps. The instrument is enclosed in a neat iron casing, which serves as a partial magnetic shield. These meters are made for direct and alternating currents, both as voltmeters and ammeters, with any range that may be ordered. Queen & Company, of Philadelphia, Pa., the manufacturer, has great confidence in the excellence of the new instrument, and supplies with each one a certificate guaranteeing the same as to accuracy and permanency.



ILLUMINATED DIAL MEASURING INSTRUMENT.

A NEW ELECTRIC HEATER.

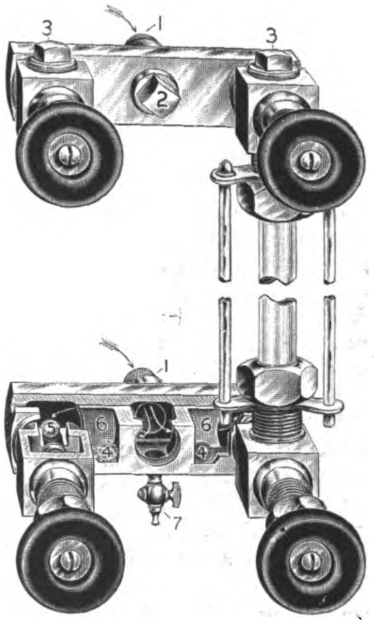
The heater shown in the accompanying illustration is made in the shape of a small steam radiator, and is 14½ ins. long, 3¾ ins. thick, 12½ ins. high, and is finished in black enamel or japan. It is made for two adjustments, half capacity and full capacity, and the switch indicates when the current is off or at which stage the heater is operating. It is adapted for 52 and 104-volt alternating currents, and also for 110 and 220 volts on direct-current circuits. The device has a wide field of application in heating small offices, bath rooms, cold corners of rooms and for general use in the spring and fall, when furnace fires are out and a raw spell comes on. These heaters are perfectly clean and do not vitiate the atmosphere. They are portable and possess in common with all other electric heaters the advantage of being always ready and of regulating the amount of heat at will. They are being placed on the market by the Western Electric Company, of Chicago.



ELECTRIC HEATER.

AN INGENIOUS WATER GAGE.

In the accompanying cut we illustrate a double automatic water gage which has many features of merit. It consists of two brass headers, if such they may be termed, which connect to the boiler directly, and the water glasses are connected between them at either end, as shown in the figure. By removing the plug, 2, the passage to the boiler may be scraped out and cleaned and all sediment removed. This is a very desirable feature, for in many water gages the impossibility of removing such accumulations renders them useless even under the care of careful firemen. The glass tubes themselves can be readily removed when broken by slacking off the packing nuts and removing the plugs marked 3. A pet-cock, 7, serves to drain both gages when that is desirable. The principal feature of this gage is the automatic arrangement for checking the flow of steam in case the glass tubes should be broken. Two brass balls marked 4 in the figure rest in pockets at the sides of the steam passage. When the glass breaks the rush of steam causes the balls to leave their pockets and forces them into the apertures at the bottom of the glass tube, thus effectually closing the outlet and preventing further escape of steam. The use of two gages is advisable, as one is a check on the other, and the determining of the height of the true water level in the boiler is too important a matter to be determined by doubtful means. The fixture is correct theoretically, and as may be readily seen from the foregoing, is thoroughly practical.

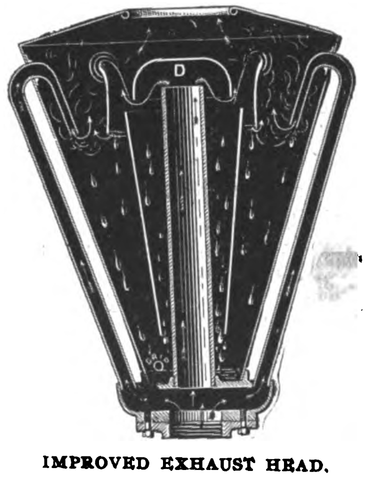


DOUBLE AUTOMATIC WATER GAGE.

This gage is manufactured by the Penberthy Injector Company of Detroit, Mich.

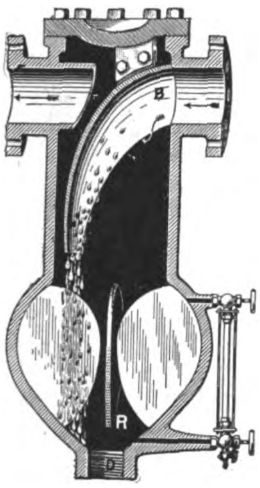
SOME NEW STEAM SPECIALTIES.

In the accompanying illustrations are depicted two important steam specialties which are the product of the Lippincott Steam Specialty Company, of New York City. The first one is an exhaust head which depends for its efficiency upon the centrifugal action caused by a quick change of direction of the exhaust steam. The special feature of novelty consists in the dividing of the steam currents into small columns, which is said to render the separation more effectual. The head is constructed of a substantial casting and is provided with a threaded central opening. The base is connected with the usual galvanized sheet iron casing, and to each of the side outlets is attached a brass or copper pipe parallel to the casing, passing to the top, as shown in the cut, at which point an elbow directs the oil to the bottom of the receiver, where a drip is provided to carry it off. The central pipe is provided with a hood which directs the steam and water, as shown by the ar-



IMPROVED EXHAUST HEAD.

rows. The casing surrounding the central tube effectually prevents the falling water being disturbed by the action of the side pipes. The side pipes afford a system of bracing which insures durability, and the large condensing surface of the head is a valuable feature.

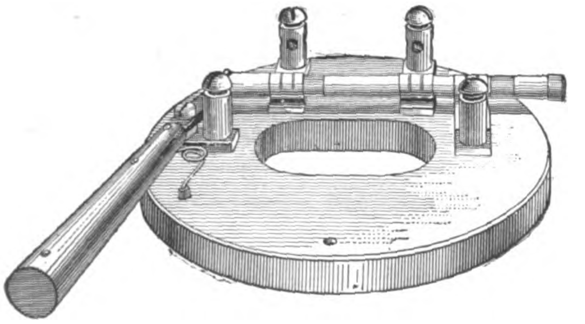


A NEW SEPARATOR.

The second cut illustrates a combined separator and oil extractor. The idea in this device is to provide a plate which will not splash the water back into the steam, as is the case where the plate is set at right angles to the inlet. This is done by making the plate of a curved shape, so that the steam and water meet it without shock, so that the latter is conducted into the receiver, where the wings prevent further disturbance by the steam. A large area around the plate is provided, so that the steam will take the course indicated by the arrows without friction. The separator is liberally designed, and is of a shape to resist internal pressure and the strains caused by the weight and contraction of long lines of piping.

AN ARC LIGHT HANGER BOARD.

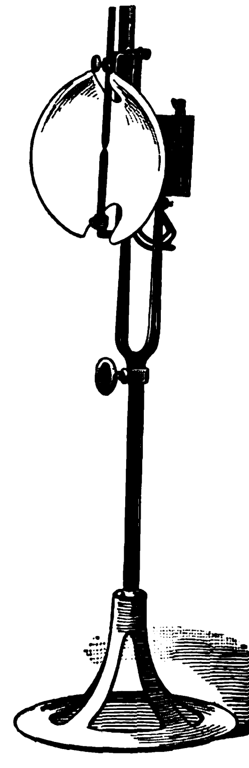
In the accompanying illustration is shown an arc light hanger board and cut-out combined. It is mounted on a fireproof base and completely cuts the arc lamp out of circuit, the action being, first, the short-circuiting of the lamp, and, second, its disconnection from the main circuit. Its merit is its simplicity. It consists merely of a rod sliding in contacts, carrying alternate sections of conducting and non-conducting material. The motion of a lever shifts this rod through the contacts surrounding it and makes the connections mentioned. A hole in the hanger board provides passage for the stack of single or double carbon lamps, enabling them to be hung very close to the board if that is desirable, and the compactness of the apparatus makes it very useful for installations in hoods for outdoor work. **The simplicity** of this board is its great attraction. It **has but two moving parts, and the four connecting blocks which all arc hanger boards** require, are simply slightly modified to include the contact rod. This combination **is a product of the K. & W. Company, of Pittsfield, Mass.**



HANGER BOARD FOR ARC LAMPS.

AN AUTOMATIC FOCUSING LAMP.

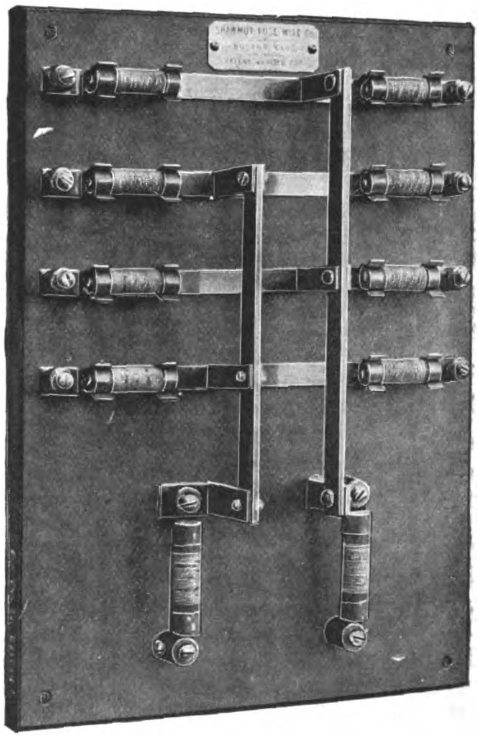
In the accompanying cut is illustrated a new type of automatic focusing lamp, for which many strong claims are made. The standard lamp is of 6000 c.p., and this can be increased when desired. The lamps will burn at any angle from the vertical to the horizontal, and are mounted on a telescopic standard fitted with ball-bearing rollers. Several of these lamps can be burned in series, thus largely saving in operating expenses. **They are so designed that they will work equally well singly or two in series, on direct current, at voltages of 110 or 220, or with the alternating current. The selling price of these lamps has been recently considerably reduced, as the maker, Chas. J. Bogue, of New York City, has largely increased his facilities and is making his lamps in larger quantities than ever before. These lamps are very popular with photo-engravers and photographers, as their intense c.p. reduces the time of exposure, thus enabling the production of more and better work in a given time.**



AUTOMATIC FOCUSING LAMP.

COMBINED TABLET AND FUSE BOARD.

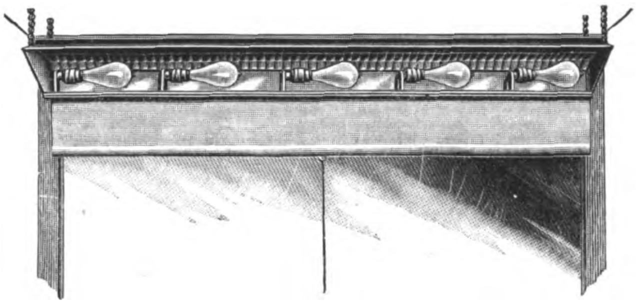
The accompanying illustration shows a combined tablet and enclosed fuse board, which it is believed will fill a demand which has existed for some time past among electrical engineers and contractors. The board is the result of some experiments, and the outcome is such that it can be manufactured at reasonable prices and cover all necessary requirements. The fuse is protected by a tube which is closed so that the gases and heated metal cannot escape. The ferrules make contact similarly to the blade of a knife switch, thereby avoiding the use of tools when fuses are replaced, a feature which will be much appreciated by those who have been obliged to place fuses in small places with a large amount of bare metal in close proximity. The device has been approved by the National **Board of Fire Underwriters, and is manufactured by the Shawmut Fuse Wire Company of Boston, Mass.**



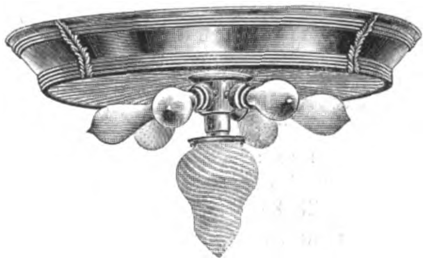
COMBINED TABLE AND FUSE BOARD.

WINDOW AND CEILING REFLECTORS.

Ninety-nine per cent of store windows are imperfectly lighted, and especially so where electric lamps are used. Most of the lamps are scattered on the bottom and at the sides of the windows where they can be seen by lookers-in, and where they attract more attention to themselves than to the goods they are imperfectly lighting. The ideal window light should light the goods and not be seen while doing so. We illustrate herewith a window reflector which is designed to be placed at the top of a window against the front glass, in such a position that it throws the light inward and downward, brilliantly lighting the window, while the glare of the direct light is shielded from the eyes of the observer. This reflector is also well adapted for lighting art galleries and telephone switchboards. Another style of reflector is shown in the illustration of a sectional glass reflector, which is intended to be placed against the ceiling, and is largely used for offices and public buildings. It can be used with or without a glass dome to conceal the lights from view, as preferred. These reflectors are manufactured by I. P. Frink, of New York City.



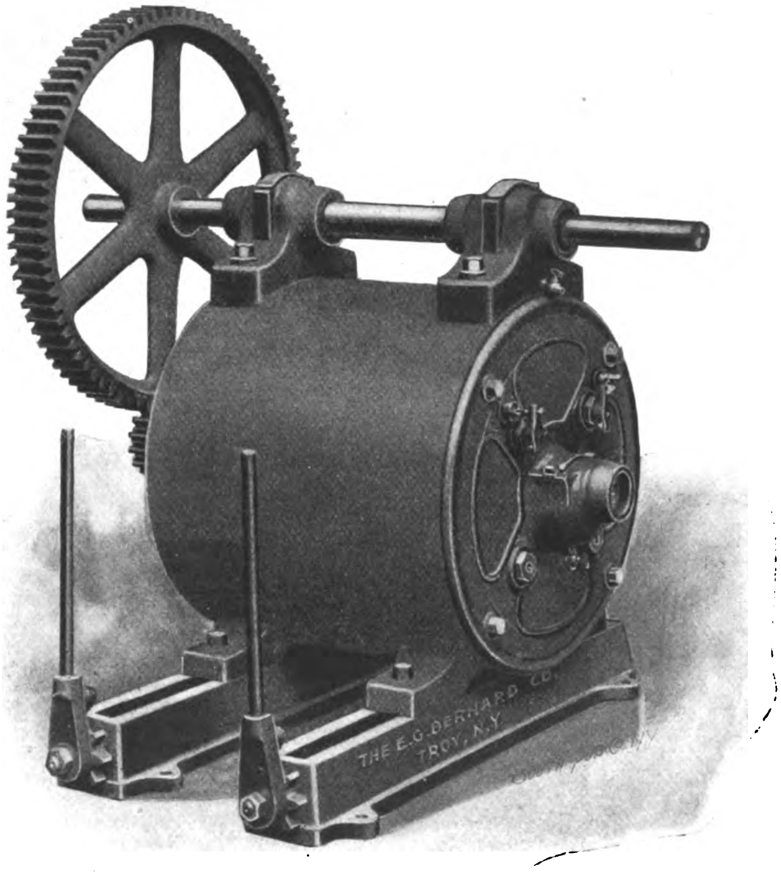
WINDOW REFLECTOR.



CEILING REFLECTOR.

A NEW ENCLOSED MOTOR.

The back-geared enclosed multipolar motor illustrated in the accompanying cut has been specially designed for direct connection to shafts, machines, elevators, pumps, exhaust fans and, in fact, for all places where dust or moisture exists or economy of space is desired. They are built for all speeds and voltages, and as dynamos, are recommended for steamer lighting. Recent installations of these motors have shown them to be very rugged, and capable of operating under the most severe conditions, and notwithstanding the short time they have been on the market there are quite a number of them in operation, from 1 to 35-k.w. capacity. They have self-oiling bearings, which are always cool, and as their enclosed form is a great protection, they require little or no attention. The highest efficiency of transformation is claimed by the manufacturers, also that this type of motor will operate without sparking and heating, and will stand large overloads. India mica insulation is used, and the material in these motors is of the highest grade throughout. Every part of the machine is easily accessible. This form of enclosed motor has been largely adopted by electrical manufacturers, and has always found favor wherever it has been installed. It is manufactured by the E. G. Bernard Company, Troy, N. Y.

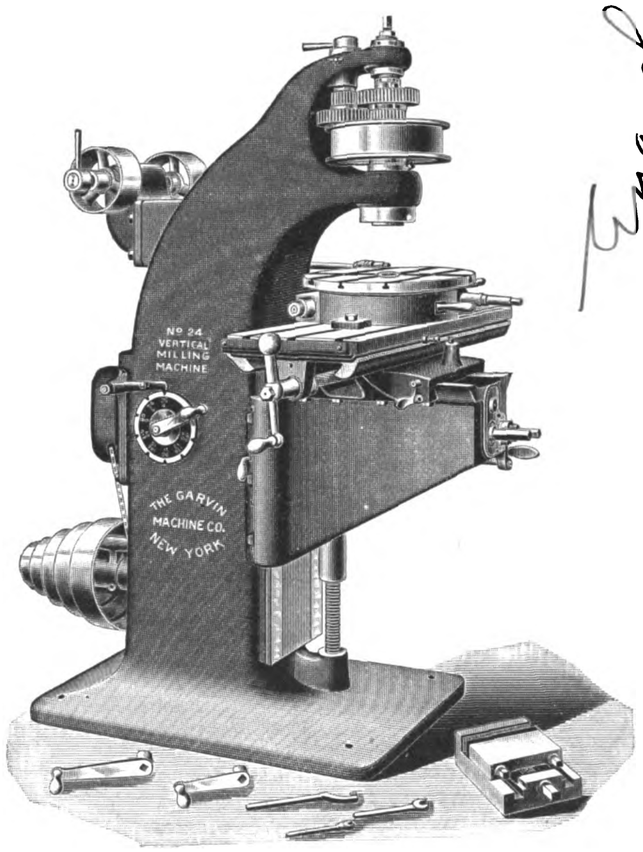


THE E. G. BERNARD CO.
TROY, N. Y.

BACK GEARED INCLOSED MULTIPOLAR MOTOR.

A NEW MILLING MACHINE.

The accompanying illustration depicts a new milling machine which is made by the Garvin Machine Company, of New York City. The milling tool, instead of being horizontal, is vertical, and the work is placed on a table which has motion in three directions. It is provided with power feed and reverse feeds in all directions, and all the feeds are thrown in and tripped by a single handle at the side of the knee. On the larger machine, known as the No. 24, eighteen changes of feed, ranging from .003 in. to ¼ in., are available for all directions. In addition to the original table provided is a rotary table which is arranged for both hand and power feed, and greatly increases the scope of work which can be done on this machine.



VERTICAL MILLING MACHINE.

The miller is provided with back gears and can take very heavy cuts on tough material, and therefore is alike adaptable to rapidly roughing out stock, or working to the thousandth of an inch.

This unique tool bids fair to become a very desirable adjunct to the equipment of machinists and manufacturers.

Eng. Society Library

NEW BOOKS.

Commercial Cuba. A Book for Business Men. By William J. Clark, Manager Railway Department, General Electric Company, with an introduction by E. Sherman Gould. 8 maps; 7 plans of cities; 400 full-page illustrations. Published by Charles Scribner's Sons, New York. One volume; large octavo. Price, $4.00.

This is one of the most important works which has yet appeared relative to our new possessions and "protectorates." Mr. Clark's reputation as a statistician and a man who does well everything which he takes hold of will be increased by this work, for the amount of material which he collected during some of his trips to Cuba and in this country has been simply enormous, and proved in the late war of the greatest service to the Government, by some of whose officials Mr. Clark was specially thanked and congratulated. Much of this information has been packed into this book, and many of the maps and city plans are here published for the first time. The purpose of the work is to make it possible for those who are planning to help develop the business enterprises in Cuba to enter the field with a full knowledge of the commercial and social conditions there and of the natives. The first two chapters deal with the characteristics and occupations of the people of Cuba, the third of its climate and the preservation of health, the fourth and fifth on its new geographical features and methods of transportation and communication, the sixth on currency, banking and government finance; the seventh on the legal and administrative system of the past and the future, the eighth on animal and vegetable life, the ninth on sugar and tobacco, the tenth on general statistics, and the seven remaining chapters on the different provinces and on the city of Havana. In the appendix is found a commercial directory of the island.

PERSONALS.

MR. J. A. WILLIAMS, of Cleveland, Ohio, has been on an Eastern trip on business for the Williams Electric Company, of which he is president and general manager. Mr. Williams has secured a large number of orders in Eastern cities for the magneto bell which is manufactured by his company.

MR. HENRY EAGER has resigned his position as superintendent of the Onondaga Dynamo Company, of Syracuse, N. Y., with which he has been connected since the organization of that concern. He has associated himself with Messrs. A. C. Powell & Son of the same city, who will hereafter manufacture dynamos and motors.

DR. S. S. WHEELER, the well-known president of the Crocker-Wheeler Electric Company, of New York, was married at Rye, N. Y., Oct. 11, 1898, to Amy, daughter of Mr. and Mrs. John Joseph Sutton. The ceremony was performed at the family residence by Rev. J. E. Bushnell, assisted by Rev. Dr. G. W. Knox. Mr. Gano S. Dunn was best man. Dr. and Mrs. Wheeler will occupy a house in the Murray Hill district, New York City.

MR. M. COKELEY, who is probably known to many in the electrical field, has been made superintendent of the works of the C. W. Hunt Company, Staten Island, N. Y., assuming the duties of that position Oct. 14 after several months' work revising the factory systems. Large concerns are beginning to relieve the office management of the providing for the details in office routine, the installation of systems, methods, etc. This work properly belongs to a specialist; one who, constantly keeping his eyes open for improvement, studying the best literature on the subject and devoting his energy entirely to this work, becomes an expert. Mr. Cokeley has made this special work his profession for some time, being for many years with the General Electric Company, and later with other prominent firms. His experience as a practical mechanic has been of great benefit in his line of work, enabling him to detect almost instantly the leaks that invariably exist, and which are so destructive to profits.

LEGAL NOTES.

ENCLOSED ARC LAMP DECISION.—In the suit of the Marks Enclosed Arc Light Company, 687 Broadway, New York, vs. Washington Mills Company, 74 Worth Street, New York, a decision has just been rendered in favor of the complainant. The suit was begun in the United States Circuit Court Sept. 10, 1897, and the decree granted to the Marks Company by Judge Coxe on Oct. 18, 1898. The patent infringed is No. 520,996, of Marks & Ransom, dated June 5, 1894. This patent broadly covers the method of operation used in all modern enclosed arc lamps. The Washington Mills Company were users of the Kinsman lamp, sold by the Electric Construction & Supply Company, 27 Thames Street, New York. The decision peremptorily stops the sale of unlicensed enclosed arc lamps by the latter company, and also involves the payment of damages by the defendant.

THE BATES MACHINE COMPANY, of Joliet, Ill., states that the proceedings instituted against it about two years ago in the United States Courts by the Excelsior Heater Company, for alleged infringement of a heater patent, have terminated in a complete victory for the Bates Machine Company, a decision of the United States Circuit Court of Appeals, at Chicago, the court of last resort in this case, having been handed down by Judge Woods on October 3 last, and the complainants' bill dismissed. The Cookson heater, manufactured by the Bates Machine Company, combining a heater, purifier and oil separator, has met with great favor among steam users, and its sales have increased rapidly of late. Now that the above-mentioned suit has been decided in its favor, the company anticipates a larger demand than ever before for its apparatus, and is thoroughly prepared to fill all orders promptly. The company guarantees the Cookson heater as to material and construction, and that it will produce a temperature of feed water from 206 to 212 degrees at all times, without back pressure.

A DECISION was handed down by Judge J. Thomas of the United States Circuit Court, Eastern District of New York, at a final hearing of the cases of Thomas F. Morrin vs. Thomas J. Lawler and Thomas F. Morrin, and the Clonbrock Steam Boiler Company vs. Edison Electric Illuminating Company of Brooklyn. The opinion was in brief that the defendants had infringed the rights secured to the complainants by patents which deal with the construction of the Climax boiler and the first and second claim of patent 463,307, as to the tubes, and also the improvements which the complainant is entitled to by patent 463,308. The characteristics of the Climax boiler which have been thus strongly upheld by the Court are as follows: 1. The radial tubes are to be heated by an annular grate surrounding an upright generating cylinder. 2. The tubes are arranged so that the upper branches of one tier overlap and enter the cylinder above the lower branches of the next tier above. 3. The tubes are set obliquely to the axis of the generator cylinder. 4. The tubes extend to an equal extent in the generator cylinder. 5. The tubes are of the ogee form.

The decrees will be prepared and settled on the usual notice, pursuant to the order of the Court. Messrs. Arthur von Brieson and Daniel O'Connell appeared for the complainants, and Messrs. Frank R. Lawrence and Edwin H. Brown for the defendants.

EDUCATIONAL NOTES.

THE COURSES OF ELECTRICAL STUDY of the United Correspondence Schools of New York City are reported to give entire satisfaction to all who have taken advantage of the opportunities they offer. Their scope enables any one who is desirous of perfecting himself or increasing his general information to avail himself of the advantages they offer. The courses mentioned are devoted to electrical engineering, station engineering, electric lighting, electric railways, telegraph and telephone, electro-plating, mechanical drawing, and the design of dynamos and motors is also taught in connection with them.

THE BROOKLYN INSTITUTE OF ARTS AND SCIENCES has issued an attractive prospectus of 167 pages. It contains a preliminary announcement of the meetings, addresses, lectures, exhibitions, department meetings, concerts, dramatic readings, schools and courses of instruction and other work which will be conducted by the Institute and its departments during the years 1898 and 1899. Active work begins on Thursday, Sept. 29, and closes on Saturday, June 3. The number of anniversary addresses, lectures, exhibitions and department meetings open to every member is 550. The members' weekly tickets admit to each of these two persons in the evening and one in the daytime. Most of the lectures and larger meetings will be held in the halls and lecture rooms of the Y. M. C. A. Building, Fulton and Bond streets, and also in the Art Building, 147 Montague street, and in the Academy of Music, Brooklyn, N. Y.

THE ELECTRICAL ENGINEER INSTITUTE OF CORRESPONDENCE INSTRUCTION, of New York City, has secured among its instructors some of the most able men that the engineering field can produce, among which may be mentioned Prof. Francis P. Crocker, of Columbia University; Charles F. Scott, of the Westinghouse Electric & Manufacturing Company; Prof. W. J. Herdman, of the University of Michigan; Elmer G. Willyoung, the well-known instrument expert; William Maver, Jr., the telegraph authority; Thorburn Reid, the well-known dynamo designer; Dr. Frederick S. Kolle, the X ray expert; Joseph Sachs, insurance inspector and authority on interior wiring; Townsend Wolcott, the well-known consulting electrical and mechanical engineer; Arthur N. Mansfield, the well-known telephone authority; Alfred E. Wiener, the electrical engineer and author; Hugh M. Wharton, of the Westinghouse Electric & Manufacturing Company; J. Appleton, of the Electric Storage Battery Company, and Herman A. Strauss, electrical engineer. Whatever these gentlemen write will be worth reading, and when written with a view to make matters clear to the uninitiated there is no doubt that their work will be of double interest to the student who is assured that he is consulting the work of well-known experts.

TRADE PUBLICATIONS.

MESSRS. HUEBEL & MANGER, of Brooklyn, N. Y., are circulating their No. 4 catalogue for 1899, which describes their bells, push buttons and other electrical goods. A great variety of household electrical appliances are illustrated, including switches, letter boxes, binding posts and parts of electrical apparatus.

THE PITTSBURGH TRANSFORMER COMPANY, of Pittsburgh, Pa., has issued to the trade a catalogue of its type K transformers, which is descriptive of its construction, and also includes a table of tests showing the performance of the transformers to good advantage. It claims many advantages of construction and economy in its product.

THE WILLIAM POWELL COMPANY, of Cincinnati, Ohio, have issued a pocket edition of their No. 7 Steam Catalogue. Besides describing in detail their very complete line of goods, this catalogue contains valuable tables for the use of steam engineers. These in themselves are of sufficient value to make the book a desirable acquisition.

THE NEW BRITAIN MACHINE COMPANY, of New Britain, Conn., is distributing to the trade two new catalogues. One is devoted to the Case high-speed automatic engines, which are well known, and are largely used for direct connection to small dynamos, which have an excellent reputation. The other describes a mortiser for woodworkers.

THE LOMBARD WATER-WHEEL GOVERNOR COMPANY, of Boston, Mass., has issued a catalogue describing and illustrating its water-wheel governor, which has made such a reputation for prompt and accurate control of turbines. The book contains many diagrams taken from various plants, which eloquently describe the merits of the device. The governor is a standard hydraulic station fixture and is well known to engineers.

THE MASON REGULATOR COMPANY, of Boston, Mass., has just completed a new catalogue of its steam devices, which is well illustrated and describes its hydraulic dampers and regulators, reducing valves, pressure regulators, balanced valves, pump governors and other well-known steam specialties. It is a valuable work of reference for the many engineers who have adopted this apparatus for their standard.

JAMES G. BIDDLE, of Philadelphia, has just issued to the trade a new catalogue known as Catalogue B, devoted to descriptions and illustrations of electrical measuring instruments. The catalogue includes data of the Jagabi portable testing sets, Weston instruments, circuit breakers and various forms of rheostatic devices. It contains data of particular interest to college and professional men, relative to electrical measurements.

THE FARR TELEPHONE & CONSTRUCTION SUPPLY COMPANY, of Chicago has just issued a new catalogue, describing its goods. The company is a wholesale dealer in telephone supplies, and handles complete box telephones of all sizes and for all purposes. Its portable telephones, long-distance telephones, generators, receivers, transmitters, switchboards and lightning arresters, together with a full line of minor telephone accessories, are described in the book.

THE ELECTRIC STORAGE BATTERY COMPANY, of Philadelphia, Pa., has issued Circular No. 45, describing the installation of the Barre-Montpelier Traction Company, reprinted from the "Street Railway Journal" of September, 1898. It will doubtless be remembered that the various forms of storage batteries of this company have been described in a series of these circulars, which are of uniform size and suitable for subsequent binding. The set, when completed, will furnish a book of valuable information on storage batteries.

A NEW CATALOGUE on focusing arc lamps is being circulated by the Baker & Fox Company, of Brooklyn, N. Y. The catalogue describes both hand and automatic lamps in detail. The lamps are very simple, and ought to be durable and efficient. They are said to be unaffected by dust or grit, and require no attention. They are made for direct or alternating currents or both. These lamps are particularly adapted for every variety of college, theatre or lecture work and photo-engraving. The company will send copies of its catalogue to those interested.

THE WESTERN TELEPHONE CONSTRUCTION COMPANY of Chicago, one of the largest independent telephone companies in the world, has recently issued a new catalogue which describes its telephones, transmitters, receivers, switchboards and telephone appliances of all kinds. This company prides itself on the high grade of its instruments and the general all around excellence of its workmanship. The catalogue is copiously illustrated and minutely descriptive of the apparatus. It is supplemented with frequent illustrations of the facilities of the company for manufacturing on a large scale.

THE NEW CIRCULAR of the Westinghouse Electric & Manufacturing Company, of Pittsburgh, Pa., on polyphase inductor generators is interesting, as it describes and illustrates in detail the machines of this type that the company is now producing, which are a distinct departure from their former practice. The rotating part or inductor contains no moving wire. The field coil is concentric with the shaft, and is stationary. The company has also issued another circular on Rotary Transformers for Electrolytic Work which is beautifully illustrated and replete with technical detail of interest and value.

THE GOULDS MANUFACTURING COMPANY, of Seneca Falls, N. Y., is distributing to the trade a new catalogue which is devoted to its electric triplex power pumps, and illustrates the many appliances and methods of connection which may be successfully used with these devices. Where so many pumps of large size are daily in use, the question of economy becomes an important item, and, as the engineering trade knows, there is no device so wasteful of its power as the ordinary steam pump, which it is believed will soon be supplanted by the electric pump. This catalogue should be interesting to engineers of all classes.

THE C. W. HUNT COMPANY of New York City has issued a catalogue entitled "Industrial Railways," which is descriptive of its practice in railways for the handling of coal, bark, cinders and other materials which it is desirable to transport in large quantities with a minimum amount of handling. The book contains upward of 130 illustrations, all of which are extremely interesting to the managers of electric power stations, founders, machinists, and everyone who, in the course of his business, has heavy weights to handle. In another catalogue the company describes mast fittings, coal scoops, pulleys and sheaves and similar devices, and in a third publication it describes the various ropes for rope drives, for which the C. W. Hunt Company has become famous. The catalogue on rope driving has an illustrated appendix containing a great deal of valuable technical data.

THE NEW CATALOGUE of the Electric Appliance Company, of Chicago, Ill., has just been issued, and is a very complete description of its telephone apparatus and appliances. It calls particular attention to a new automatic hook of the company's own design, and very strong claims are made for it. The hook is easy to install and occupies but little space. It is assembled and adjusted before shipping, and is certain to reach the customer in good order. The contacts are visible upon opening the door, which facilitates inspection and wiring. It is constructed with a cam at the back to prevent the lever from being bent out of shape, and is apparently a very useful article. The catalogue contains ninety-six pages, and is well indexed, and every appliance is well illustrated and described, making the book particularly desirable and valuable for the trade files of the contractor and engineer.

"IMPROVED BRUSH ARC LAMPS" is the title of an artistic brochure just issued by the General Electric Company dealing with the modifications introduced in the latest types of single and double Brush arc lamps, as experience with the operation of past types has dictated. Each detail of improvement is explained clearly and concisely, and in conjunction with first class half-tone illustrations, so that even persons unfamiliar with the Brush lamp mechanism will find no difficulty in grasping the import of the various changes and improvements. The leading features are summarized, each under its own heading, and the brochure concludes with a full catalogue of the parts not only of the improved lamp, but also of lamps 30 and 31. The pamphlet is issued from the General Electric Company's own printing office, and in general artistic appearance, letter press and illustrations, compares well with the work of our best catalogue makers. It will be sent to those interested on application to any of the company's sales offices.

THE ELABORATE TREATISE ON MECHANICAL DRAFT recently issued by the B. F. Sturtevant Company, of Boston, Mass., is unique as a trade publication, in that it presents no personal claims for the merit of the system or the apparatus necessary for its operation, but relies solely on the statements of unbiased witnesses to emphasize its features. For this reason the following quotation from this important work is of especial interest and value. It consists of a summary of the especial advantages of mechanical draft as presented by the well-known engineer, Mr. Alfred Blechyden, in a paper before the British Institution of Mechanical Engineers. He says: "First, it seems fairly well established that, if the boilers are well constructed and are provided with ample room to insure circulation, their steaming power may without injury be increased to about 30 to 40 per cent over that obtained on natural draft for continuous working, and may be about doubled for short runs. Secondly, such augmentation is accompanied, in normal cases, by an increased consumption per i.h.p. But, thirdly, the same or even greater power being indicated it may, with moderate assistance of forced draft, be developed with a smaller expenditure of fuel, the grates, etc., being properly proportioned. Fourthly, forced draft enables an inferior fuel to be used; and, fifthly, under certain conditions of weather, when, with normal proportions of boiler, it would be impossible to maintain steam with natural draft, the normal power may with forced draft be insured. In particular cases any or all these advantages may be a source of economy, and the first of them may render possible that which would otherwise be impracticable.

BUSINESS NEWS.

THE OTTO GAS ENGINE WORKS, Philadelphia, state that they have recently installed two 120-h.p. Otto engines for street railway service, at Stockton, Cal.

A. C. BECKEN, of Chicago, Ill., reports a brisk demand for the Paillard non-magnetic watches. These watches are unaffected by electrical machinery or other powerful magnetic influences.

M'LEOD, WARD & COMPANY, of New York City, report unprecedented sales of their Kinsman desk lamps. The Ward orchestra lamps are also meeting with a large demand from all parts of the country.

THE BOSSERT ELECTRIC CONSTRUCTION COMPANY, of Utica, N. Y., is manufacturing a switchboard to be used in the post office at Atlanta, Ga. Kingsbury, Samuel & Company of Baltimore, have the contract.

THE CENTRAL TELEPHONE & ELECTRIC COMPANY, of St. Louis, Mo., is doing a large business in telephone supplies, and has installed a telephone repair business, which is a new development in the telephone field.

THE C. McINTIRE COMPANY, of Newark, N. J., the well known manufacturers of terminals and connectors, is now making a specialty of fuse wire, fuse links and strips, which are finding much favor among contractors.

PHILLIPS INSULATED WIRE COMPANY.—The increase in the business of this company has made it necessary to begin the erection of a large four-story-and-basement brick addition to their present factory at Pawtucket, R. I.

WILLIAM ROCHE, of New York City, is now offering to the trade a miniature battery, oval in form, 1⅝ in. by 1⅛ in. over all, which is especially intended for necktie pins, cataphoresis and similar purposes. The Roche No. 2 cell is meeting with great favor among telephone men.

THE BECKER NAME PLATE COMPANY, Boston, Mass., is sending out to the trade an attractive paper knife and envelope opener, which will be found a useful souvenir as well as serve to remind manufacturers that the Becker Company is prepared to supply all demands for ornamental and handsomely finished name plates.

THE MONTAUK MULTIPHASE CABLE COMPANY, of New York City, reports excellent business, and states that its cable is finding great favor. It has received a communication from the Milwaukee Auxiliary Fire Alarm Company, indorsing and authorizing the use of its cable in connection with the auxiliary system of Milwaukee, Wis.

ELECTRICAL WORKERS' UNION NO. 3 will hold its annual ball at Murray Hill Lyceum, New York, Nov. 7, 1898. As the receipts are to be turned into the fund for the benefit of the sick and the relatives of the deceased members of the organization, it is hoped there will be a large attendance. An unusually interesting programme has been provided.

THE AMERICAN ELECTRICAL HEATER COMPANY, of Detroit, Mich., reports a good business in its newly designed portable electric heater. The company has had a great deal of experience in portable heaters, and the simplicity and efficiency of its latest product, together with its good workmanship and low price, is responsible for its popularity.

THE BUCKEYE ELECTRIC COMPANY, of Cleveland, Ohio, says that its special coiled filament lamp represents that which all manufacturers have striven to produce, namely, the lamp which shows practically a straight line c.p. curve for 500 or 600 hours when burned at normal voltage. The company is now carrying a large stock of lamps at its Chicago office.

THE LIPPINCOTT STEAM SPECIALTY COMPANY, of New York City, is doing a good business in the manufacture of steam engine indicators, oil filters and a full line of engine and steam supplies. The company's headquarters is at 169 Broadway. It has already circulated copies of its new catalogue, and is preparing a special catalogue for distribution among engineers.

THE CROUSE-HINDS ELECTRIC COMPANY, of Syracuse, N. Y., has an excellent equipment for turning out the finest class of work on switches and panel boards. The company carries a large line of these goods, which are described in its catalogue. It has a large corps of engineers and draughtsmen, and is in a position to quote prices on all kinds of special work of this class.

A DIVIDED CIRCUIT TOLL LINE TELEPHONE SYSTEM is being brought out by the Stromberg-Carlson Telephone Manufacturing Company, Chicago, that is claimed to be entirely free from the broad claims of the Carty patent on the bridging system, recently upheld in Pennsylvania as valid. It is said to have some new and improved features, compared with the regular bridging or series systems.

THE ROE STEVENS MANUFACTURING COMPANY, of Detroit, Mich., states that its Scott gate valve and the globe angle and safety valves are very popular abroad, where they have been tested in some of the more important government work. They have recently made large shipments to London, Hamburg and Christiania, and are making a second shipment of six 30-in. gate valves to Honolulu and Hawaii.

MR. H. T. EDGAR, who is in charge of the New England office of the Jandus Electric Company, states that its inclosed arcs are to be installed in the new Boston Terminal Station, which, when completed, will be the largest structure of this kind in the world. The lamp was selected by Westinghouse, Church, Kerr & Company, who are installing the entire equipment of the electrical plant.

THE PHOENIX IRON WORKS COMPANY, of Meadville, Pa., reports an excellent business, having recently taken orders for tandem compound engines aggregating about 2000 h.p., and in addition quite a number of simple direct connected engines. The company has supplied five engines for the Park Row Building in New York City, which is thirty stories high and, without doubt, the highest office building in the world.

THE SNOW STEAM PUMP WORKS, of Buffalo, N. Y., reports that it has secured the contracts for furnishing the pumps on a Russian battleship and cruiser and also the American battleship "Maine," which are now being constructed. It is understood that the contract was awarded on competitive plans, and speaks well for the high degree of excellence which has been achieved by the Snow Steam Pump Works in its well-known apparatus.

THE KEASBEY & MATTISON COMPANY, Ambler, Pa., is manufacturing a magnesia covering for steam pipes and all heating purposes. Robert A. Keasbey is the sole agent in New York State. It was incorrectly stated in our last issue that the boilers and steam pipes in the plant at the Grand Central Depot were covered with magnesia covering. The work was done by the H. W. Johns Company, of New York, which used its well-known asbestos covering.

THE H. C. ROBERTS ELECTRIC SUPPLY COMPANY, of Philadelphia, Pa., though not quite one year old, has made active progress, and is now classed among the largest electrical supply houses of the country. The success of this house is largely due to Mr. Roberts himself, who is a hard worker of large experience. The prompt attention which the company gives to its orders has undoubtedly done much to secure and hold its large and rapidly increasing business.

THE CABINET MANUFACTURING & SUPPLY COMPANY, of Cleveland, Ohio, states that it has purchased the business of the Cabinet Manufacturing Company, of Steubenville, Ohio. The headquarters of the new company are at Cleveland. The company manufactures all kinds of cabinet woodwork, and makes a specialty of telephone woodwork. It wishes to inform the trade that it is in business to stay, and has ample facilities for filling all orders promptly and with satisfaction to its patrons.

THE ORIENT ELECTRICAL COMPANY, Youngstown, Ohio, reports that its factory is running overtime to keep up with numerous large orders received for its well-known incandescent lamps. The company is making extremely low prices on its product, and the experience of thousands of users has demonstrated the reliability of the company's claims regarding the quality, long life and high efficiency of its lamps. Lamp users will do well to get prices from the Orient Company before placing orders.

THE AMERICAN PEGAMOID COMPANY, of New York City, recommends its aluminum paint, which has many qualities which are valuable in electrical industries. It dries quickly, is untarnishable, washable and water, oil, grease and weather proof. It is stated to be excellent for protecting and decorating motors, dynamos, lamp brackets and metal work of all kinds. It possesses the important property of being very adhesive to the article to which it is applied, and electrical manufacturers will do well to look into its merits.

THE RICE & SARGENT ENGINE COMPANY, Providence, R. I., has in operation in the machine shop of the Brown & Sharpe Manufacturing Company one of its cross-compound condensing engines, of 350 i.h.p. This new engine took the place of a pair of non-condensing simple engines of the Corliss type, one of which was built in 1872. The change has effected a saving of 10 tons of coal a week. The gain in economy illustrates the great advance made in steam engineering during the past twenty years, and, moreover, speaks volumes for the efficiency of Rice & Sargent engines.

THE EUREKA ELECTRIC COMPANY, of Chicago, Ill., has opened a telephone business, and will manufacture telephones, switchboards, receivers and electrical appliances. It proposes to supply to the trade high-grade instruments at reasonable prices. The management is one of wide telephone experience, and comprises the following gentlemen: Mr. I. J. Kusel, president; Mr. H. J. Kusel, secretary and treasurer, and Mr. A. J. Kusel, superintendent of the factory. These men have long been in the telephone field in both its commercial and technical phases, and their wide experience and ability will undoubtedly insure the company's success.

THE ROCKWOOD MANUFACTURING COMPANY, of Indianapolis, Ind., has just made arrangements with Mr. George Child, Monadnock Block, Chicago, to represent it in the Central States. Mr. Child will handle the Rockwood patent friction pulleys, which are already so well and favorably known among power users. This company reports a large number of sales recently made for export service, and it is becoming quite evident that power users abroad are rapidly awakening to the valuable efficiency and economy of another American product. The Rockwood Company is to be congratulated over the enviable success it has attained with these pulleys.

ROUSSEAU'S ELECTRICAL WORKS, New York City, report the receipt of a large number of orders for their window and door springs, and also electric gas burner attachments. A large stock of these specialties is now being manufactured, so that all orders, no matter what size, can be filled promptly. Mr. Randolph Meikleham, secretary of the company, exercises careful supervision over all work turned out, and his long experience in this business is a guarantee that none but the best workmanship and the best material are used in the company's product. Supply dealers and others are invited to correspond with him for prices and other information.

JOHN STEPHENSON COMPANY, New York City.—On application made by Charles H. Davis, president; L. M. Delamater, secretary and treasurer, and A. L. Phillips and B. P. Flint, directors, Justice Cohen has appointed Albert A. Wilcox and Louis Stern receivers of the above corporation. The petition states that the company cannot meet its maturing obligations. The Stephenson Company is one of the oldest and largest manufacturers of cars in the world, and is at present carrying out a number of important and valuable contracts from which, if they can be completed, considerable profit can be realized which will be of benefit to the creditors of the company. The assets are stated at $1,175,776, and the liabilities $788,772.

WICKES BROS., the well-known builders of boilers, Saginaw, Mich., have found it necessary, on account of their rapidly increasing business, to open a Chicago office, at 1214 Marquette Building. This is in charge of Mr. W. S. Huyette, the contracting engineer of the company, who has been eminently successful in his past efforts for this company. Messrs. Wickes Bros. have just closed a contract with Armour & Company, Chicago, for eight 250-h.p. units for Armour & Company's new elevator, which, it is said, will be one of the largest in the world. In addition, they will install twelve vertical water tube boilers, of 375 h.p. each, in Armour & Company's new central station plant at the Stock Yards. This installation will be one of the largest in the West.

THE GOUBERT MANUFACTURING COMPANY, of New York City, states that it is exceedingly busy, and has recently booked the following orders: One 3000-h.p. heater for one of the New York & Pennsylvania Company's pulp mills; one 3000-h.p. heater for the Cleveland Electric Railway Company, of Cleveland, Ohio; one 5000-h.p. auxiliary heater for the Metropolitan Street Railway Company, of New York City, making 35,000 h.p. now building for that company alone. It has also just delivered a 3000-h.p. heater to the People's Electric Light Company, of Newark N. J. These orders are in addition to the regular calls on the Goubert Company for heaters of smaller sizes, and are certainly suggestive of the magnitude of modern steam plants.

THE ABENDROTH & ROOT MANUFACTURING COMPANY, of New York City, is the sole manufacturer of spiral riveted pipe, which has demonstrated its great strength, durability and the ease with which it can be handled. The company reports that its business in that commodity is constantly increasing. Among the large orders it has received recently are the following: Sheely & O'Shee Company, of Lincoln, Neb., 12,000 ft. of pipe, which will be used in extending the waterworks at Lanesboro, Minn.; 10,000 ft. to the city of Milledgeville, Ill., and 15,000 ft. to the city of Augusta, Wis. The U. S. & Steam Supply Company, contractors, of Kansas City, has also placed an order for about 5000 ft. of pipe, which will be used at Concordia, Mo., and 6500 ft. are to go to J. L. White, contractor, Wyoming, Ill.

THE JENNEY ELECTRIC MANUFACTURING COMPANY, of Indianapolis, reports that it is very busy, and is having about all the work it can turn out with its present equipment. This company has, however, just begun the installation of a 23-in. American turret lathe, built by the American Turret Lathe Company, of Chambersburg, Pa. This lathe is the first of its type, and especially constructed for rapid work on motors and dynamos, being the largest ever built for this particular class of work, the total weight being 10,000 pounds, and being adjustable to cut a shaving of from a fraction of an inch to 10 or 12 ins. With this and the other approved appliances which the Jenney Company is putting in, it will be enabled to meet the large demand for the Jenney apparatus, the reputation of which is undoubtedly excelled by none.

POWER TRANSMISSION FOR ORILLIA, ONT., CAN.—Active steps have been taken by the municipal council of the corporation of Orillia, Ont., Can., toward the development of an electrical power transmission plant, for the supplying of current for municipal and commercial purposes. Tenders will be asked at the earliest opportunity for the necessary electrical and hydraulic apparatus and construction work for a plant capable of transmitting 1500 h.p. as a first installment, from a point called Ragged Rapids, on the Severn River, to the town of Orillia, a distance of eighteen miles. The enterprise has been placed by the council in the hands of Mr. Roderick J. Parke, consulting electrical engineer, of Toronto, Can., who is now preparing specifications to gov-

IN GOING TO ST. PAUL AND MINNEAPOLIS

The wise traveler selects the Chicago, Milwaukee & St. Paul Railway.

Why?

It is the best road between Chicago and the Twin Cities.

It has the most perfect track.

Its equipment is the finest.

Its sleeping cars are palaces.

Its dining car service is equal to the best hotels.

Its electric-lighted trains are steam-heated.

Its general excellence has no equal.

It is patronized by the best people.

It is the favorite route for ladies and children as well as for men.

It is the most popular road west of Chicago.

For further information, apply to nearest ticket agent or address Geo. H. Heafford, General Passenger Agent, 410 Old Colony Building, Chicago, Ill.

ern reception of tenders. A polyphase current of not less than 10,000 volts potential will in all probability be adopted.

THE STANDARD THERMOMETER & ELECTRIC COMPANY, Peabody, Mass.—The plant of this company is one of the most complete of its kind in this country. Everything that is necessary to an arc lamp, with the single exception of the glass globe, is manufactured from the raw material in the company's own factory. This insures the careful supervision of every detail in the manufacture of a lamp, and does away with the annoyance of waiting for parts not made by the manufacturer before the lamp can be assembled. The business has steadily grown from the time that a part of one floor was all the space required, to the present time, when it completely fills the large four-story building now occupied by the company. The factory is now running night and day to its fullest capacity. Orders for their new alternating arc lamp are especially large, many of these being from large users abroad, where these lamps have met with much favor.

THE WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY has received a letter from Mr. R. G. Vance, Jr., superintendent of the Stevens Coal Company, which makes the following statements regarding the Baldwin-Westinghouse electric mine locomotive in operation in their mines: "It gives us pleasure to say that this motor is giving the very highest possible satisfaction, and is attracting considerable attention in this valley. It has been running since May 1, and has not cost a dollar in the shape of repairs, excepting a new valve for sandbox and a headlight base broken in a collision with a car. It is running on a road of 25 lb. steel 4000 ft. long, over undulating grades varying from 1 to 6 ft. per 100 ft. Its regular load now consists of twenty cars of 1½ tons capacity, and the time required for each round trip is from 17 to 19 minutes. We have pulled up as high as twenty-five of these cars at one trip, which it did with all ease. When necessity requires we can pull thirty cars, giving 50 per cent more capacity than you guaranteed." This is evidence of the superior qualities of this mining locomotive, which is characteristic of the work done by the Baldwin and Westinghouse companies.

THE BULLOCK ELECTRIC MANUFACTURING COMPANY, Cincinnati, Ohio, will probably move into its new factory at Norwood, Ohio, in about two weeks. The company has been so rushed with orders that it has been unable to spare time to build the electrical apparatus for its own use in the new factory. It is building two large generators, which are to be direct-connected to a cross compound engine, built by the Lane & Bodley Company, of Cincinnati. These generators will furnish power for the machine shop, which is to be operated entirely by electric power. The Bullock Company is getting out a new type of enclosed motor for use in factories and machine shops, for direct connection to cranes and machine tools. The Pacific Coast Borax Company ordered ten of these motors, aggregating 160 h.p., to be geared to various tools. The Midland Steel Company has ordered some of these motors for its traveling crane, and the Bullock Company has received two orders for this type of motor to be placed directly in headstock of lathe. The New York "Sun" has just ordered from the Bullock Company another 30-h.p. press equipment, to be a duplicate of the equipments the company furnished them before. This equipment is for the Bullock Teaser System. The Toronto "Globe" also has ordered from the Bullock Company a like equipment of 40 h.p. for a large Hoe press. Unwin Bros., of London, have ordered another press motor like their last. The Bullock Company also has entered orders for a couple of generators for direct connection to gas engine, and a 100-h.p. motor and 150-k.w. generator, slow speed, three bearings, for J. B. King, Roslyn, L. I. Besides the above, the Bullock Company has received many orders for its standard apparatus. The above is a sample of the various types of machines for direct current which one company is building.

THE "CLARK" WIRE

In a Letter from the Inspector of the Boston Fire Underwriters' Union, he states:

"A Thoroughly Reliable and Desirable Wire in Every Respect."

For Switchboard, Railway and Motor use, we make all sizes of Stranded and Flexible Wire and Cables with Clark's Insulation.

The Clark Wire has been before the public and in use for the past nine years, and has met with universal favor. Thousands of miles of this wire have been sold, and are in use throughout the United States and foreign countries, and the demand for it is constantly increasing, because it always gives perfect satisfaction.

The Rubber used in insulating our Wires and Cables is especially chemically prepared and will not deteriorate, oxidize or crack, and will remain flexible in extreme cold weather, and is not affected by heat.

We guarantee our Insulation wherever used, Ærial, Underground or Submarine, and our net prices are as low, if not lower, than any other first-class Insulated Wire.

We shall be pleased to mail catalogues with terms and discounts for quantities.

LOCK BOX 75, STATION D,
CLEVELAND, OHIO.

PROPOSALS INVITED.

PUBLIC AND PRIVATE LIGHTING

VINCENNES, INDIANA.

Sealed proposals will be received for lighting the streets, alleys and public places of the City of Vincennes, Indiana, with arc lights of not less than 2000 candle power each, for a period not to exceed 20 years, from the 25th day of December, 1900, for all night and every night in each year. Also to furnish commercial and private lighting to the citizens of said city for the same period of time. In submitting proposals separate bids must be made, viz.: Street, commercial and private lighting, specifically stating the kind and number of lights and the maximum price for each public light; for private and commercial lighting. No proposition will be considered unless accompanied by full and complete plans and specifications, by which it is proposed to furnish the light, which must be attached to each proposition submitted. And all bids must be deemed to cover and include all incidental matters and things necessary to the full and complete working of a first class modern lighting plant. Said proposals must be filed on or before the 2nd day of January, 1899, with the City Clerk of said city, and final acceptance will be made only after full and complete investigation by the Common Council, as to the merits of each and every bid submitted, and an Ordinance covering the proposition accepted has been passed by said Common Council. The Council reserves the right to reject any and all bids submitted. All information desired by bidders will be furnished on application to the Clerk. None of said bids to be opened unless by order of and at a regular session of the Common Council.

Why the Paiste is the Best Socket.

It must be admitted that it takes somewhat longer to install **PAISTE SOCKETS** than other kinds—and it takes longer to drive a screw than a nail, too.

The **PAISTE SOCKET** is put together to stay. It doesn't "get rattled" by doors slamming and buildings shaking. Notice its firm, solid base, twice the usual thickness; and see how the screws in the cap sink **into** the porcelain, not merely pressing **against** it.

Don't imagine that you are getting the best socket if you haven't seen the **PAISTE.** Send for a sample. FREE to trade only.

H. T. PAISTE CO., {CHICAGO. PHILADELPHIA.

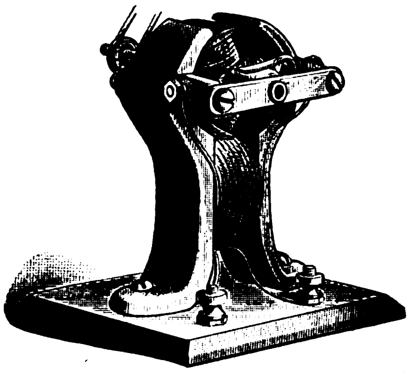
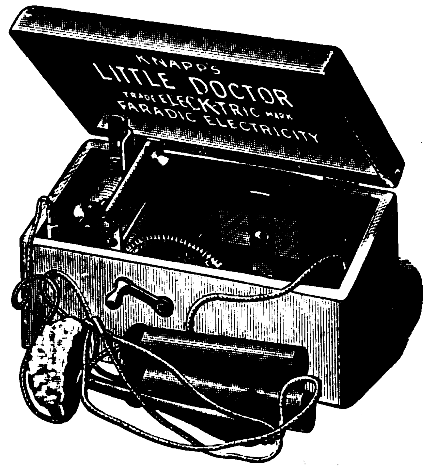
51 WARREN ST., NEW YORK.





The H. B. Camp Co.'s Vitrified Clay Conduit

For UNDERGROUND TELEPHONE, TELEGRAPH and ELECTRIC LIGHT WIRES, and UNDERGROUND TROLLEY SYSTEM FOR ELECTRIC STREET RAILWAYS. . . .

Manufactured by **The H. B. CAMP CO., Aultman, O.**

Our conduit is made of specially prepared clays, is thoroughly vitreous and glazed, making it acid, gas and water proof, and is not affected by electrolysis. Standard size is 3 inch internal diameter. However, we can make any size or multiple duct. Our patent mandrel used in laying our conduits prevents the possibility of shoulders, and insures good alignment of bore. We claim for strength, economy, durability, cheapness and perfect insulation it is the best, and is used by the most prominent companies. Any information promptly given. Write for catalogue.

THE H. B. CAMP COMPANY, AULTMAN, OHIO, U. S. A.

TELEPHONE MEN

will be glad to know that a COMPREHENSIVE TREATISE ON TELEPHONY has at last been produced.

American Telephone Practice,

By KEMPSTER B. MILLER, M. E.,

is now in press and will be ready for distribution in a short time.

This work will include all of the matter published during the last two years in the AMERICAN ELECTRICIAN under the same title, revised and brought strictly UP TO DATE, together with a large amount of matter never before published.

Mr. Miller's experience as telephone expert in the United States Patent Office, and his subsequent experience as chief electrician and superintendent of one of the largest telephone manufacturing companies in this country, has enabled him to write on the subject from its practical as well as its theoretical side.

It will cover the PRACTICAL FEATURES OF TELEPHONE WORK with an attention to detail not found in any other book.

What E. B. Newcomb, Manager, says:

OFFICE OF WESTBROOK ELECTRIC LIGHT AND POWER CO.,
S. D. WARREN & CO., Props.
WESTBROOK, ME., February 15, 1897.

Belknap Motor Co., Portland, Me.

Gentlemen:—The Chapman Voltage Regulator put into our station in the Fall of 1895 has proven its ability to control the voltage with a varying speed amounting at times to 25 per cent. above the normal, holding the voltage within 2 per cent. This Regulator, which was connected up with four 80 h. p. Mather 500-volt direct current dynamos, was, we understand, one of the first of these Chapman Regulators ever manufactured. Having made a careful examination of the Regulator as it is at present made, we can see that there has been a vast improvement; especially is this true in regard to the addition of an attachment whereby the Regulator compensates properly for the drop in the line due to all variations of the load.

You may enter our order for a Regulator for our K. W. T. H. Monocyclic Generator, as per our recent conversation. Yours very truly,

WESTBROOK ELECTRIC LIGHT AND POWER CO.
E. B. NEWCOMB, General Manager.

What the Edison Electric Illuminating Co. say:

TOPEKA, KANS., Oct. 27, 1897.

Belknap Motor Co., Portland, Me.

Gentlemen:—In reply to your recent letter regarding Voltage Regulators can say we are very well satisfied with our purchase, and as for wanting additional regulators, will say the two we have regulate the fields of three pair of 45 k. u. Edison Machines, and when we require more than three engines on the bus bars we switch them in with the machines on the regulators and find we get very good results by using the hand rheostats to divide the load as we want it, your regulators keeping the voltage on all the machines constant within three volts.

As I say, we are well pleased with the regulators and could not be without them now we know their worth. Yours very truly,

EDISON ELECTRIC ILL'G CO., C. R. MAUNSELL, Supt.

LONG DISTANCE ELECTRICAL TRANSMISSION OF STEAM POWER.

THE PLANT OF THE COLORADO ELECTRIC POWER COMPANY.

BY RALPH D. MERSHON.

THE Cripple Creek mining district, though not far from some of the best coal fields of Colorado, is about 5000 ft. higher than the most accessible of them. This lift of 5000 ft., making itself felt through the medium of freight rates, means high-priced fuel, and, in consequence, steam power is expensive, especially in the case of such intermittent work as hoisting, which constitutes the major portion of the work done in the mines. Another condition contributing toward a high average cost of power is the existence of numerous small users, for, although the large mines of the district consume much power, both for steady and intermittent work, there are many small mines and prospects whose aggregate power consumption equals or exceeds that of the large mines. For these reasons, in addition to the fact that many of the mines operate continuously, the Cripple Creek district furnishes a market especially favorable to the profitable transmission and distribution of power by electricity. Recognizing this fact, the late O. B. Shallenberger, of Rochester, Pa., and D. V. Donaldson, of Colorado Springs, undertook in the summer of 1897 the formation of the Colorado Electric Power Company, a company whose primary object was to supply power to "the greatest gold camp in the world." The brilliant reputation of the former of these men in electrical work and the confidence reposed in the latter by all who knew him, made the floating of the enterprise easier than is usually the case with such ventures, and in the fall of 1897 work was begun on a transmission plant which has now been in operation for some months, and which is one of the most complete of its kind in this country.

After careful consideration of water power for this work it had been decided that, in view of the existing irrigation rights on the streams within reach of the market and the large reservoirs which would be necessary in order not to interfere with these rights, it would be cheaper to generate power by steam than by water. A site for the power station was therefore chosen at Cañon City, Colo., a point offering many ad-

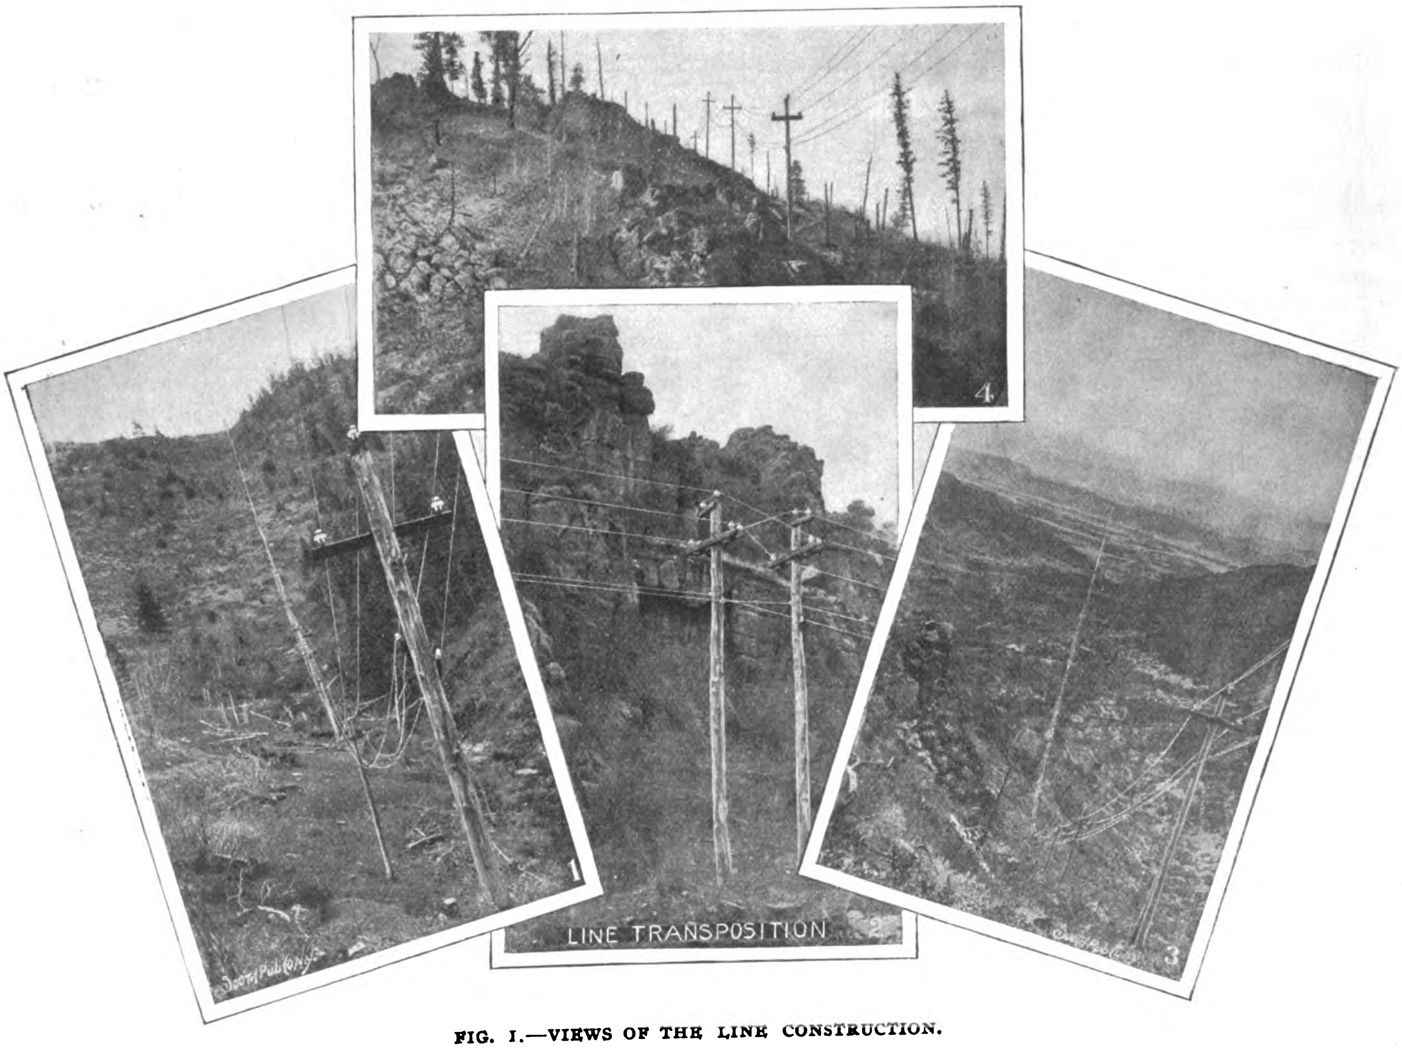

FIG. 1.—VIEWS OF THE LINE CONSTRUCTION.

vantages for the economical generation of power, chief among which is its nearness to the coal fields.

The station is located so as to be accessible from both of the railroads entering Cañon City; coal can be delivered from either of them on to a side track and unloaded thence directly into the coal bunkers. It is near the Arkansas River, from which water is taken for condensing purposes, and, if it should become necessary, coal may be delivered to it by a downhill wagon haul from the mines owned by the company.

The building is a substantial structure of brick and steel, and at present represents just half of what the completed structure will be, as both the building and equipment have been laid out with a view to an increase of capacity when business shall demand it, the increase to be made without interfering in any way with the operation of the plant. The general arrangement and dimensions of the building are shown in the ground plan, Fig. 2.

The fire-room equipment, shown in Figs. 3 and 4, consists of a battery of Heine water-tube boilers, manufactured by the Heine Safety Boiler Company, of St. Louis; the condensing apparatus, consisting of surface condensers with combined air and circulating pumps, made by the Snow Steam Pump Works, of Buffalo, N. Y.; Snow feed pumps; Wainwright corrugated tube heaters, made by the Taunton Locomotive Manufacturing Company, Taunton, Mass. The boilers, pumps and condensers have such a capacity and are so arranged that one unit is always idle as a reserve in case of emergency. The stack is of steel, guyed, and resting upon a substantial brick base. The water supply for the surface condensers is taken from the Arkansas River at a point about 400 feet above the station, and is brought by a wooden flume to the settling tank, whence it is drawn by the circulating pumps, sent through the condensers and discharged again into the river.

The steam equipment of the engine room consists of the three main engines, and two exciter engines. The main engines are Hamilton-Corliss cross compound condensing engines, with receiver and reheating coil, made by the Hooven, Owens & Rentschler Company, Hamilton, Ohio, They take steam at 125 lbs., and their speed is 100 r.p.m. Though they normally run condensing they may be run non-condensing in case of emergency, and will carry their load under those conditions. Each one is direct connected to a Westinghouse three-phase generator delivering current at 500 volts and 3600 alternations per minute, 30 cycles per second. The exciter engines are Westinghouse "Standard," running at 350 r.p.m. They take steam at the same pressure as the main engines and exhaust into the heaters, as do also the pumps in the fireroom. Each exciter engine is connected by means of a spring coupling to a Westinghouse 125-volt direct-current dynamo. Either of the exciter rigs is capable of exciting all of the main generators. The nominal rating of the main generators is 470 k.w each, but the specifications on them and the engines were such that the three generating units are together capable of delivering something over 2000 h.p. In operation, one of the main generators will be kept idle as an emergency reserve.

The current from the main generators and exciters is carried by cables in tunnels under the station floor, each to its own switchboard. The exciter switchboard is of the Westinghouse standard type, consisting of two marble panels—one for each exciter—on which are mounted the usual instruments and switches. The main switchboard has four panels—three generator panels and one load panel. Each generator panel has besides the usual field plugs, rheostat and main switch, three ammeters, one for each machine lead, and two Shallenberger indicating wattmeters, the sum of whose reading gives the output of the generator.

The load panel has three ammeters and two wattmeters. The sum of the watt-

FIG 2.—GROUND PLAN OF POWER HOUSE.

meter readings is the total output of the bus bars. The ammeters, however, do not indicate the bus bar currents; each measures the current to one of the three step-up transformers, and is thus a ready means of detecting and locating any incipient trouble in the transformers or any unbalancing of the load. The additional instruments are three voltmeters and a synchroscope mounted as an arm at one end of the board so as to be visible from each panel. The synchroscope can by means of plugs be used for synchronizing any machine with the bus bars. One of the voltmeters can be plugged on to any phase of any machine.

Of the remaining two voltmeters one at all times indicates the voltage of the bus bars; the other in connection with a compensator indicates at all times the voltage on the secondary distribution circuits at Cripple Creek, and thus enables the station attendant to hold the distribution voltage at any desired value.

None of the instruments on the board carry the main current; they receive current from the secondaries of series transformers, whose primaries are in the main leads. These series transformers are mounted upon a rack behind the switchboard. As will be seen from the illustrations, there has been left between the main switchboard and the exciter board a space for additional panels, when the plant shall be extended. Mounted upon a mahogany panel, which will form a part of the completed switchboard, are a steam gage, vacuum gage and recording pressure gage, this arrangement bringing the operation of both the steam and electrical machinery under observation at one place.

The connections of the wattmeters are shown in Fig. 10. 1, 2 and 3 may represent either the three bus-bars or the three leads of any machine. A and B are the two indicating wattmeters. S, S, S, are series transformers, each included in one of the three leads. C is a single coil shunt trans-

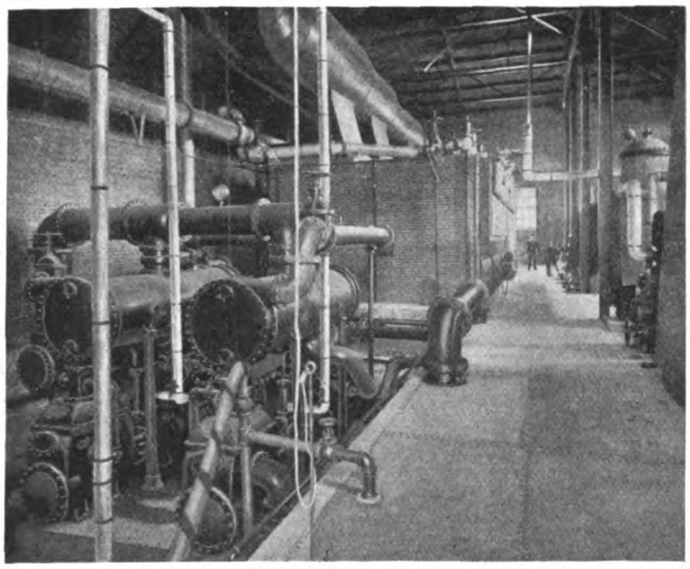

FIG. 3.—COMBINED AIR AND CIRCULATING PUMPS.

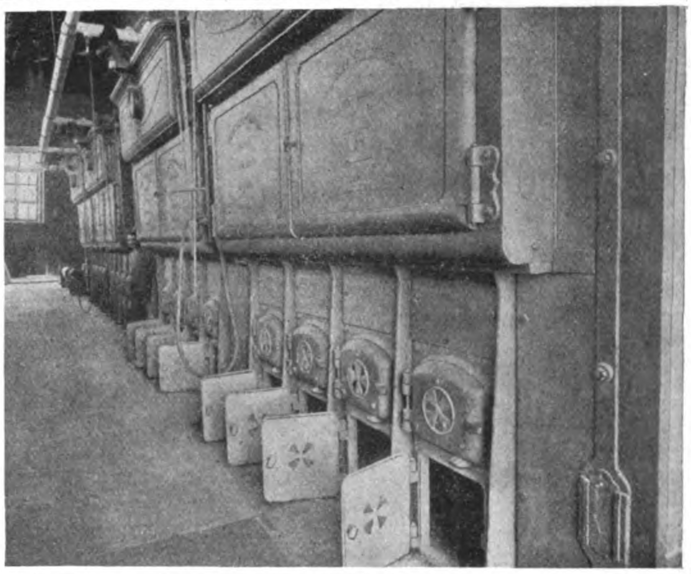

FIG. 4.—THE BOILER PLANT.

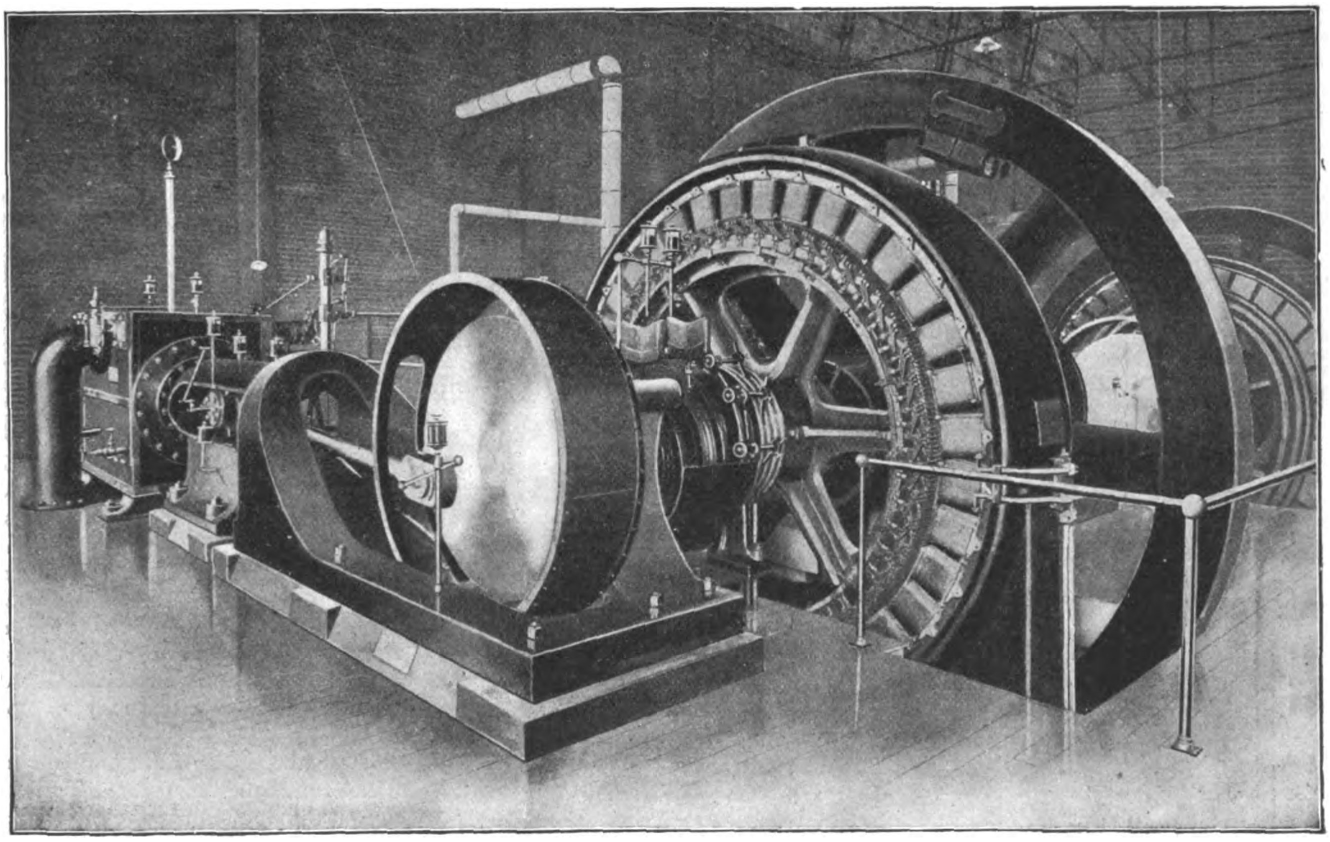

FIG. 5.—ONE OF THE MAIN UNITS.

former having a terminal brought out at its middle point. As will be seen from the diagram, the wattmeter, A, receives the current for its series coil from the series transformer in the lead, 1, while its voltage coil is connected from lead No. 1 to the middle point of the single coil transformer C. Wattmeter B receives for its series coil a current which is a resultant obtained from the two series transformers in leads 2 and 3. Its voltage coil is connected between the leads 2 and 3.

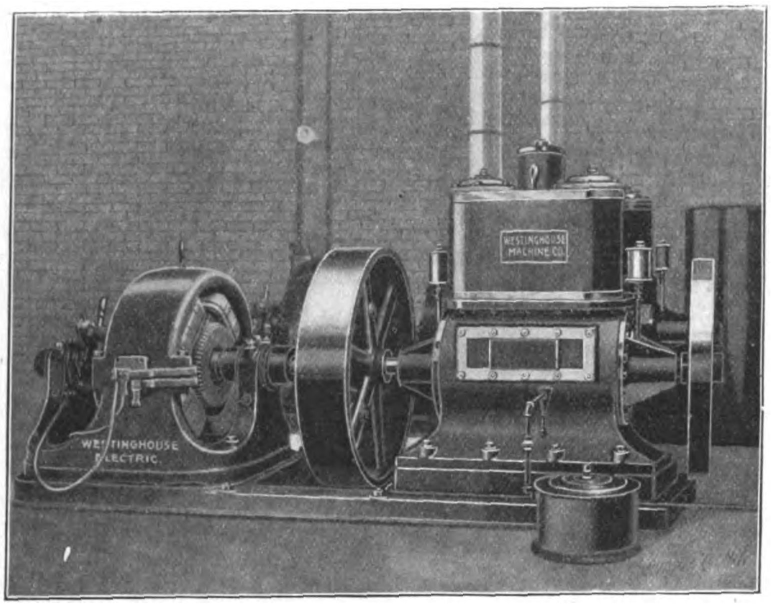

FIG. 6.—AN EXCITER SET.

From the switchboard the current goes overhead to the step-up transformer house. The cables carrying it are brought down along the wall of this building to the transformer switches, which are mounted upon the wall opposite their respective transformers. From the switches cables go under the floor to the transformer foundations and pass up through them to the transformers.

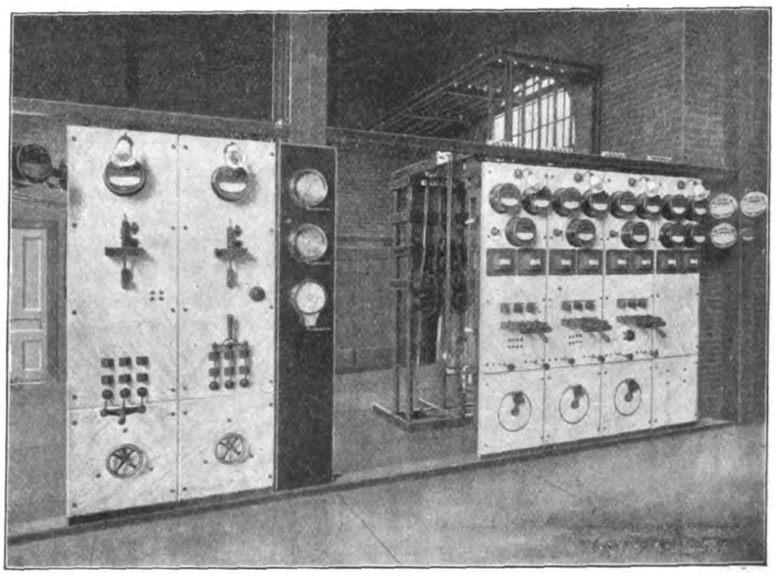

FIG. 7.—THE SWITCHBOARDS.

The step-up transformers are four in number, one being always idle as a reserve. They are the Westinghouse self-cooling oil transformers, the tanks containing them being made of sheet iron and with a number of corrugations for obtaining the necessary radiating surface. They raise the voltage from 500 to 21,000 volts. Both the high and low-voltage coils of the three transformers in service are connected in delta, so that one transformer may at any time be cut out without interfering with the running of the plant. This allows a damaged transformer to be replaced by the reserve transformer without interrupting the service, an advantage which the Y-system of connection lacks. The arrangements for throwing in the relay to replace one of the transformers in service are simple, and such that the substitution can be made in a few minutes. It is accomplished on the low-voltage side by means of a pair of relay cables and double throw, double pole switches for each of the three transformers normally in service; on the high-voltage side by means of double pole circuit breakers, of which there is one for each transformer, and long-handled plugs, by means of which the relay is plugged onto the proper pair of 20,000-volt bus bars.

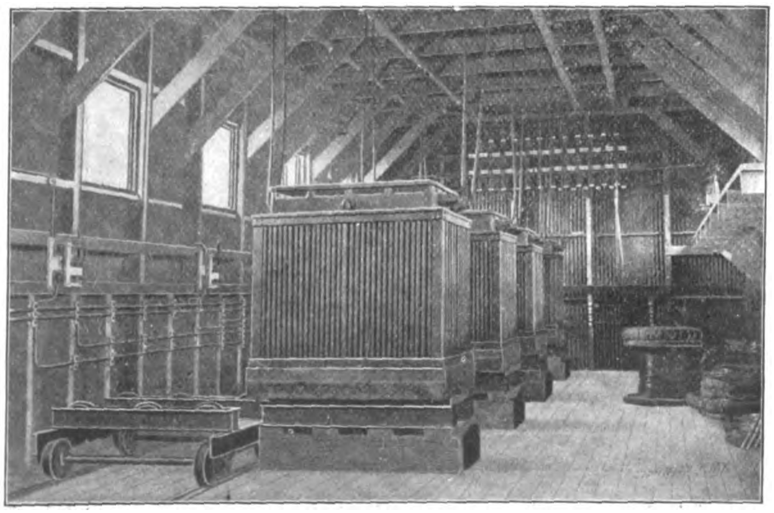

FIG. 8.—STEP-DOWN TRANSFORMERS AND TRUCKS FOR HANDLING.

In addition to a hand-tripping device the high-voltage circuit breakers are arranged to open automatically whenever energy passes through them in the wrong direction; that is, whenever a transformer becomes disabled its circuit-breaker will disconnect it from the 20,000 volt bus bars. Any trouble in a transformer which will cause its high-voltage circuit breaker to open will also blow the fuses in its low-voltage leads. The result is that a damaged transformer is automatically cut out. Two of the raising transformers are capable of carrying the full output of the station indefinitely, so that as far as continuity of service is concerned there is a reserve transformer capacity of 100 per cent.

From the 20,000-volt terminals of the transformer the current is led straight up to the high-voltage circuit breakers, and from there to the high-voltage bus bars. Both the circuit breakers and the bus bars are carried up on a wooden rack overhead—everything out of reach, with the exception of the insulated handles for operating the circuit breakers. On this same rack are mounted the plugs and sockets for switching the 20,000-volt end of the relay transformer. From the bus bars the

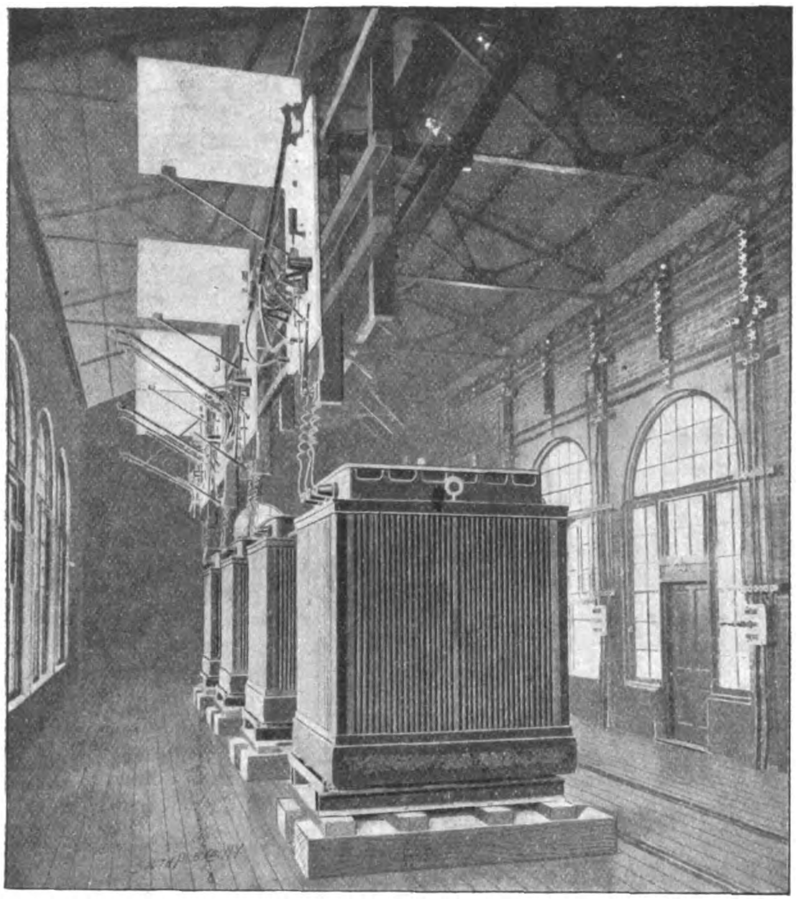

FIG. 9.—STEP-UP TRANSFORMER BANK AT STATION.

current passes at 20,000 volts through the main plugs for disconnecting the main line from the high voltage bus-bars, main fuses and choke coils, which, in connection with a bank of Wurts non-arcing arresters, protect the station from lightning discharges. All this apparatus is overhead. From the choke coils the three 20,000-volt leads pass through glass tubes in the end of the building to the transmission line.

It will be noted that all the low voltage mains and switches are confined to one side of the building, while the high-voltage apparatus is all on the other side, overhead, and out of reach.

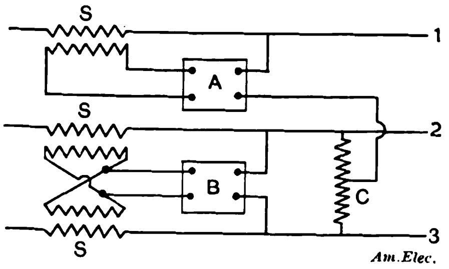

FIG. 10.—WATTMETER CONNECTIONS.

The method of handling the transformers is worthy of note. Each transformer tank has fastened to the bottom of its cast-iron base two bars of iron which serve as rails. These rails each rest upon three flanged wheels, free to revolve when the transformer is pushed along over them, but not free to change their positions, since the pins upon which they revolve are held between two pieces of channel iron which are fastened down to the transformer foundations. These wheels thus held form a mounting exactly similar to that shown on the truck in Fig. 8, When it is desired to take one of the transformers out of its tank the truck mentioned above is rolled along upon its track until the mounting upon it is opposite that under the transformer base. The transformer is then pushed off of its mounting onto that on the truck. The truck, with its load, is then rolled to one end of the building, and under an I-beam, to which chain blocks are attached and the transformer raised from its tank. This method of handling is a convenient one, and besides being cheaper than an overhead crane, there is no danger from nor interference with the overhead wires.

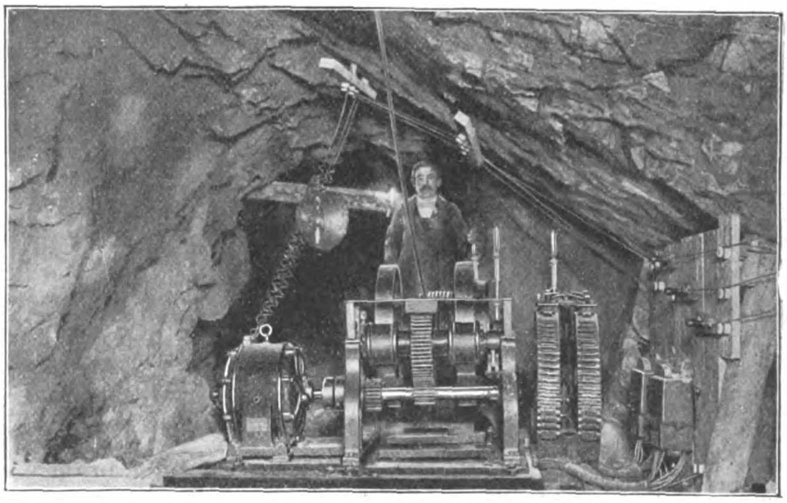

FIG. 11.—MINING HOIST.

The transformer foundations, instead of being solid, consist each of two brick piers. On each pier is set one of the mountings above described. The space between the piers connects, by means of a tunnel, with the outside of the building. Thus there is at all times supplied to the transformer a current of cool air which, on becoming heated, passes up through the ventilator in the roof of the building and carries with it any fumes there may be from the oil. The transformer fuse blocks are located below the transformer, between the piers above mentioned. Here they are out of the way, but easily accessible.

The transmission line extends from Cañon City to the heart of the Cripple Creek mining district, its length being a little under twenty-five miles. In part it passes over rolling park land where construction is easy. On other portions of the line construction is exceedingly difficult, not only because of the amount of blasting necessary, but also on account of the difficulty of delivering material. The accompanying illustrations of the more rugged portions of the line do not convey an adequate idea of their steepness and roughness.

The power line consists of three No. 3 bare copper wires arranged in a triangle, one wire being at the top of the pole. The wires are carried on glass insulators that are especially designed for the voltage at which the plant is operated. The insulator pins and cross-arms have been specially treated to preserve their insulating qualities and protect them from the weather. The two wires of a telephone circuit are carried upon bracket pins below the power wires, and by careful attention to transposition the telephone service has been made perfectly satisfactory and safe.

The poles are white cedar, the standard length being 30 ft., although some are of necessity considerably longer. The triangle formed by the power wires is not quite an equilateral one, and for this reason the power wires are transposed twice in the length of the line. All angle poles have double cross-arms and fixtures and are substantially braced. All spans longer than the standard length (125 ft.) have double poles on each side of them, each pole having double cross-arms and fixtures.

In addition to the lightning protection at each end of the line, in the power station and receiving station, there are Wurts lightning arresters installed at four intermediate points on the line.

At present there is one receiving station at Cripple Creek; another is in course of erection. Here the current is transformed from 20,000 to 500 volts, and distribution is made at the latter voltage. The arrangement of the apparatus in the substation is in general similar to that in the transformer house at the power station, about the only difference being that here the circuit breakers for automatically cutting out a disabled transformer are in the low-voltage circuit, and the transformer fuses in the high-voltage circuit.

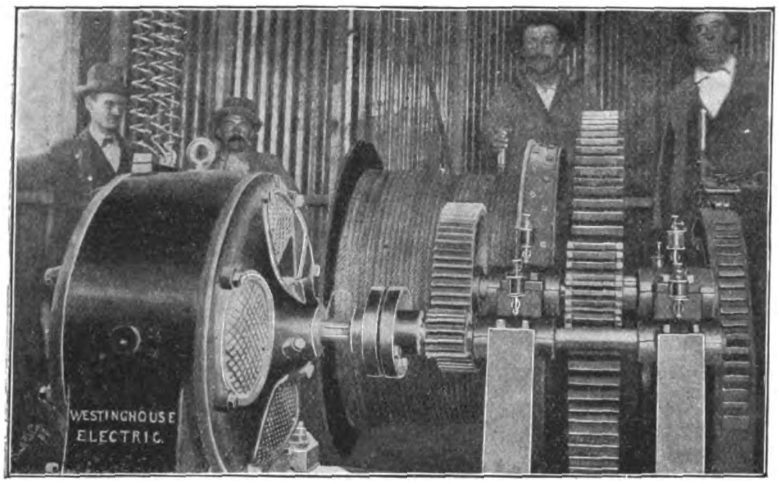

FIG. 12.—MOTOR AND GEARS OF ONE OF THE HOISTS.

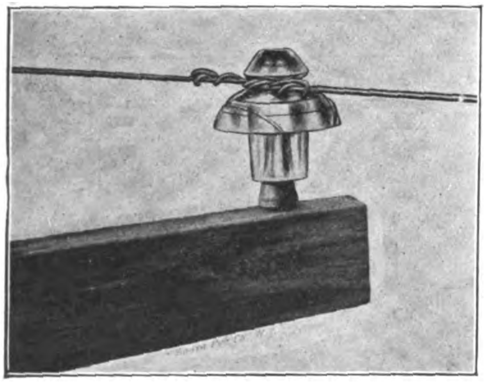

FIG. 13.—ONE OF THE 20,000-VOLT INSULATORS.

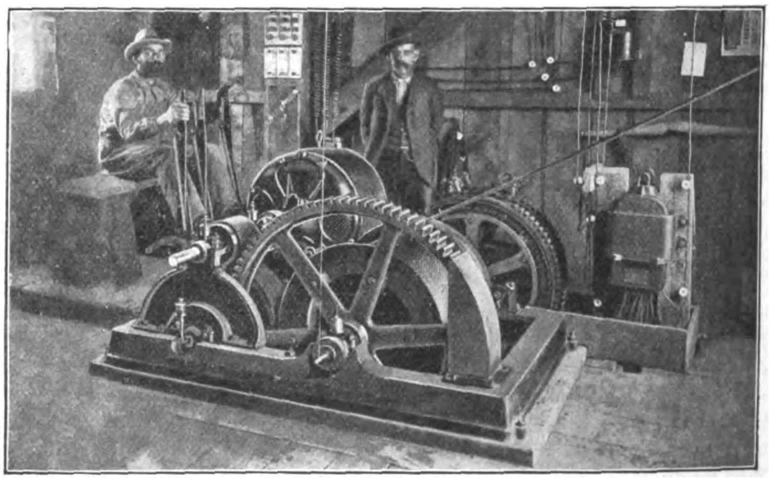

FIG. 14.—TYPE OF MINING HOIST.

So far only hoists are being operated, though a number of motors are being installed for driving mills, pumps and compressors. Some of the hoists are illustrated in Figs. 11 to 13. They are driven by means of Westinghouse three-phase induction motors, whose speed is controlled by means of auto-converters in connection with a commutator type controller. The method of handling these hoists is as simple as that of the steam hoists which they replace, and the men who run the latter find no trouble in operating the electric hoist. The starting of the electric hoist is more gradual and the running smoother than the steam hoist. There is no boiler to fire and keep in repair and no coal and water to look after. Of the hoists illustrated in this article, those in Figs. 13 and 14 were supplied by the Stearns-Roger Mfg. Co., of Denver, and that in Fig. 11 by the Hendrie, Bolthoff Mfg. Co., Denver, all being operated by Westinghouse induction motors.

The cost of power in the Cripple Creek district when generated by steam is high, not only because of the price which must be paid for coal, but because in most cases water for the boilers must be hauled by wagon from some distance and up steep grades. In some cases the cost of water for the boilers equals that of the fuel. Power is being supplied by the Colorado Electric Power Company at a price considerably less than the cost when steam is used, especially in the case of small plants. This, in connection with the advantage of greater flexibility and ease of operation, creates a steady demand for electric power which is being filled as rapidly as motors can be obtained. It bids fair to be but a short time until the present plant is loaded to its full capacity.

TWO-RATE METERING.

BY LYMAN C. REED.

The subject of two-rate metering is one which admits of many aspects. The following arrangement of arriving at a mode of two-rate metering is one which it is hoped will interest those seeking a solution of the problem without the employment of a clock mechanism. In all meters of the mechanical or motor type the power factor necessarily forms one of the main objects of consideration in the accurate measurement of current. The present article does not presume to deal with all the meters of the motor form, but taking the Thomson wattmeter as a fair sample of the type, we will proceed to give a description of a new and perhaps interesting departure in meter practice.

One of the problems which confronts all central station managers is the correct metering of current sold by them to consumers. That this is a consummation which is far from being realized is granted. For instance, we will take as an illustration the case of a large store or dwelling, in which we will say there are installed 400 to 500 lights. As the maximum number of lights is turned on occasionally, it is necessary to put in a meter of capacity large enough to carry the full load. Under circumstances such as these, when a few lights are turned on, the consumer pays only a nominal amount for them, as meters of large capacity are very inefficient on small loads. To remedy this trouble and also to furnish a basis of two-rate charging for current, the system as shown in diagram is found to operate successfully. On the three-wire low-potential direct-current system, carrying 115 volts on a side, a meter of 100-ampere capacity would be put in on an installation of from 400 to 500 lights. This meter, adjusted to run correctly, on full load, will, on loads of from 1 to 10 per cent of the maximum, register far below what it should.

A carefully conducted test on a meter of 100 amperes capacity in series with a 7½-ampere meter with a variable load of from one to ten lights, showed a difference of 30 per cent in the amount registered, in favor of the small meter. This experiment led up to a solution of the problem by placing two meters in parallel, having the load on each controlled by an automatic switch of simple design.

The diagram shows a 7½-ampere meter in parallel with a 100-ampere meter, both meters being in connection with the switch as shown. The switch consists of a double-wound solenoid, each coil being respectively in series with the fields of the small meter, but of sufficient capacity to carry the full load of the installation. The pull of the solenoid on the iron armature is balanced by an adjustable weight placed on the other end of the lever, and permitting of being set to cut in the larger meter at any desired load. On the other end of the lever are mounted contact points which plunge into mercury wells when the switch operates to cut in the large meter. We will assume the switch to be regulated for a load of 10 amperes on a side; then, for all loads under this amount, the small meter is the only one in circuit. When the load reaches 10 amperes the armature is pulled down and plunges the contacts into the mercury wells, thereby putting the large meter in parallel with the smaller. The fields of the small meter have approximately twelve times as much resistance as the larger meter, the current divides itself accordingly, and the large meter receives 9.15 amperes and the smaller .85 ampere. As the load increases the ratio remains the same, and both meters are working under the same percentage of load with respect to their rated capacity. The small amount of day burning and the number of lights left on all night after the store closes, are under the present system of measurement practically lost to the central station, while the system described above registers accurately all current consumed.

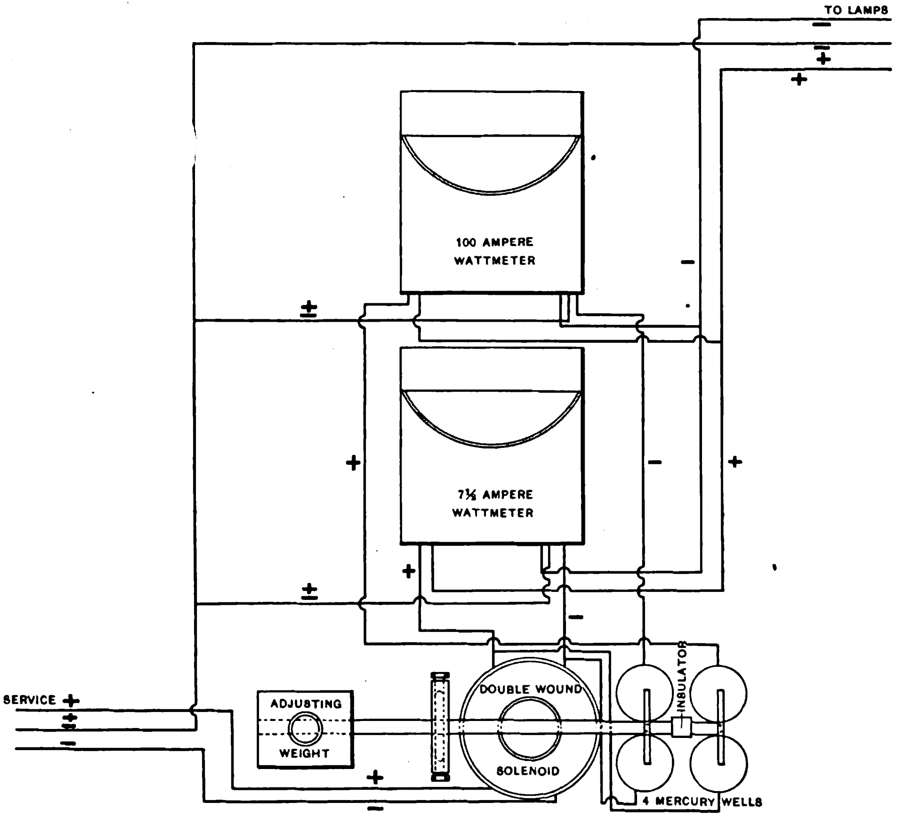

FIG. 14.—METHOD OF CONNECTION FOR TWO-RATE METERING.

The feature which presents itself as an outcome of this parallel metering, and on which we wish to dwell at more length, is that it affords a solution of selling current at two rates. The small and long-hour burning would be registered on the small meter, the short heavy-hour burning on the large and small together, but as the ratio is fixed between the two, this fixed percentage would be deducted from the register of the small meter and added to the register of the large meter, in order to keep the large and small consumption entirely distinct. Under the usual conditions prevailing in general private lighting, the heavy load would be carried from about 5 to 10 P. M. There are some rare cases where the day load would be the heavy load and, of course, the rate in that case could be adjusted to suit the customer.

The usual method of charging on the two-rate system where a clock is used for switching over at fixed periods, admits of the serious objection of not meeting the requirements for which two rates are given. It has been found by careful investigation that current can be sold more cheaply at the same profit at different periods of the day. When the peak of the load is on and the station is strained to its utmost to meet the demand, the conditions of economical running-are not as favorable as under normal load, and hence it is considered good practice to encourage day burning by giving a cheaper rate, from, we will say, 10 P. M. at night until 5 P. M. the next day. Now, when a sudden rain storm comes up in the daytime, and in a few minutes the plant is compelled to put out an enormous increase of current, the conditions for economical running are very adverse, and should be met in some way. It will be seen that under these conditions the automatic switches would cut in the large meters, whose registers are charged for at the higher rates, thus affording compensation for the additional operating expenses at the plant.

The installing of two-rate meters on very small consumers is out of the question as an economic practice, as the first cost and maintenance of the meter is too great. The same consideration would apply to the arrangement just shown, and would only be practicable with the large consumers. The cost of installing two meters and an automatic switch, as shown, is less than the two-rate meter, and we think has points of advantage which make it well worth consideration. It does away with all troubles relative to clock mechanism, is entirely automatic in action, takes care of all sudden increase in load, and affords a much more perfect method of registering current consumed. Anything which adds to the accuracy sought leads to further development, and encourages the belief that at no distant day the much vexed question of how to meter correctly will be solved.

The Electric Plant of the Battleship "Oregon."

ELECTRICAL EQUIPMENT OF THE U. S. BATTLESHIP "OREGON."

BY ALEX. J. DICKIE.

To the mind of the layman, the term "battleship" brings a very vague impression. Even seen through the eyes of many of "our special artists," the modern man of war presents a most grotesque spectacle.

It might be well, then, before entering into a detailed description of her electrical equipment, that we show the reader just what this ship, the "Oregon," is.

In the Naval Annual she is described as a first class coast line battleship. She is first class in that she is formidable enough to fight with the best ships afloat; coast line, in that she has low freeboard, and is not specially designed for sea-going qualities; battleship, in that her business is fighting.

All modern battleships are in the nature of a central, heavily armored citadel, with a ship built around it. The citadel contains the fighting material. The ship serves to float the citadel, and also to house the officers and crew, and the various stores. In the "Oregon," the ship body is 348 ft. long, 69 ft. wide, and has a draft of 24 ft. The citadel is about 200 ft. long, and about 69 ft. wide. The weight of the whole is about 10,200 tons. The citadel and its turrets and watch tower are heavily armored. The rest of the ship is not. Within the citadel are the engine and boiler rooms, the dynamo room, the magazines, and all the heavier guns.

The engines of the "Oregon" are triple expansion, developing 11,000 h.p., and on her trial they drove the huge hull through the water at the rate of 16.68 knots per hour.

Her armament consists of four 13-inch breech loading rifles; eight 8-inch breech loading rifles, and four 6-inch. Besides these there are twenty-eight rapid-fire guns of different calibres, and six torpedo tubes. The 13-inch guns are contained in two turrets, one at each end of the citadel.

The magazines, handling rooms and engines for turning these turrets are located directly beneath them, when practicable.

Such, in brief summary, are the salient features of ships of the "Oregon" type.

The dynamo room, in which the power for lighting this ship is located, lies almost in the center of the citadel. It is just between the forward and aft main boiler rooms, and immediately beneath the auxiliary boiler room. One would think this a pretty hot place for such work, but, thanks to the efficient system of ventilation, the boiler rooms are comparatively cool on this vessel.

The generating plant consists of three General Electric generators, of 224 k.w. capacity, direct-connected to Union Iron Works' upright compound engines, running at 400 r.p.m. These generators supply 300 amperes apiece, at 80 volts. They are of the same type as all navy machines—four-pole, cross-connected, and compound wound for constant potential.

The bed plate for the engine and dynamo is cast in one piece. The commutator has to be made very large on account of the small rise in temperature allowed by navy specifications.

The switchboard and the various circuits for the distribution of this current conform to the naval standard.

There are in all 500 incandescent lamps to supply, of 10, 16, and 32 c.p., four searchlights, a complete signal apparatus, two stationary and four portable fan motors, and four motors for the 8-in. ammunition hoists.

The signal apparatus consists of five double signal lanterns, their cable connections and a keyboard for their operation. The lanterns are in halves, each half being fitted with a Fresnal lens; the upper half is red, the lower half clear. The signals are made by combinations of these lanterns. Sixty-two of these combinations are used, and each one is accomplished by a single motion of a key. Both lanterns and keyboard are water tight.

On the "Oregon" the signal lanterns are arranged along a back-stay, which is stretched between the signal yard and the center of the port forward 8-in. turret. There are four lanterns seized to the backstay, the masthead light forming the fifth of the signal set. The lanterns are spaced 12 ft. apart. There are two 32-c.p. lamps to each lantern. The cable connecting these lamps with the manipulator consists of 11 insulated copper conductors, of which one forms a common return for the two lamps. This cable is carried inside the military mast until a point is reached above the upper military top. From thence to the masthead it is carried by the backstay seized to the same, above and below each lantern. At each lantern two of the wires forming the cable are left out and connected to the proper lamp, and a branch from the common return is connected to each lamp; thus we have four wires entering into each lantern.

The keyboard, which is the most ingenious part of this system of signals, consists of a circular water-tight box. On the top of this box there is an annular

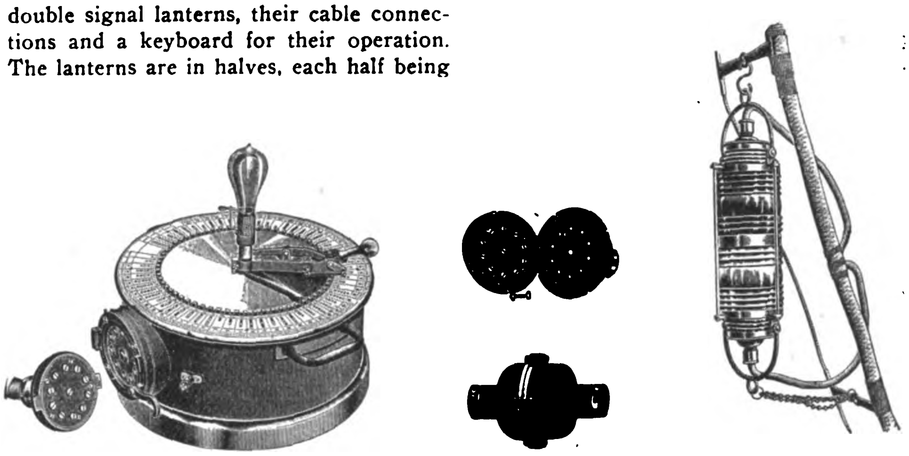

FIG. 2.—ARDOIS SIGNAL LAMP, KEYBOARD AND COUPLING.

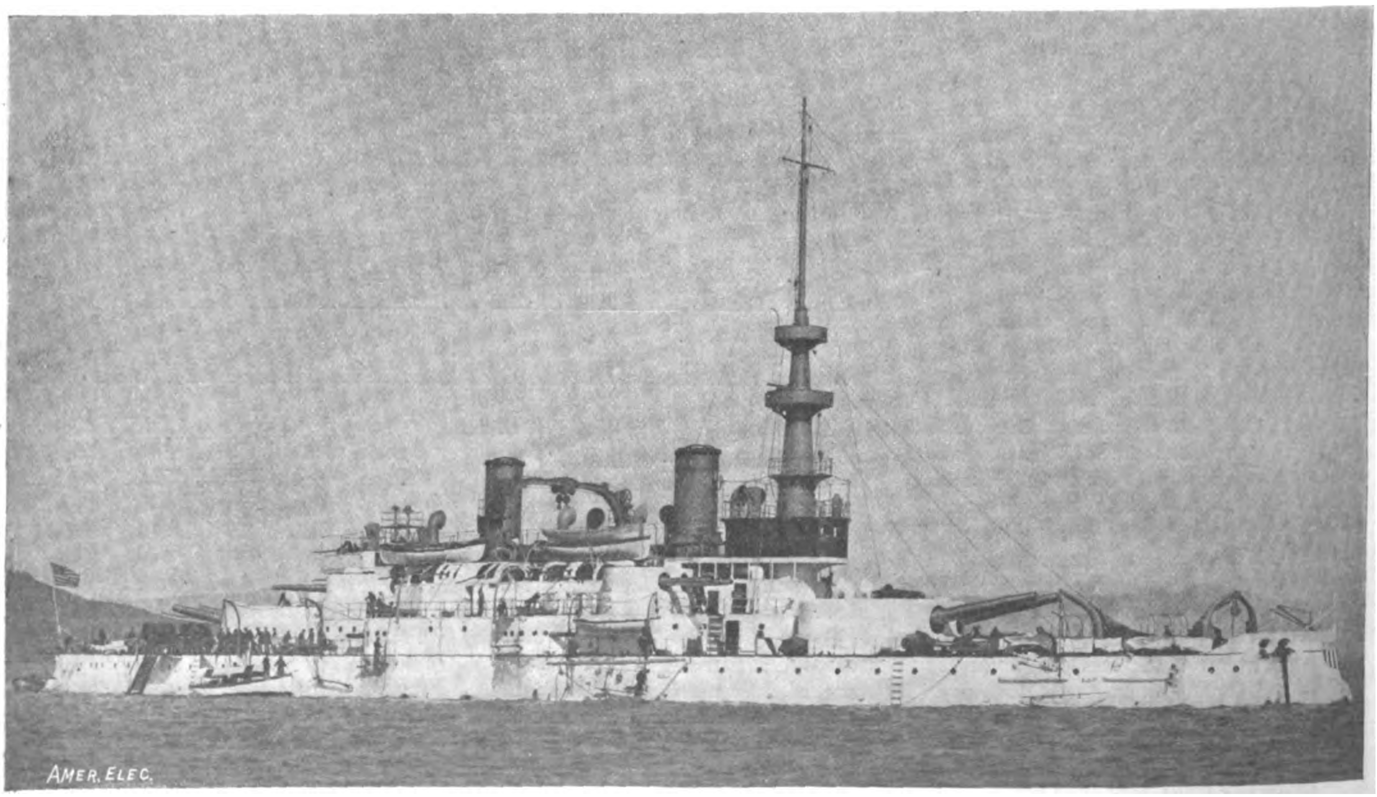

FIG. 1.—THE U. S. BATTLESHIP "OREGON."

ring, on which are engraved all the sixty-two possible combinations of the lamps. Below this plate are ten flat annular discs of brass, insulated from each other, and each connected with one of the lamps. On these discs, below each of the divisions of the index plate, are projections corresponding to the combination of lanterns which is marked on that division under which they appear. Inside the index plate there is a brass cover plate, which revolves on a central spindle and carries with it, near its outer edge, a contact post. This post has a spring projecting point for each of the brass discs. The apparatus is operated in this way:

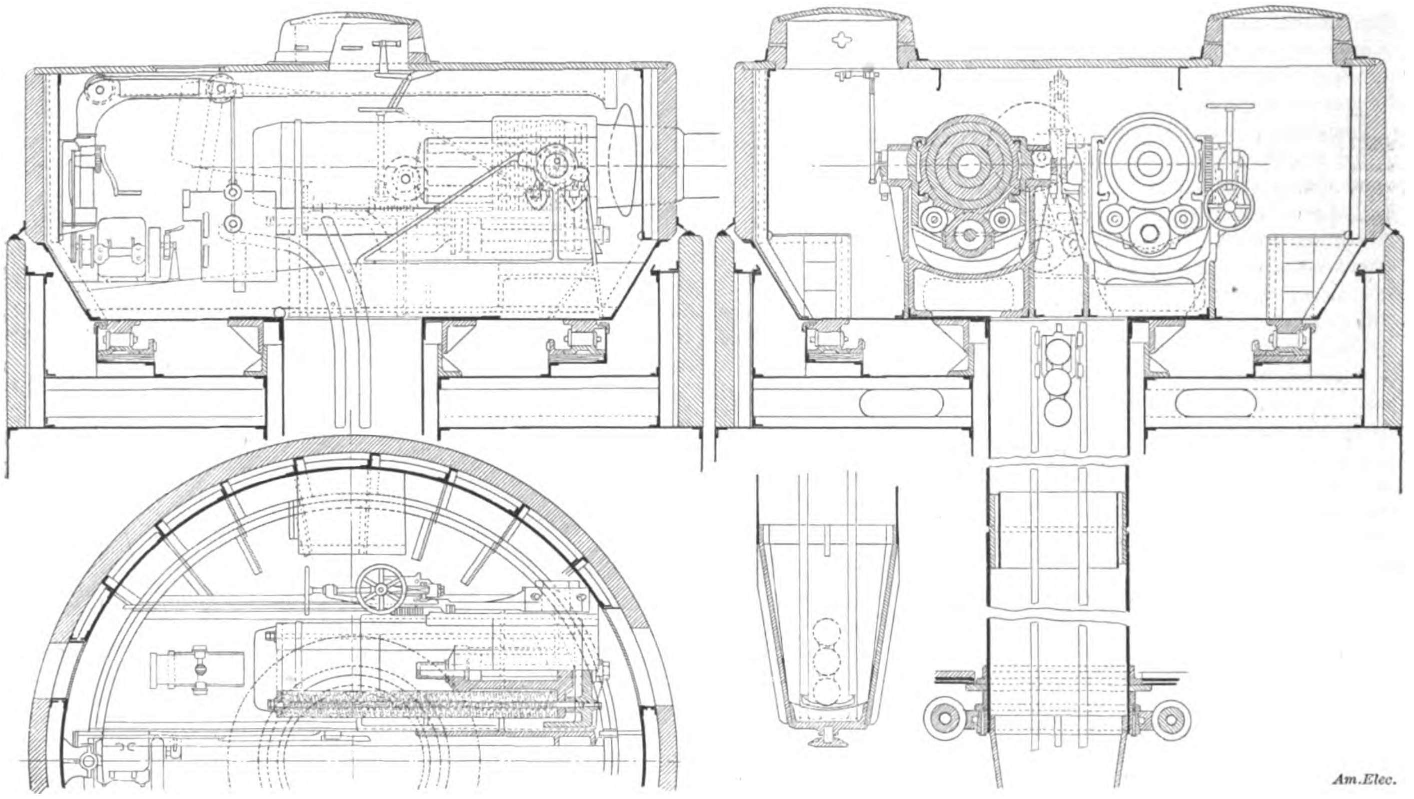

FIG. 3.—SECTIONAL VIEW OF THE TURRETS.

The handle on the brass cover plate is turned until the index points to the desired combination. Then, the plates being clamped, the manipulating spindle is turned through 90 degs., thus bringing the projecting points into contact, and lighting the lamps.

Four of the combinations are used as keys for sets of signals. A code of signals has been formed, comprising as many chapters as there are combinations, or fifty-eight chapters of fifty-eight signals each. The four key signals indicate the change in title of these chapters. Thus we have under each key signal 3364 distinct signals, or a total of 13,456 signals. This system of signalling is unsurpassed for squadron purposes, or for short distance day and night work.

But let us return to the description of installation on the "Oregon."

Next come the fan motors. The two stationary fan motors are used to drive the ventilating fans for the dynamo room. The two sets are exactly similar, consisting of a 2-h.p. electric motor, direct-connected to a Sturtevant blower fan. The fan delivers 2200 cu. ft. of air per minute at a speed of 1570 revolutions. One set forces air into the dynamo room, the other forces the air out.

The portable fan sets are used to ventilate small compartments, such as those in the double bottoms, while the men are examining or cleaning such compartments. Each consists of a blower fan direct-connected to a ¼-h.p. motor, the fan being fitted with 50 ft. of hose. The fan delivers 400 cu. ft. of air per minute, at 1863 revolutions. The fan and motor are rigidly connected, and are very easily moved about.

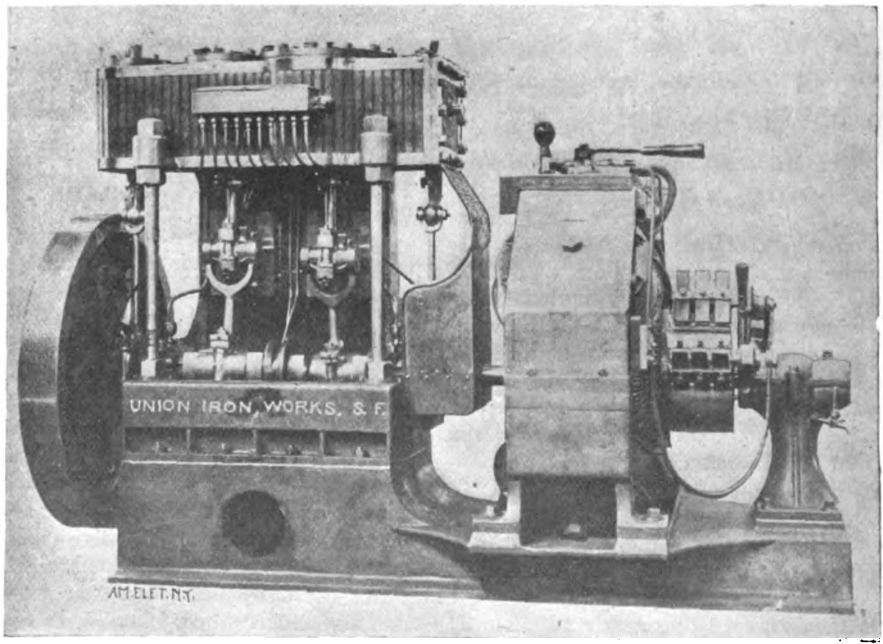

FIG. 4.—ONE OF THE GENERATOR SETS.

The searchlights, four in number, are located two on the chart house forward, and two on the hammock berthing above the superstructure aft. They consist of 60 centimetre Mangin projectors and French lamps. The lamps consume 80 amperes. They are of combined automatic or hand control, and may be electrically controlled from various stations on the ship.

The 8-in. ammunition hoist motors were supplied by the Government. As shown in the drawings of turrets, they consist of an inclosed electric motor, geared to a drum. This drum hoists, by means of a cable, a cage which contains three compartments, one for the projectile and two for the charges. A small swinging crane, shown in the drawing, swings the charge to either rifle. There is a hand hoist attachment in case of break-down. Placing the motor on the turret itself gives the control over the hoist into the hands of the gun crew—a very efficient and convenient arrangement.

The switchboard is arranged with the necessary apparatus and connections for controlling nine incandescent, four searchlight and three power circuits. The pressure board has points for each dynamo and for the searchlight circuits. There is a ground detector which can be thrown on either arc or incandescent circuits, when operated separately.

The system of wiring used is the two-wire system. All the incandescent circuits on the same deck have their ends interconnected through double pole switches, so that if through any cause a circuit or its main is broken, throwing in a few switches restores the light—a very important feature, especially in battle mains. All of the mains for lighting outside the citadel are run as nearly as possible the full length of their deck amidships. They are all fed into their centers by feeders direct from the switchboard. The battle mains inside the citadel are run in the wing passages just inside the armor belt. They light the coal bunkers, magazines, ammunition passages and handling rooms. Those on either side of the same deck are connected by thwartship mains at their centers, and are fed by a single feeder from the switchboard.

The arc light or searchlight circuits are four in number, one for each searchlight. They lead directly from the main switch, and are controlled there by minor switches and cut outs. They have no connections with each other, or with the lighting circuits, except those provided for at the switchboard. All the wiring has a cross section of not less than 1000 cir. mils per ampere at full load, on a basis of .05 amperes per candle power.

It will be noticed in the foregoing description that there are three separate systems on this ship; the incandescent lighting, the searchlight and the power systems. When this plant was installed, the question of electric transmission of power on shipboard was just beginning to be agitated. Consequently little of the current generated on the "Oregon" was used for power purposes. Electrical engineers, however, took hold of the problem with characteristic energy, and to-day the wonderful superiority of electric transmission and electric machinery in the auxiliary mechanism of battleships is fully recognized. In efficiency it equals, while in flexibility and lightness it exceeds, its two chief competitors, hydraulic and steam power.

Thus in the new battleships of the "Oregon" class, we find a much larger installment of electric power. They have eight 32-k.w., instead of three 24-k.w. units, the additional power being nearly all taken by the various motors. Nearly all the ventilation is accomplished by electric power. Motors drive all the ammunition hoists, and are used to train the turrets.

As we more nearly approach the point where the whole auxiliary power of a vessel is electrical, we more clearly see the advantages of that system. We may, therefore, hope that the day is not far distant when electrical marine machinery will less grudgingly receive from the naval powers that recognition of its merits which is certainly deserved.

Types of American Lightning Arresters.

BY HENRY E. RAYMOND.

For use on arc circuits supplied from their machinery, the Western Electric Company manufacture a unique form of arrester. It is designed for use on arc work only and is for use only on their dynamos, being, as it is, incorporated in the assembly of the generators. It forms part of the terminal boards, and is on the same base with the main cutout switch. Apparently it is the intention of the manufacturers to produce a device which cannot be overlooked, and in which simplicity of action and construction are distinctive features. One of the most unique features is the method of rupturing the ensuing arc. The magnetic lines of the main field coils are used to accomplish this. This is not clearly shown in available illustrations, but probably the stray field lines of force are used to accomplish this useful work.

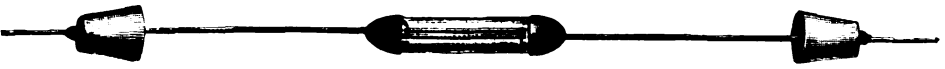

FIG. 1.—FUSE OF AJAX ARRESTER.

The arrester consists simply of a carbon plate and two carbon or metal pencils. The carbon plate is set on the base edgewise and stands in a vertical position, its plane crossing that of the base as a perpendicular line. To this plate ground connection is made. On either side of this plate is one of the pencils. These are connected one to each terminal of the generator, and are so arranged that their position in relation to the carbon plate is adjustable. The complete device is placed upon the dynamo in such a position that the field magnetism will force out and rupture any arc which might set up after a static discharge had taken place.

FIG. 2.—FIBRONE CHUTES OF THE AJAX ARRESTER.

The manufacturer of the Ajax arrester has produced a device which is a class by itself. The action depends upon an exceedingly small gap and a fuse which forms a part of this gap. The destructible nature of the discharge points is the distinctive feature of this arrester, and the makers hold that such a condition is necessary to effective work. In so far as protecting the dischargers from the effects of a rush of dynamo current succeeding a discharge there not only is no provision made, but there is a certain arrangement of contact which makes their destruction practically certain. The construction of the arrester places in the path of a static discharge a resistance almost negligable and offers no inductive opposition either in shunt or series with the gap. The instrument consists primarily of fuses, almost direct to the ground, and an automatic arrangement for bringing successive fuses into contact with the line. These fuses are not continuous from line to ground, but are in two pieces, separated in the middle. The two ends meeting at the middle are then overlapped and sealed in position with small wax pellets. They are made of No. 26 brass wire, wrapped with silk. This covering is not removed and serves as the dielectric which fills the gap. This fuse, Fig. 1, has a small glass tube inclosing the overlapping portion, which is about 1 in. long, which serves to keep out dirt and moisture. The silk wrapping holds the ends about .002 in. apart when the arrester is to be used on pressures not over 125 volts. For voltages greater than this the gap must be increased proportionally. The extremities of the fuse are passed through soft rubber plugs, which hold the fuse in place in the Fibrone chutes, Fig. 2, provided for that purpose.

In Fig. 3 we have a view of the general assembly of the arrester. This cut represents the station type, and is a cross sectional view of a switchboard on which it is mounted, showing the choke coil mounted on the back. The back of the arrester is of porcelain, with grooves for the line and ground terminals. On either side of these two grooves and in respective con-

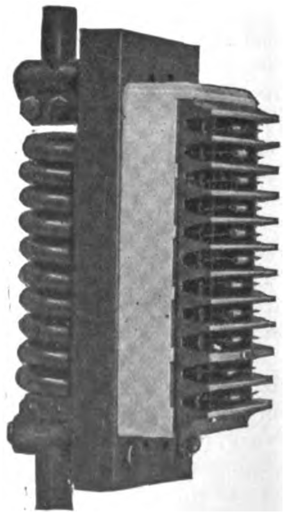

FIG. 3.—GENERAL ASSEMBLY, AJAX ARRESTER.

nection with each, are two other grooves containing contact springs which press against the fuse terminal connections when the cover which holds them is put in place. One end of each fuse, of which there are eleven, is attached to a common connection which is in contact with the ground terminal spring. The opposite ends project into a semi-cylindrical chute in the back of the cover, the back of which is metal in contact with the line terminal spring, but not touching the fuse ends. This metal trough, which is vertical, contains a carbon ball which is free to move up or down. Normally this rests on the highest fuse end, and brings it into connection with the line. Any discharge is followed presumably by the current, and the fuse in contact with the ball is instantly vaporized. As each fuse is destroyed the ball drops to the next below, bringing them successively into contact with the line terminal. The very small gap in this arrester permits the use of an idea which in almost any other form would be strictly unallowable. This idea is to have the contact between the fuses and carbon ball so imperfect that even were the gap portion of the fust not destroyed the end part would instantly be vaporized.

The inventor bases his claims of superiority on the principles that a very short gap is necessary, that fuses are cheaper than armatures, and that the necessary attention required by the insertion of new fuses is a distinctive gain.

The Universal Non-Arcing Lightning Arrester is another rather distinctive type. The dealers state that it was originally designed to meet the requirements of long distance transmissions in mountainous districts, and that it was so successful that its use was extended into other fields. It is now adapted for use on incandescent, arc and power circuits, for alternating or direct-current, long or short transmissions and is applicable to any location. The dealers' description will probably give a clear idea as to its action. They say:

"Embodying the old and well tried principle of air gaps enters into the first essential requisite of this instrument. Placed in a block form between two serrated metallic conductors are several alternate layers of non-arcing metal and mica. All the parts are thoroughly insulated from each other, supported on a porcelain base and protected by a spun brass cover, and can be attached to a pole or switchboard by means of an iron bracket." It will be seen in Fig. 4 that the two serrated plates are fastened at the top and bottom of the arrester case, and that the gap to the non-arcing layers is quite small, probably to make up for the extra dielectric strength interposed by the layers of mica.

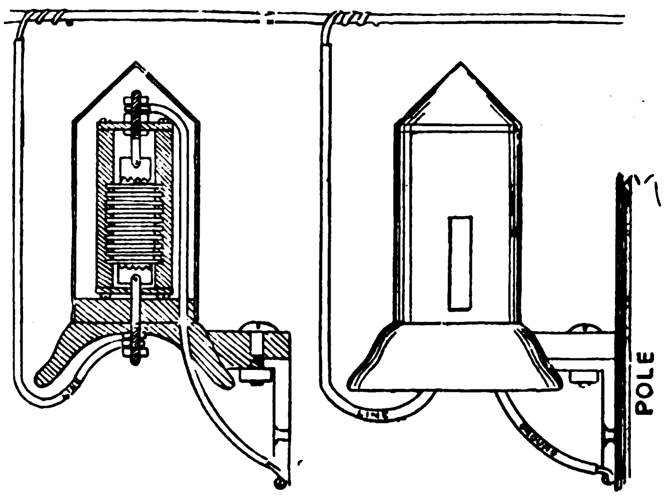

FIG. 4.—UNIVERSAL NON-ARCING ARRESTER.

These mica sections are as thin as possible and certainly offer great opposition to the passage of dynamo currents. It is intended that the discharge, after passing the first gap shall be disrupted into a number of minute sparks so small that only an infinitesimal amount of current can follow. It is claimed that the discharge is so broken up by the time it reaches the second gap that it is utterly unable to start any arc composed of dynamic current. The arrester is free from movable contacts, magnets and fuses, and it is claimed to be independent of attention. It possesses apparently a fairly high striking voltage. It is manufactured for all purposes in practically the same way, the greatest difference lying in the quantities of alloys used in the metallic plates.

◆

ELECTRICAL TURRET TURNING GEAR.

Lieut. Wm. R. Rush, who had charge of one of the turrets of the U. S. S. "Brooklyn" during the late war, in a recent report indorses fully a report of a Board in favor of electrical turning gear, as follows:

"The Board begs to reiterate its unqualified approval of electricity as the power for training turrets. To anyone who has trained turret guns upon a target by electricity, and who has afterward attempted to do it by any other means, the contrast is too striking ever to be forgotten. The electric motor and controller give perfect control and fineness of train to an ideal degree."

Lieut. Rush adds that after experience in handling turrets under fire in a running fight of four hours he found the temperature of the closed handling room of the steam turrets was terrible in comparison with that of the electric turrets. There was also the danger of death to everybody in the handling room from shell cutting a steam lead.

THE PREVENTION OF SPARKING. AND THE SELECTIO OF TYPES OF ARMATURE CORES AND WINDINGS.

BY PROF. A L. RICE.

In order to understand the use of methods to prevent sparking, it is necessary to understand the causes which produce sparking. A spark is always formed when a current is broken, and the larger the current, the larger will be the spark. The main current of a dynamo or motor is not broken as the brush passes from one bar to the next, for an ammeter in circuit shows no such effect; hence the spark must be due to the breaking of some other current.

A brush is always wide enough so that, as it passes from bar to bar, it will bridge the insulation for a short time. This will give a chance for a local current to flow around the coil thus short-circuited (see Fig. 1), and through the brush; as the resistance is small, even a small e.m.f. will produce quite a large current. As a coil moves to the position where the bars to which it is connected are joined by the brush, it is near the point of no action; i. e., where no e.m.f. is generated in its conductors by revolution in the magnetic field. There would be no current established if it were not for the self-induction. This tends to prolong the current as it dies away; as the leading end of the coil reaches the brush the whole current due to one circuit is flowing through it, forced by the other coils in the circuit. (See coil 1, Fig. 1.)*

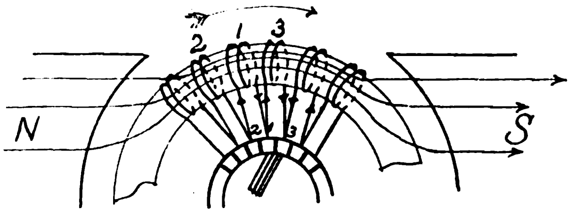

FIG. 1.—ILLUSTRATING COMMUTATION.

As the brush short-circuits coil 1, the current gradually changes from bar 1 to bar 2, and coil 1 tends to go out of action. But the self-induction prolongs the flow of current so that there is a considerable amount flowing, as indicated in Fig. 2, when it becomes time for the brush to break with bar 1 and for coil 1 to receive current from coil 3 in the opposite direction. Unless it is previously done by external means this current must be stopped and the current from coil 3 set up at the instant that bar 1 leaves the brush; thus a spark will be produced and heat generated, which heat will melt a small bit of the edge

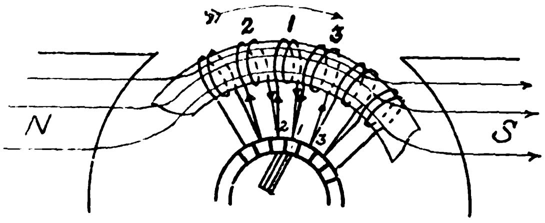

FIG. 2.—ILLUSTRATING COMMUTATION.

---

*The figures and discussion have been made from a Gramme ring armature, but the same principles apply to either drum or ring construction.

of the bar and thus produce cutting. Evidently, in order to stop sparking, the current in coil 1 must be stopped and reversed before bar 1 leaves the brush. The larger the current being drawn from the armature, the larger will be the current flowing in the coil during the time of short circuit, and the greater will have to be the means employed to prevent sparking. If the field be displaced so that the short circuiting occurs while e.m.f. is still being generated in the coil, the current will be larger and the sparking more violent.

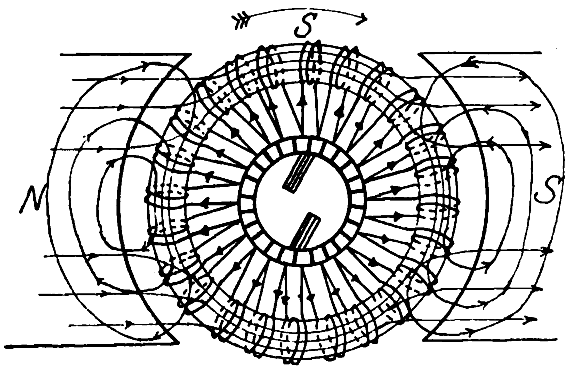

FIG. 3.—DISTORTION OF MAGNETIC FIELD.

It is a well known fact that current flowing in the armature tends to magnetize the core at right angles to the magnetization produced by the field poles. (See Fig. 3.) This tends to twist the field around in the direction of rotation, thus making the leading pole tips strong and the trailing tips weak, because in the following tips the lines created by the armature oppose those set up by the field winding, and in the leading tips assist them.

If the brushes are set half way between the pole tips, the short circuiting will occur while a coil is still in the edge of the field, due to the strong pole tip. The larger the current drawn from the armature, the greater will be the cross magnetization of the armature core, the more will the field be twisted around, and the greater will be the sparking if the brushes are kept half way between the pole tips. The brushes may be set forward in the direction of rotation as much as the magnetization is shifted, and it will take care of the effect of the cross magnetization due to armature current, if the amount of shifting is varied as the armature current varies.

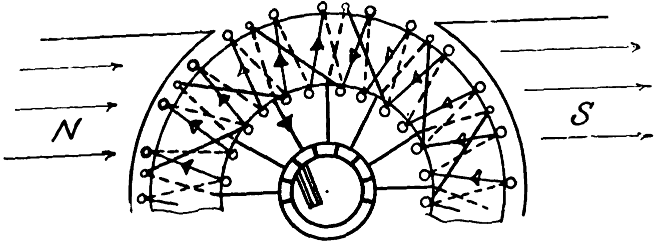

FIG. 4.—SAYERS WINDING.

This will not prevent the sparking due to self induction, but that may be overcome by shifting the brushes still further ahead, until the e.m.f. due to the rotation in the field of the following pole tip is sufficient to neutralize the e.m.f. of self-induction before bar 1 leaves the brush. This amount of shifting will also have to be varied as the amount of armature current varies.

Good design will do much to reduce the amount of sparking. The larger the number of turns in a coil the greater will be the induction, so that it is best to use few turns per coil, but this for high voltage means many coils and commutator bars, which will make the construction expensive. The usual practice allows about 5 volts between adjacent bars for a 125-volt machine and about 15 volts for 500 volt generators.

To reduce the distortion of the magnetization the forward pole tips may be so shaped as to be nearly saturated at no load, and, for a toothed core, the saturation of the teeth will work toward the same end. This saturation will tend to make a "stiff field," i. e., one not easily distorted, and thus reduce the twisting effect of cross magnetization. Special forms of winding have been devised to reduce the sparking, among the most prominent being the Sayers and the Ryan.

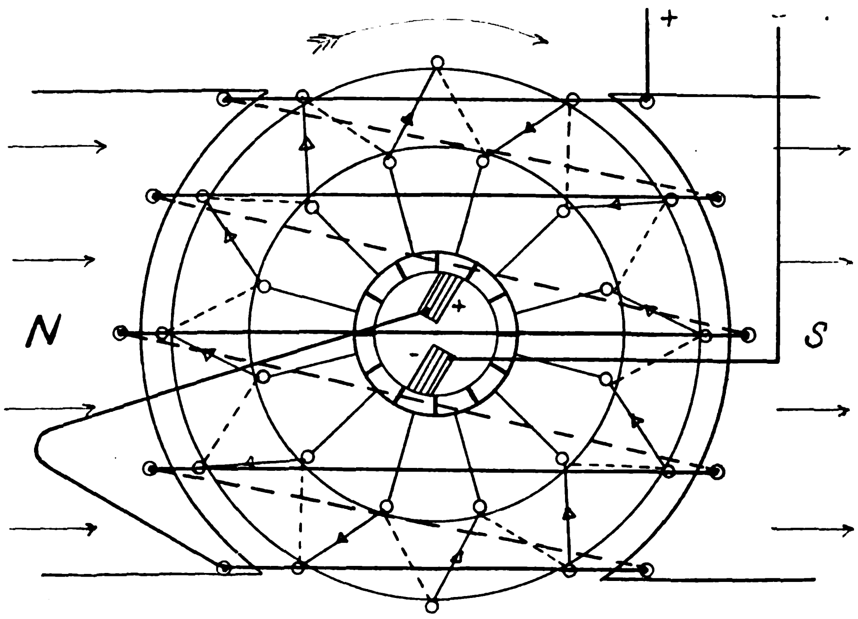

FIG. 5.—RYAN WINDING.

In the Sayers winding the coils are connected together without taking leads to the commutator (See Fig. 4.) The connection is then made to a commutator bar from the junction of two coils, through a "commutating coil," which coil is wound on the armature core in opposition to the main coil, but placed behind the main coil against the direction of rotation far enough so that, as the main coil is being commutated in the position of no field, the commutating coil on account of its position will generate a back e.m.f. sufficient to overcome the e.m.f. of induction in the main coil, and also the effect of the cross magnetization. (See Fig. 4.) Since the coils are in opposition, they will neutralize each other's cross magnetization and induction; and the current will increase in both at the same time, so that induction effect will be neutralized independent of the load. The commutating coils are only in circuit at the time of commutation; at other times the current flows through the leads from coil to coil without passing through the commutating coils. This device introduces some complication, but is, perhaps, as successful as anything yet devised, though not extensively in use in this country.

The Ryan winding consists in putting a compounding or series coil wound in slots or tunnels in the pole-pieces on the dynamo, so that the effect of armature cross magnetization will be just neutralized at each point. (See Fig. 5.) In this way, the distortion of the field is prevented and, if the lead be made sufficient to neutralize the e.m.f. of self-induction all sparking will be avoided, no matter what the load.

In deciding on the style of winding for any machine, the points to be considered are convenience in winding and in repairing winding, size of wire to be used, cost of making punchings, probable sparking, mechanical strength and amount of magnetization required. Between the wire-formed coil, the bar and the cable windings, it is a matter of size of wire to be used and number of wires to be connected.

The wire wound armature is often used for small sizes where the wire is too fine to wind well into a formed coil and would not hold its shape well when wound; it is also often used for Gramme ring armatures with toothed cores where it would be impossible to put on formed coils. For small drum armatures, this winding is difficult to repair on account of the crossing of the coils at the ends, and it is inconvenient to wind and to insulate for high potentials; to get mechanical strength the winding must be well bound into place. The Gramme ring winding is expensive to apply, but is more readily repaired, as there is no crossing of coils; since the coils surround the core there is necessity for only enough binding to prevent sliding of the wires around the core if it be smooth.

The smooth core is almost entirely abandoned at the present time. It necessitates rigid binding to keep the wires in place, and a long air gap in order to get room between the core and the poles for the armature conductors. The method of holding conductors by binding is not good mechanically, and the long air gap necessitates a large amount of copper in the field winding; the only advantage of the smooth core is that the long air gap gives a field not readily distorted by the cross magnetization of the armature.

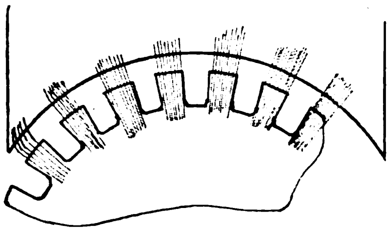

FIG. 6.—DISTRIBUTION OF FLUX IN TOOTHED CORE.

The toothed core provides a firm mechanical support for the conductors, protects them from injury and makes it possible to cut down the distance between core and poles to that which is needed for mechanical safety. The difficulty with this form of core comes from the fact that, if the spaces between the tops of the teeth are made large the flux becomes tufted (Fig. 6), thus setting up eddy currents in the pole faces as the tufts sweep across them. This causes heating of the poles. Also, the small gap makes a field easily distorted by the armature cross magnetization, thus making a machine more likely to spark with change of load. The tufting can be avoided by using overhanging teeth, Fig. 7, but this makes a slot into which it is more difficult to get the coil than if the straight sided tooth be used.

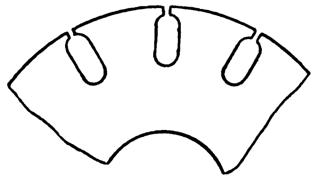

FIG. 7.—OVERHANGING TEETH.

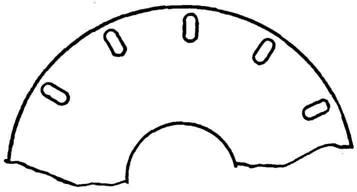

FIG. 8.—TUNNELED CORE.

The heating of the poles may be avoided by using laminated pole-pieces or narrow slots cut in the pole face parallel to the laminations of the armature core.

The field distortion can be remedied by using teeth of such small cross section that they will be nearly saturated at normal load, thus giving a high magnetic resistance to take the place of that removed by shortening the air gap, and making a quite "stiff" field.

The formed coil winding is the one most in use at the present time for dynamos of moderate output. It is easily made and applied, and a coil can be easily replaced; a toothed core with rather wide openings between the tooth tops must be used, but the openings should never be more than 2½ times the length of the air gap if tufting is to be avoided.

For large size machines, the wire becomes too stiff to be easily made into formed coils. Resort must then be had to bar or to cable windings. The bar winding is used in many cases where coils might be used, because rectangular bars are more economical of space than round wires. The insulation and connecting of the bars is more expensive than the winding of formed coils, but not much more so than the winding and connecting of cables or heavy wire. Either bar or cable windings are generally put into tunnels made by punching holes in the armature discs, Fig. 8. The joining of the tooth tops tends to increase somewhat the leakage of magnetic lines from one pole to another, but it makes a disc which is somewhat easier to punch than is the disc with separated teeth.

If the spaces between tooth tops have been made too large, so that heating and sparking are present, it may sometimes be remedied by winding on the surface of the core a layer of iron wire, thus making practically a tunnel for the conductors. For the toothed or tunneled core, the slots generally have parallel sides in order to make convenient winding, though the use of a wedge shaped slot, larger at the inside end, holds the wire more firmly in place.

The toothed and tunneled cores carry the flux entirely in the teeth and thus avoid eddy currents in the conductors themselves, but the self-induction of the coils is increased by the iron inside them. The bedding of the conductors in the core makes insulation for high voltages more difficult and necessitates a larger space for insulation.

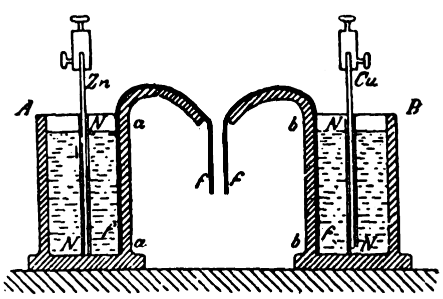
The appropriate use of various forms of winding has been discussed under each form in previous articles, so need not be mentioned here. In general, lap windings are used for bipolar machines, wave for multipolar. The multiple windings are used for medium voltages and medium currents; the series windings for high voltage; and the telescope windings for low voltages and large currents.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Experiments on the Use of Blast Furnace Gases for Engine Driving.—M. Aimé Witz writes in "La Revue Technique" a very complete description of experiments recently made upon the utility of blast furnace gases for the operation of large gas engines. The engine used was of a single cylinder type, about 32 ins. diameter by 40 ins. stroke, running at 105 r.p.m. with a compression of 110 lbs. and 200 nominal h.p. The gases were taken directly from four furnaces or could be passed first through a gas holder of about 55 cu. ft. capacity. A friction brake was used to absorb the power of the engine, arrangement being made for supplying it constantly with cooling water so that it could be used during a 24-hour run. The water used for cooling the cylinder and for washing the gas in scrubbers was very carefully measured. The consumption of gases averaged 117.5 cu. ft. per effective h.p. hour, the consumption of water being 220 lbs. and of oil and grease less than ½ oz. These averages were made during tests extending over a period of twenty-four hours.

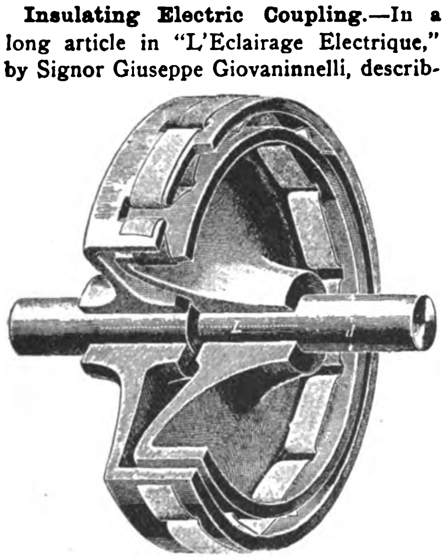
Copper Sulphate Standard Cell.—In "Elecktrotechnische Zeitschrift" Herr Grotian describes a modified form of the Daniell cell, which is very easily constructed, and useful as a standard cell. It is not so constant as the Clark or Weston cell, but sufficiently so for most purposes. The figure herewith, taken from an abstract in the (London) "Electrical Review," shows the arrangement adopted by the author: Two cells are provided, of porcelain, hard rubber or other suitable material, each having a long lip on one side. One of these cells contains the zinc and its solution, while the other contains the copper and its solution. The plates are held in the cells in a fixed vertical position by any simple means. A piece of blotter or filter paper is hung down over the end of the lip of each cell, as shown in the illustration, each being saturated with its own solution, and the two are allowed to come into contact at the bottom. The liquid flows over by capillary attraction and drops fall off the ends of the paper. The copper plate should be given a coat of pure electrolytic copper, and the zinc plate should be of pure metal, well amalgamated. The zinc solution should have a specific gravity of 1.2 and the copper



COPPER SULPHATE STANDARD CELL.

solution of 1.1. The e.m.f., as determined by the Reichsanstalt, is 1.101 volts. The resistance is several thousand ohms and the cell will stand short circuit without injury. When the cell is not in use its e.m.f. rises at the rate of two or three thousandths of a volt per day.

Insulating Electric Coupling.—In a long article in "L'Eclairage Electrique," by Signor Giuseppe Giovaninnelli, describing the installation at the Falls of Kerka in Dalmatia, a most simple and ingenious flexible coupling is illustrated. The illustration, which is reproduced herewith, requires little explanation. Two castings, as shown, are mounted on the extremities of the shafts, which are brought close together, but not in contact. A number of windows are cut in the flanged circumference of each and through these an endless cotton belt is passed, in the way shown in the illustration. The great advantages of this simple coupling are that it will work quite well when the shafts are not exactly in line with each other, that it possesses considerable elasticity and that it forms an effective insulation where this is desirable, as in the case of a dynamo direct-driven from an engine or turbine.



INSULATING FLEXIBLE COUPLING.

Electrical Canal Haulage.—Mr. A. H. Allen read before the recent meeting of the British Association an interesting paper having the above title, which is printed in full in the "Mechanical Engineer." The system about to be tested on one of the large British canals is fully described. On the tow path is built, at a height of 9 or 10 ft., a rigid structure composing two Z-bars braced together at one side and supported at intervals of about 30 ft. on cast-iron or wooden posts. Each of the Z-bar rails constitutes a track for a number of locomotives. These consist simply of a motor mounted on a four-wheel carriage so that two of the wheels run on the upper side of the rail and the other two on the lower. Fig. 1 shows an end view of two locomotives passing, and Fig. 2 shows a side elevation of one of the motors. As may be seen from the latter, the motor shaft carries a worm at each end gearing with a worm wheel on each of the four axles, so that all of the wheels are drivers. It is stated that the tractive force required to tow a barge carrying 100 tons of freight on an ordinary canal at the rate of 2½ miles per hour, is from 250 to 300 lbs. or about 2 h.p. In order to get up speed in a short time the motors are made capable of giving a pull of about 600 lbs., the weight of the motor and carriage being less than 1000 lbs.

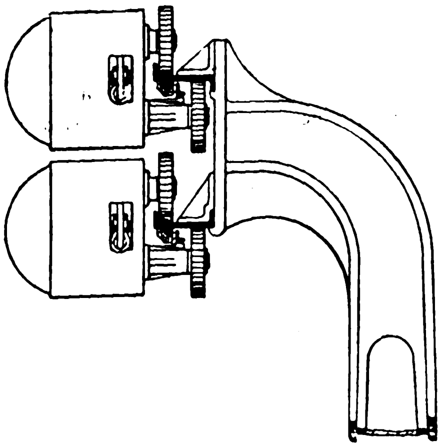


FIG. 1.—ELECTRIC CANAL MOTOR, END VIEW.

To the left side of each rail is bolted a continuous creosoted wooden batten which supports the strap copper conductors. These are insulated from the wood with porcelain insulators. The position of the conductors, which is clearly shown in Fig. 1, is such as to shield them from the weather and from mechanical injury. In passing, the boat being towed by the motor on the lower track steers close to the towing path, while the other steers wide, the ropes thus passing clear without any danger of entanglement. A light cord runs from the boat to the motor controller and a simple switch is arranged so that alternating pulls on the controlling cord open and close the circuit. It is stated that on a level canal 30 miles in length, with an annual traffic of 100,000 tons per mile, the cost per ton mile and the time occupied in transit will be as follows:

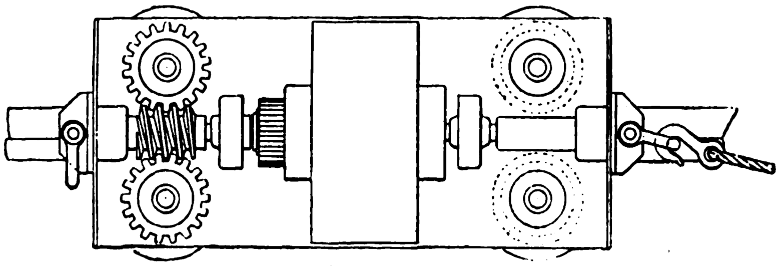

FIG. 2.—ELECTRIC CANAL MOTOR, SIDE VIEW.

	Cost.	Time.
Haulage by horses at 2½ miles per hour...........	.039 cents.	15 hours
Electric haulage at 2½ miles per hour..........	.016 cents.	12 hours
Electric haulage at 4 miles per hour..........	.020 cents.	7½ hours

The Action of Electricity on Plants.—An interesting paper was read by E. H. Cook before the recent meeting of the British Association, and is abstracted in "The Electrician." It appears that experiments upon the influence of electricity on plants were made as long ago as 1806, but the results were generally negative or uncertain.

The author's experiments extended over a period of twelve years, and were described under three heads: Those relating to the germination of seeds, to the growing of plants in soil, and to the lower forms of plant life, such as algæ, fungi, etc. In the case of seeds, barley, wheat, peas, etc., through which a current of 1 to 10 milliamperes was passed while they were germinating, an increased development of from 10 to 20 per cent was noticed over seeds not electrically treated. Electrification with a Wimshurst machine seemed to result in the germination of a larger proportion of seeds thus treated. Upon growing plants the electric current seems to exert no appreciable influence. Electrification, however, from a high tension machine showed a marked increase in the rate of growth. The curious fact that hyacinths grown from the same bulbs and negatively electrified, produced different colored flowers from those positively electrified, was also noticed. The results with experiments with the lower plants seemed to be indefinite. A quotation was made from the work of some French experimenters along the same lines, and most remarkable results are alleged to have been obtained by the use of a sort of lightning conductor set up in the middle of a field and connected to a system of wires running under the soil near the roots of the plants. An increase of 50 per cent in the weight of potatoes grown in patches of the same size, or an increase in the money value of the crop amounting to about $45.00 per acre, is said to have been thus obtained. The author did not attempt to account for the phenomena observed.

A Primary Battery Without Acids.—"L'Industrie Electrique" contains a description of an interesting new type of primary battery. This cell is really a variety of accumulator which recharges itself through atmospheric oxidation. The principle is as follows: A fresh surface of lead becomes covered in a short time, when exposed to the air, by a skin of oxide. Such a plate treated with sulphuric acid has this oxide changed to a mixture partly of lead and partly of lead sulphate. This mixture of the sulphate and the metal is a solid coating adhering to the mass of the lead plate and is, on account of this peculiar condition, quite different from the ordinary white sulphate of lead. A plate thus treated and a zinc plate, in a solution of sulphate of zinc, form the battery. It remains entirely inert on open circuit, but on the establishment of a current, the sulphate of lead is reduced to a metallic state and the zinc dissolved, with the formation of sulphate. When all the lead sulphate has been reduced by discharge, all that is requisite is to expose the lead plate to the air until it has oxidized on the surface, and then treat it again with sulphuric acid.

This article goes into an elaborate description of the details of construction of a battery of this character, arranged for the withdrawal of the liquids, and the airing of the plates, etc., in place. The constants of a cell of this type are given as follows: Weight of the lead plate, 15.5 lbs.; e.m.f. 0.54 volts, initial current, 6 amperes. Total discharge, 187 ampere hours. The price of current generated by this means is said to be in the neighborhood of 53 cents per k.w. hour.

The Water Power Station at Sihl, Switzerland.—A station possessing many points of interest has recently been built at the village of Sihl, in Switzerland, to serve the region along the west side of Lake Zurich, a neighborhood well filled with small industries. The hydraulic works required for the development of the water power are on a scale of considerable magnitude and are well shown in the map, Fig. 1, herewith, taken from "Le Génie Civil." From a dam on the river Sihl a tunnel about 3 miles long conveys the waters of the river to a pond formed by damming a narrow valley, the tunnel being able to deliver a maximum of 750 gals. per second. The construction of the tunnel was one of great difficulty, as the soil through which it was driven was full of blocks of stone and boulders separated by earth, thus requiring a masonry revetment throughout its whole length. The pond into which this aqueduct delivers the water contains about 52,000,000 gals. From it to the power plant extends a metallic conduit about 5 ft. 6 ins. in diameter, built of steel about ¼ in. thick and fortified externally with a heavy layer of concrete. It is supported at numerous points by heavy cast-iron collars resting on concrete foundations The lower section of this tube is ½ in. thick. On account of the great length of the conduit (nearly half a mile) unusual provisions were necessary for the avoidance of the shock due to the sudden stoppage of the stream of water. At a point near the bottom of the conduit was constructed a chimney or vertical standpipe. 7 ft. 6 ins. in diameter and 67 ft. high, built of 3-16 in. steel and permanently connected with the conduit (Fig. 2). The lower part of this standpipe, which is under ground, is surrounded with a heavy shield conduit.

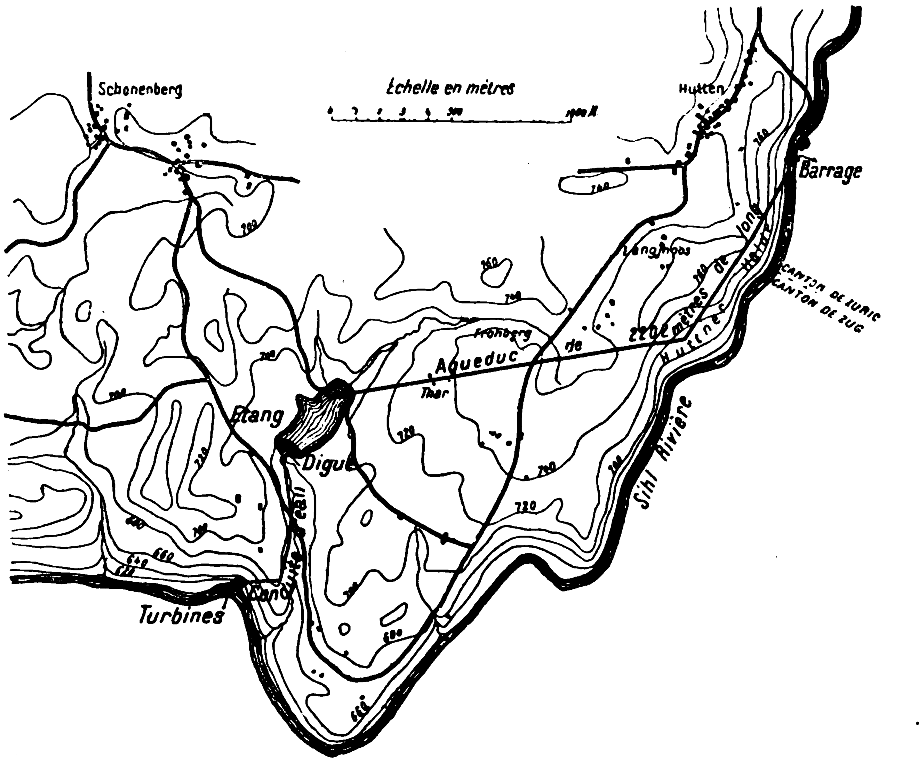

FIG. 1.—MAP OF THE SIHL INSTALLATION.

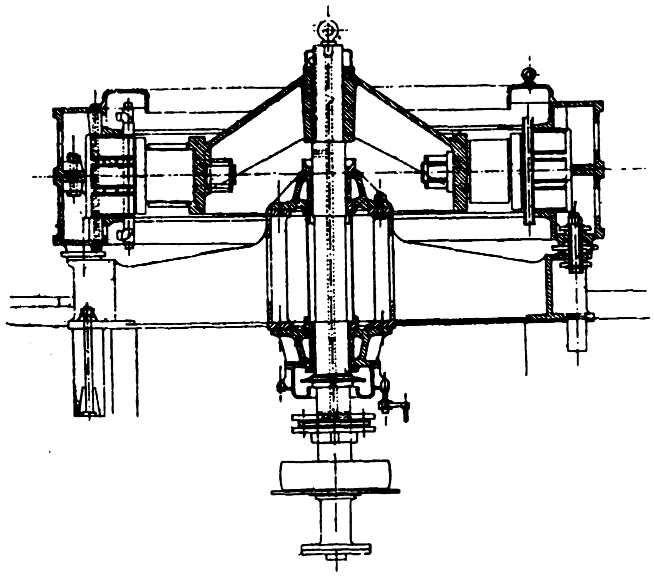

FIG. 3.—VERTICAL CROSS-SECTION OF DYNAMO.

Vertical shaft turbines are used, carrying the revolving field of the dynamo on their upper extremities. The installation comprises five machines, each of 400 h.p., running normally at 360 r.p.m. The dynamos, of which Fig. 3 shows a cross-section, are the well-known Brown-Boveri type, generating directly a pressure of 5000 volts at forty-two cycles per second. These dynamos are arranged so that the whole output may be taken off at a two-phase current or as a single-phase current. There is nothing specially noteworthy about the transmission lines and sub-stations, which are of the usual excellent Swiss type. Only induction motors are used on the system, and the power motor is said to be 80 per cent.

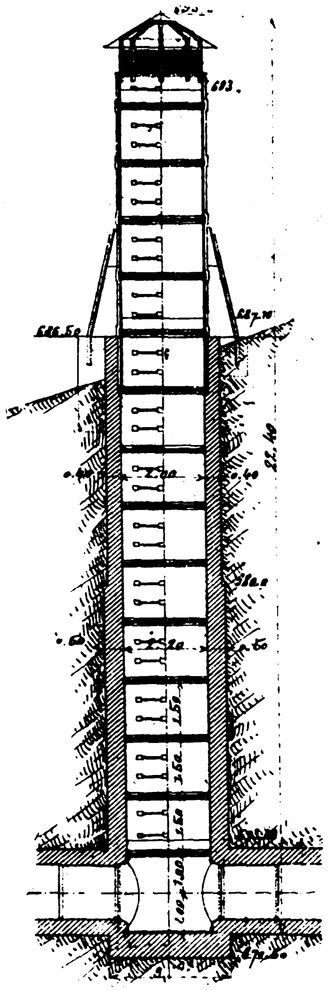

FIG. 2.—STAND-PIPE ON TURBINE PENSTOCK.

A New Type of Storage Cell.—The "Electrician" describes an interesting new type of accumulator designed by Mr. Marquand. Lead is cast in solid ribbed plates, which are then packed in sets of two or three, imbedded in powdered sulphur in moulds. The boxes of lead plates and sulphur are then arranged in racks so that the hot gases from a furnace pass around them and allow them to slowly heat up to the melting point of lead, at which temperature they are kept for about an hour. A skin of sulphide forms on the surface of the plates and prevents any deformation or running of the lead, as if it were encased in a tight envelope. This sulphiding process being complete, all of the plates are converted into negatives in a forming bath, positives being afterward made from these by reversing their polarity in a similar bath. It is said that plates of this type can be turned out complete ready for service in twenty-four hours.

Memorial to Maxwell.—The (London) "Electrical Engineer" announces that a suitable memorial is to be erected to the memory of the late James Clerk Maxwell in Corsock Parish Church. The eminent Professor Maxwell was closely connected with this church throughout his life, and it is considered a most appropriate place for a memorial to his memory. Subscriptions fixed at one-half guinea should be sent to Rev. George Sturrock at Corsock, by Dalbeattie, N. B.

Electro-Thermic Mining Cartridges.—"La Nature" gives a short account of an original proposition made by Major M. H. Shaw at a recent meeting of the Institute of Mining Engineers for the use of cylinders of water brought to a high temperature by means of an electric current in place of dynamite or such other explosives in dangerous coal mines. Of course this explosive is very much less powerful than dynamite, but it is considered to be sufficiently strong for coal mine work and is, of course, perfectly safe, not only on account of no fire being concerned in its explosion, but also because the cartridges can be handled with entire safety by anyone.

The English Corps of Volunteer Electrical Engineers.—Not the least of the many services for which the electrical profession owes a debt of gratitude to the late Dr. John Hopkins, says "Lightning," is the formation of this corps. Last year its officers were chosen and went through a preliminary training at Fort Victoria on the Isle of Wight. During the present year over 100 volunteers have been enrolled from members of the electrical professions. It is said that the officers of the regular army are greatly pleased with the work of these volunteers so far, but it is expected to increase the corps to seven companies in the near future.

Now that the military forces of this country are receiving so great a share of public attention, it seems a fitting time for the formation in the United States of a corps similar to this. In the early days of the late war with Spain a trained corps of electrical engineers skilled in telephone, telegraph and signal work, the laying of cables and mines, the installation of all sorts of electrical apparatus, and drilled to make the best of sudden emergencies, would have been absolutely invaluable. It is to be earnestly hoped that the movement which resulted in the formation of the first volunteer regiment of engineers, who are at this writing in Porto Rico, will be continued until it results in the establishment of a volunteer corps of electricians having a status similar to that of our Naval Militia.

A Plastic Insulating Substance.—"L'Électricien" gives the following formula, due to M. F. A. Magdolf, for a plastic insulating substance which soon hardens. Gum-lac, or a mixture of this gum with other resins, is dissolved in alcohol or any other convenient solvent which will mix readily with water. In this solution are stirred insoluble substances, such as powdered asbestos, powdered glass, silica, metallic oxide, coloring matters or other such things as may be desired, and water is then slowly added while the mixture is stirred. The gum is thrown down in a finely divided precipitate, intimately mixed with the powdered substance. The mass soon hardens and, if desired, may then be pulverized and moulded in a hot mould under pressure.

Monazite Mines.—The "Mechanical World" contains an interesting note on the mines of monazite in Brazil. This material is the principal source from which the rare earth oxides composing Welsbach mantles are obtained. The most extensive deposits are in the district of Bahia and occur in the shape of banks of sandstone on the sea coast. The sands are quite rich in monazite and may be loaded directly on vessels. The same mineral has recently been discovered in the United States of Colombia and Buenos Ayres.

Wireless Telegraphy.—In a somewhat ponderous editorial on Wireless Telegraphy, the "Electrician" discusses the efficiency of space signaling, both in the arts of peace and war, and comes to the conclusion that there are a number of ways in which this variety of signaling can be turned to good account. The possibilities of space telegraphy in communicating between moving trains have not been thoroughly exploited, and it is thought that this may be a profitable direction for future endeavor. For signaling the arrival and departure of vessels at various coast points, for communicating between vessels at sea and as an accessory to lighthouse service, it is perfectly possible that the ether-wave telegraph system may find uses.

It has remained for this country to originate the most recent and remarkable application of this variety of space signaling. A well-known inventor has just proposed to use electric waves for communicating between points on shore and automobile torpedo boats which are to prowl around the coast at night and strike terror into the heart of invaders. The mechanism of this craft is so remarkable that it is proposed to exhibit it in Paris during the forthcoming exposition while the inventor operates it from his office in New York!

Electric Boats for the Russian Government.—"L'Eclairage Electrique" gives some data of the new electric boats ordered from an English company by the Russian Government. These boats are 32 ft. long, 8 ft. beam, draw 40 ins. of water, and can accommodate twenty passengers each. They are built of mahogany with bronze trimmings, and each is operated by forty elements of accumulators in water-tight, hard-rubber boxes. All of the elements are permanently connected together in series, and speed regulation is accomplished by the use of two separate windings on the motor armature, which is provided with two commutators. These windings are put in series or parallel after the well-known fashion used in street railway motors. With 10-h.p. the speed of these vessels in still water is 12 miles per hour, and the outfit can run at full speed for four hours. At an output of 5 h.p. the battery will work for eight hours without recharge and the speed is very little reduced.

Electrolytic Cooking Utensils.—There has been, according to "L'Elettricità," some difficulty encountered in the electro deposition of copper in hollow matrices for the manufacture of pots and other cooking utensils because the finished vessel is only separated with difficulty from the mold. A new process provides the matrix with a valve at a convenient point. When the copper is thick enough water under high pressure is admitted by this valve at a point between the copper and the matrix and strips off the former easily. It is said that these vessels are not only stronger than those beaten by the ancient process, but also much cheaper.

Recording Pyrometers.

To the Editor of American Electrician:

The pyrometer described on p. 422, September number of the "American Electrician," can scarcely be called new. About ten years ago Le Chatelier brought to notice the use of a thermo-couple of platinum and platinum-rhodium alloy (10 per cent rhodium), for the measurement of high temperatures, and about seven years ago Prof. Roberts Austen designed a recording form of apparatus, the records being made on rapid bromide paper by means of a spot of light.

Several of these pyrometers are in use in the Cleveland district for indicating the heat of the blast supplied to the blast furnaces. At our works (blast furnaces) we have used two electric pyrometers (platinum and platinum-rhodium couples) for the last six years, one for the use of the foremen and stove minders, and the other a recording instrument. By using a switch operated every half minute by clockwork, we get the records of two furnaces on one sheet of paper. The galvanometer used is a Holden-d'Arsonval reflecting, and, being rather too delicate, a resistance of German silver wire is inserted in the circuit.

Mr. Stansfield's arrangement of the photographic plate seems rather crude compared with our arrangement, which is a sheet of rapid bromide paper wrapped round a drum which is revolved by clockwork. I have used many kinds of pyrometers, but for simplicity and accuracy the thermo-couple is easily first. I should think that these pyrometers will be in use at many of the American blast furnaces for indicating the temperature of the blast. They are certainly far ahead of any other pyrometer in use. H. L. MUNNOCK.

Loftus, England.

Accuracy and Permanency of Switchboard Instruments.

To the Editor of American Electrician:

In the November issue of the "American Electrician" I notice an article entitled "Accuracy and Permanency in Switchboard

Instruments," in which it is stated that the electro-dynamometer principle constitutes an ideal form of switchboard instrument, possessing all possible virtues and no defects. I write to take exception to the statements made in the article, for I have had several years' experience in the manufacture of switchboard and portable instruments, and spent over a year in the endeavor to produce such a type of instrument as described for switchboard use, but found that it was thoroughly impracticable.

To start with, the dynamometer system is more susceptible to the influence of external fields than any form of instrument I have ever tested, and, when used on direct current circuits, it is necessary that the direction of the current flow should be reversed and the mean of the two readings taken in order to ascertain the actual current flow. This in itself is sufficient to prohibit the use of such an instrument on direct-current switchboards. If an attempt is made to shield such an instrument by the employment of an iron case, a certain amount of shielding will be effected, but the instrument will be seriously in error when employed on the alternating current; that is, there will be from 2 per cent to 5 per cent difference in the indications of the instrument for the same potential, depending on whether that potential is direct or alternating, and the necessity of reversing the direction of the current flow on direct current still remains.

Considering the question of a voltmeter, it is necessary to construct the moving coil so that it will have small weight, and, if this is done, it will be found that, if the axis carrying the moving coil is set horizontally, after some weeks of service the coil will become deformed and errors will be introduced in the readings. The alternative is to place the axis of the moving coil vertical, which involves a very awkward construction and a badly placed scale.

For ammeter use a serious objection is encountered when you consider the fact that it is necessary to place the moving coil in series to the fixed coil, and provision must be made to carry the current from one to the other. Consider for a moment the difficulty which would be experienced in providing a perfectly flexible and frictionless connector capable of carrying 1000 amperes. Such a connection has never been successfully made, except by the use of mercury contacts, only applicable to a vertical type of instrument, as exemplified in the commercial laboratory dynamometer of to-day. Again, if one has had any experience in using the laboratory dynamometer, he will understand the many precautions necessary to insure absolute accuracy. Tests and corrections must be made for the influence of external fields, the difference in the self-induction of the fixed and moving coils on alternating current, and the influence of iron in the framework of the instrument or in its immediate vicinity.

As a shunt instrument, the electro-dynamometer is distinctly not a success, since the resistance is entirely too high for the quantity of current necessary to operate it, and a shunt block would have to be constructed which would permit an abnormal flow of the current across its terminals at a drop which would be prohibitive. For instance, the best results which I have seen in the attempt to produce a shunt instrument on the dynamometer principle required a drop of 10 volts and a current flow of .05 of an ampere. These two factors may be changed, but the watt energy required remains constant. Attempts have been made to utilize the drop in the fixed coils to actuate the moving coil, and this again has resulted in absolute failure, for the reason that an energy of about 5 watts is essential to carry the pointer to full scale, and this amount of energy requires a drop in the fixed coils which would necessitate the introduction of a large resistance into the series circuit.

Again, it is stated in the article that an equally divided scale can be obtained "by the ingenious placing of the counterbalance or the employment of several weights successively brought into play." In this connection I would say that there may be such a method, and if there is I would appreciate details. A vast amount of money and time has been expended in the attempt to produce an instrument on the electro-dynamometer principle which would have a practically equally divided scale, but up to date I have never heard of a single successful result. If one bears in mind the fact that the deflection of the pointer in such an instrument is proportional to the square of the current, he will appreciate the impossibility of producing an equally divided scale unless the moving coil and fixed coil are separately excited, in which case we have a wattmeter rather than a voltmeter or ammeter.

For portable instruments I am willing to grant you that the dynamometer system is absolutely ideal, that is, so far as wattmeters and voltmeters are concerned, but it is not practicable in the case of portable ammeters, except in the commercial form of an electro-dynamometer with mercury contacts and leveling screws. Such a line of instruments the company with which I am connected have been making for a number of years with most excellent results as to permanency and accuracy; the voltmeter having a scale which starts at about 1-10 the total reading, while the wattmeters have an approximately equally divided scale, the scale divisions being rather smaller at the start and finish than in the center.

If you will look into the past and present history of switchboard instruments you will find that the electromagnetic type has proved itself eminently satisfactory when properly constructed. It is true that there are many types on the market to-day in which serious errors due to lag or hysteresis exist, but this is the fault of the designer or constructor, rather than the fault of the general principle employed. Scientifically accurate results and absolute permanency of calibration may be obtained by the employment of the electromagnetic system, if the design is correct and all the various component parts properly selected and treated. Very truly yours,

Philadelphia, Pa. J. F. STEVENS.

[Replying to Mr. Stevens' communication, I will take up his objections in order. The dynamometer is indeed susceptible to external fields, but this is true of any instrument. Even a highly magnetized d'Arsonval type is also thus susceptible, and must be carefully placed on the switchboard with reference to minimizing such an effect. It is not at all uncommon to find the voltmeter in a station removed from the main switchboard and at a distance from the generators, to avoid the influence of stray fields. The ammeter, which is of less importance, is usually left on the switchboard.

The influence of magnetic fields can be largely eliminated by the use of a heavy iron casing, which should be properly made so as not to introduce errors. It should be large, thick and of soft homogeneous material. These are by no means impossible conditions, commercially or practically; nor does the added weight constitute an objection. When used for alternating currents, the dynamometer is unaffected by magnetic fields and needs no shield.

It is not to be presumed that a switchboard instrument could be used without change for both direct and alternating currents, but the only requirement necessary to adapt an instrument to measure either would be to change its containing case and its scale. This a manufacturer of instruments should find no hardship, and it seems to the writer that it would be cheaper and easier to build different types of containing cases than to build different types of mechanisms.

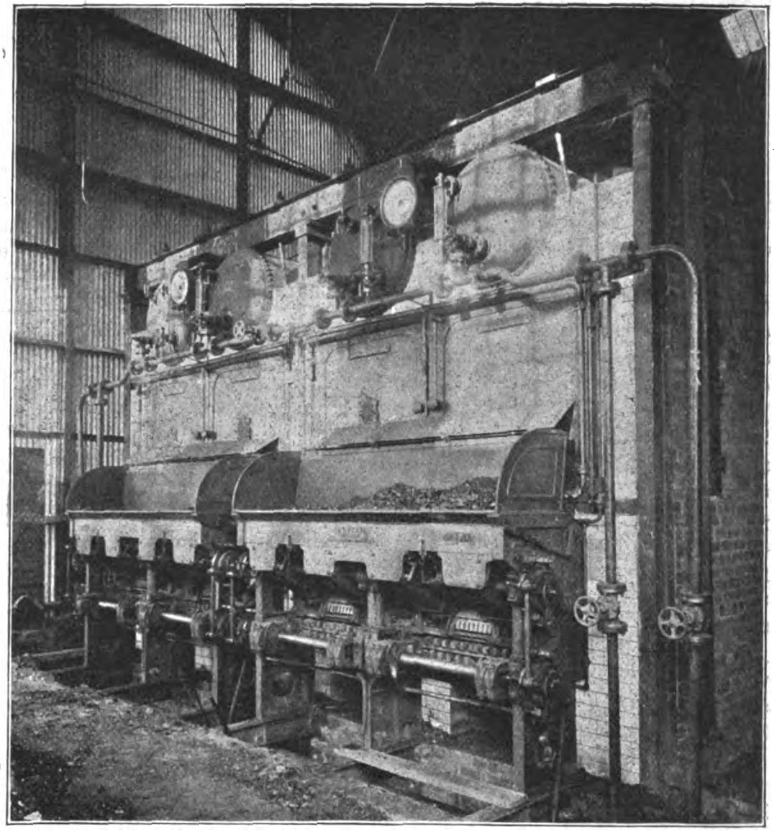
The statement that if the moving coil is made light enough for voltmeter purposes it is likely to be deformed, is somewhat of a surprise to me. From the very nature of the instrument the forces which act on the dynamometer coil must be minute, and it ought not to be difficult to build a coil stiff enough to resist them. The statement that it is impossible to have a mercury contact combined with the horizontal axis of rotation is also a surprise to me. In the "American Electrician" for November, in Figs. 1 and 2, page 510, is illustrated an electro-dynamometer mechanism constructed with a horizontal axis and mercury contacts, and, as far as this method of making contacts is concerned the writer's experience has been that it is very successful, although in instruments which are to indicate over 300 or 400 amperes it would not be suitable. When such a large amount of energy as this is measured the percentage of energy that it is permissable to use becomes quite a liberal quantity, and sufficient to actuate dynamometers on the shunt plan.

Regarding the statement that the ingenious placing of counter weights will give an evenly divided scale, I would say that the simple device of a cam placed on the shaft and winding up on its surface a cord carrying a weight can be constructed, which will easily follow the intricacies of the square function and much more complicated ones. The contour of the cam is a mere matter of mathematics.

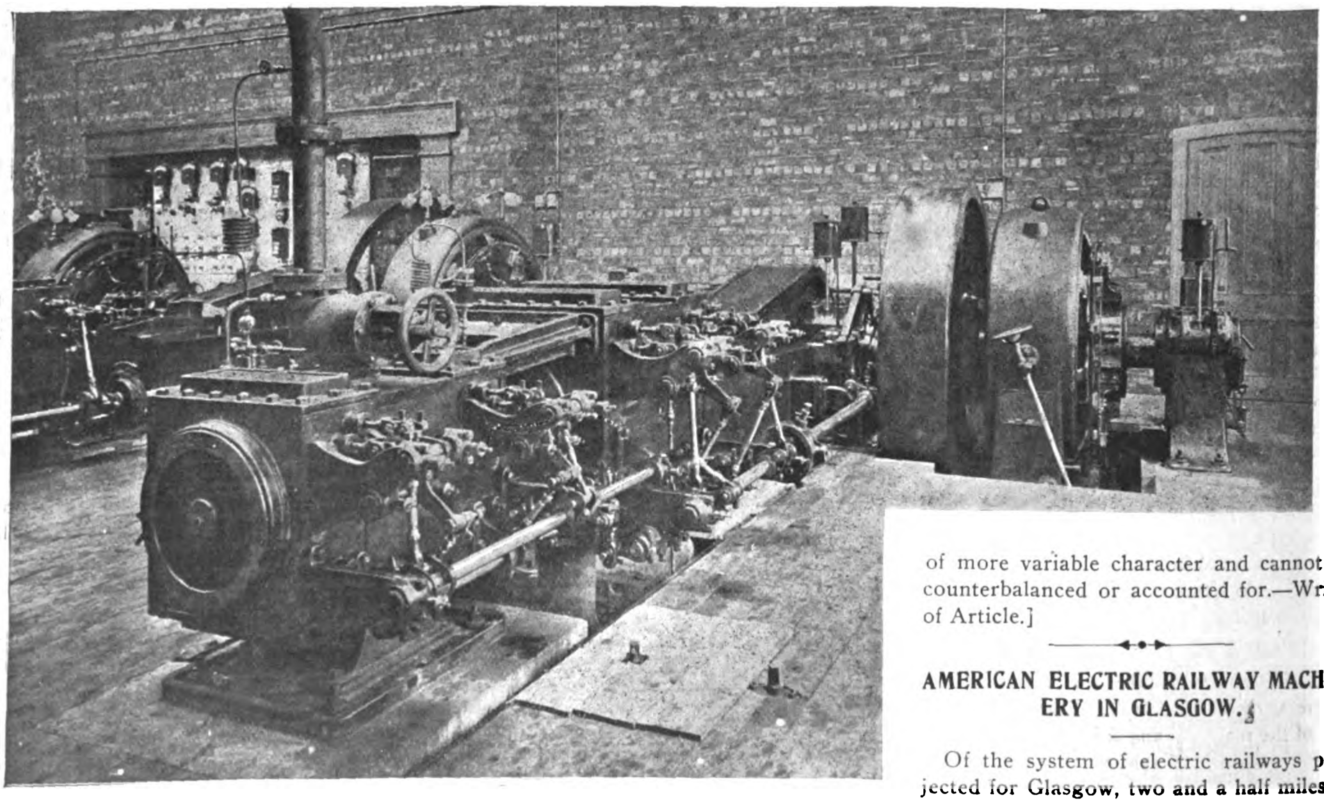
Regarding what Mr. Stevens says about his portable instruments, I would suggest that it is perhaps the key to the cause of his criticism of dynamometer switchboard devices, and his standard of accuracy, while highly creditable from a technical standpoint, is not commercial. The excellent results which he has attained with portable instruments has led him to be loath to accept anything inferior in switchboard instruments, while as a matter of fact the public will not pay for absolute accuracy in switchboard instruments, and possible errors of from 2 to 5 per cent are accepted if economy in the first cost can be obtained.

As far as the past and present history of the electromagnetic instruments is concerned, the writer's experience has been that they are anything but satisfactory, as they all contain moving iron. Iron has a very apt and retentive magnetic memory, and the deflection of the instrument depends as much upon what has been previously indicated as upon what it ought to indicate. If Mr. Stevens has himself been successful with electromagnetic instruments and produced types in which errors from lag and hysteresis are not appreciable, I think the electrical fraternity will agree that he ought to be congratulated as a pioneer.

To sum up, an electro-dynamometer, like other instruments, should be removed from magnetic influences as far as possible, and can be shielded from them. It can be made sufficiently strong to withstand deflecting forces and still pass as a commercial instrument. A type can be selected in which the mechanism is so constructed that it can be built as a voltmeter, an ammeter and a wattmeter, and when once properly installed, need not be recalibrated. It can be made cheaply. The very fact that Mr. Stevens has succeeded in perfecting it as a portable instrument argues its possibility for switchboard work, for with a portable instrument the requirements are made more exacting, the magnetic fields and other disturbing influences are strong and of more variable character and cannot be counterbalanced or accounted for.—Writer of Article.]



AMERICAN BOILERS IN GLASGOW POWER HOUSE.



AMERICAN GENERATORS AND ENGINES IN GLASGOW ELECTRIC RAILWAY POWER HOUSE.

◆

AMERICAN ELECTRIC RAILWAY MACHINERY IN GLASGOW.

Of the system of electric railways projected for Glasgow, two and a half miles of double track have recently been completed and opened for traffic. Of particular interest to America in connection with this railway, is the very large use in its construction of American apparatus and material. The engines were made by the McIntosh, Seymour & Company of Auburn, New York, and are three in number, of the horizontal tandem-compound type and an indicated horse-power of 300 to 450. The steam generators are Babcock & Wilcox boilers, two being at present installed, each of 250-h.p. capacity. Worthington condensers and Blake-Knowles pumps are employed. The trolley poles were supplied by Morris, Tasker & Company, of Philadelphia, and are of a particularly ornamental design. The electrical generators were furnished by the Westinghouse Company, and are three in number, of the Westinghouse eight-pole 200 k.w. type of 380 amperes at 550 volts. The switchboard is also of Westinghouse type and equipped with Weston voltmeters and ammeters. The cars are equipped with Westinghouse No. 39 motors, with Westinghouse controllers, switches, circuit breakers, lightning arresters, etc. It will thus be seen that with the exception of the cars, every important feature of the operating plant is of American manufacture. The accompanying illustrations show the steam and generating plants.

NOTES.

Electrical Excavator.—The London "Engineer" in a recent issue describes an electrical excavator used in excavating in the tunnel of the Central London Railway. This was specially designed to suit the clay found on this section of the undertaking, where large boulders up to 3 ft. and 4 ft. in diameter were encountered. Any machine constructed on the principle of the rotary cutter was out of the question in dealing with such material. The machine consists essentially of a dredger ladder, the working end of which can be moved vertically, horizontally and longitudinally, each motion being so arranged that a slow definite feed can be given, and so that a point of the ladder having been moved to any position in the face is rigidly held down. The ladder itself is 17 ft. long, and is provided with an extension screw arrangement for keeping the bucket chain tight. The buckets, of which there are 37, consist of a bottom and back only, the back being fitted with teeth. These teeth are of wrought iron, chisel-pointed, and dropped into recesses cast in the back of the buckets. About 6 ft. from the driving tumbler end of the dredger the ladder is supported by two chains passing to the winding longitudinal shaft. The fore-and-aft traveling gear is worked from a pulley on the other end of the motor which drives through the king post by the countershaft and worm gearing. Two barrels are placed one of each side of the under frame. From these barrels wire ropes are led fore and aft of the machine and fastened to the sides of the tunnel. Each of these traveling, raising, slewing and fore-and-aft motions is worked by means of worm gearing, so that without the use of a brake the point of the ladder is held definitely wherever the feed takes it. The lever for working the motions, the reversing switch and the ten-way switch for turning on the current, are brought together within easy reach of the driver, who stands on a small platform at the left side of the machine. When the machine had been in use for two or three months, the time occupied in pushing the shield and erecting the iron was very much reduced, and during the last few weeks' work of the machine eight rings were put in several times during the two shifts. The average number put in, however, was three 20-inch rings per shift of ten hours. The number of men at the face, including the driver, was usually eight, but was reduced latterly to six. The number of men employed at the same work by hand was fourteen.

Design of Transformers.—A highly mathematical paper by Mr. Frederick W. Carter, entitled "The Design of Transformers," was read at the November meeting of the American Institute of Electrical Engineers, in which the author attempts the useless, if not impossible, feat of laying down a system of transformer design consisting entirely in the use of equations, more or less complicated. The accompanying table is taken from the paper, giving the data of six transformers, columns 1 and 4 relating to types of commercial transformers, and the other columns to designs calculated by the author.

Co-Operative Electro-Technical Research.—The Council of the American Institute of Electrical Engineers has appointed a committee on "Co-Operative Research," whose duty it will be to suggest problems for research and submit them for investigation to the various colleges and other laboratories, the results to be published by the Institute. The following is a list of the investigations thus far suggested:

(1) The effect of sustained high temperature upon the insulation resistance of dielectrics. (2) The influence of sustained high temperature upon the dielectric strength of insulating materials. (3) The influence of sustained high temperature upon the hysteretic coefficient of commercial iron. (4) The influence of chemical impurities in iron or steel upon the hysteretic coefficient. (5) The hysteretic coefficient of magnetic alloys. (6) The temperature coefficient of resistivity in commercial copper wires. (7) The temperature coefficient of resistivity in commercial aluminum wire. (8) The temperature coefficient of resistivity in alloys commercially employed (it is desirable to include analysis of the alloys tested as well as their physical properties). (9) The highest conductivity obtainable in copper wire at any standard temperature. (10) The highest conductivity obtainable in aluminum wires at any standard temperature. (11) The analysis of dielectric losses between parallel copper wires maintained at high e.m.f.; 1, alternating and, 2, continuous, into component parts, such as chemical, electrical and mechanical. (12) The influence of wave form of alternating e.m.f. upon the dielectric strength of dielectrics. (13) The influence of wave form of alternating e.m.f. upon the sparking distance between needle points in air. (14) The influence of the room temperature upon the temperature elevation of dynamo machines under a given load, as computed from their increase in resistance under load. (15) The distribution of temperature elevation in field coils of dynamo machines, as dependent upon their form and dimensions. (16) The relations between the "load loss" and "short-circuit core loss" of an alternator. (17) the counter-e.m.f. of electrolytic deposition cells at potential differences ranging between the maximum polarization voltage and zero. (18) The seat of the increased counter-e.m.f in storage cells during rapid discharge. (19) The magnetic properties of alloys containing iron, nickel and cobalt. (20) The magnetic retentivity of powerfully twisted iron and steel wires, or of magnets composed of such twisted wires. (21) The permeability of magnetic materials at low values of magnetizing force. (22) The dielectric strength of different substances employed for insulating, at different frequencies of alternation. (23) The influence of very high frequencies of alternation upon the sparking distance between needle points in air (the highest attainable frequencies preferred). (24) The dielectric strength of vapors of different substances. (25) Influence of wave form upon efficiency of rotary converters. (26) The influence of magnetic field upon electrolytically deposited bismuth. (27) The conditions giving rise to sparking at commutators.

An Electrical Paradox.

On other pages of this issue we print a number of communications brought forth by a letter in the preceding issue, describing an apparent electrical paradox. The subject is so thoroughly elucidated in the letters printed, particularly in that of Mr. Carl Hering, that comment is unnecessary. It might be added, however, that the paradox considered, as well as other strange conclusions sometimes arrived at concerning electrical circuits, are due to directing attention to a local part alone of a circuit, and having no eye as to the manner in which the entire circuit, and consequently the current, are affected by a change in any part. It should be borne in mind that the current in a circuit, the e.m.f. and the resistance are bound up together, and that if a change in any one of these factors is made the effect can only be determined by calculations considering all three—that is, the circuit in its entirety.

The Electrical Transmission of Power.

In another column we print a description of the transmission plant at Cañon City, Colo., the article being from the pen of Mr. Ralph D. Mershon, chief engineer of the plant during its construction. This installation has many features of interest, not the least notable of which is that it distributes power generated by steam, the economy lying in the many small units supplied, the intermittent work in most cases, and the fact that otherwise coal taken to the Cripple Creek gold camp would have to be freighted to a high altitude at considerable cost. As the views of the line show, the line construction was of an unusually difficult nature, but here, as in every part of the installation, the work was carried out in the most permanent manner. A novel feature of the installation is the use of a compensator system, which indicates at the station the voltage at the receiving end of the line, taking account of current, power-factor, reactance and resistance, but not employing a pressure wire extending to the receiving end. An account of this system will be found in an article by Mr. Mershon, in our issue of June, 1897.

Decorative Incandescent Lamps.

Since the advent of the electric sign, incandescent lamps have been largely used for decorative purposes, and very frequently at great expense, for many lamps are required to form the necessary designs. Moreover, the wiring and fixtures add to the first cost, while the constant renewal of lamps is no small item. Incandescent lamp manufacturers are always seeking for an attractive novelty and also for a good high-voltage lamp, and it happens that both these two qualities may be very happily combined in a single construction.

The standard practice in lamp filaments has been to shape them in the form of a loop or coil between two adjacent terminals. It does not seem by any means an impossibility to stretch the filament in a straight line in a tube connecting two terminals at either end thereof. The construction is certainly cheap, and practically very feasible. One of the most prolific sources of failure in high voltage lamps is the inability of the filament to retain its shape. It either droops against the glass or, after continued use, springs apart from its own tension. The first lamps were made with straight filaments on the old hack saw plan, simply because it was easier to do this, and the carbon had a longer life; and while the modern lamp is a triumph of expert construction with its long filament in close, compact form, this has been achieved rather at the expense of the life of the filament than otherwise.

The electrician who is using incandescent lamps for decorative purposes would welcome the advent of long straight tubes with terminals at either end, containing straight filaments. Lamp manufacturers can now easily construct lamps of this kind, not only for 220 volts, but even higher voltages. It is difficult to conceive of anything better for lighting show windows or bordering electric signs, or even, with the aid of some curved tubes, for tracing out the contour of letters. There is certainly opportunity here for a novel and long lived lamp, whose use in display illumination will cut down the cost of wiring, the number of connections and section of conductors.

Tesla and His Critics.

We have received from Mr. Nikola Tesla, with a request that it be printed in our columns, a letter containing a personal attack on the editor of one of our electrical contemporaries. Owing to the personalities contained, which form the greater part of the letter, we regret that our editorial policy will not permit us to print the communication in full, and we will therefore only notice such parts as may be considered to have a journalistic or public bearing.

Mr. Tesla accuses our contemporary of having done him an injury by reprinting in its columns a paper read by him before a medical society; and of having cast a shadow on his honor and attacked his honesty in an editorial comment apropos of the said paper. Aside from their personal bearing, these charges involve the right of a journal to reprint matter that has passed out of the hands of a writer and become, through publication, the property of the world at large; and the right to criticise, as a professional journal, public announcements of scientific discoveries pertaining to the profession which it represents.

As to the first charge, our contemporary in answer prints satisfactory evidence that the republication in its columns of the paper in question was authorized by the chairman of the medical society before which it was read. Even in the absence of such authorization, however, it is difficult to see what justification there can be for Mr. Tesla's statement: "By publishing in your columns of Nov. 17 my recent contribution to the Electro-Therapeutic Society, you have finally succeeded * * * in causing me a serious injury." The paper was presented before a national professional body, and, therefore, it is to be presumed, was maturely composed by its author with a knowledge that such presentation constituted publication to the world, and laid the statements contained open for comment or criticism from any source—not even excluding an electrical journal.

As to the second charge, a careful reading of the editorial upon which it is based leaves only the impression that the writer was actuated by a kindly motive in reminding Mr. Tesla of the many unfilled promises he has made to the public in recent years—promises of light without heat, a revolution by means of his "oscillator" in the generation of electrical energy, the transmission of electricity without wires, the destruction of fleets by means of an application of the coherer—to which list might have been added the expulsion of microbes by means of an electrification of the body and other announcements which, with those noted, have earned for Mr. Tesla the popular title of "The Wizard." Surely this constituted a legitimate subject for editorial comment by an electrical journal, and the manner in which the warning was conveyed—that Tesla had arrived at the stage when fulfillment of some of the many promises made had become vitally necessary to his reputation—was not such as to call for a violent attack on his critic.

The truth plainly stated is, that for several years Mr. Tesla has only escaped similar criticism in professional and scientific journals on account of the high esteem in which he is held personally, and through recollection of the magnificent boon he bestowed on the world by the invention early in his career of the polyphased system. The manner in which he has permitted himself to be exploited by the sensational newspaper press has been a source of pain to his friends, and has largely alienated from him the sympathy of the electrical profession. Moreover, his periodical promise of being on the point of accomplishing some wonder that would revolutionize electrical science has had an untoward effect on the electrical industry, for among laymen it has tended to produce the belief that at any moment one of Tesla's great discoveries may materialize and destroy all present investments.

The Efficiency of Small Motors.

In the early days of motor construction the chief aim of manufacturers was to produce a machine that would really run, drive some load and not burn up every few days. In the case of very small motors, what load they would drive or what current they would require and stand were matters usually determined after the machine was built. Efficiency was not considered or even mentioned—the gilt striping on the magnet was infinitely more important. The armature core was of cast-iron, the coils few but not far between, and the magnet yoke had about one-eighth the cross-section of the core. This sort of thing was built in sizes as large as half a h.p. until the clamor for serviceable and moderately efficient motors of 1 h.p. and under resulted in the construction of machines from fan-motor size up, with laminated armature cores and a "real dynamo style of magnet." Efficiencies then rose from a negligible figure to 15 and 20 per cent. The design of both small and medium size machines—up to 10 h.p. capacity—steadily improved up to a few years ago, when the improvement apparently stopped. Since 1894 the efficiency of small motors has remained at about 40 per cent for a ¼ k.w. motor, 50 per cent for 1 k.w., 60 for 3 k.w., and so on.

One reason for this undoubtedly lies in the fact that changes in design are expensive to a factory producing a complete line of machines. In some cases it is simply poor designing that keeps down efficiencies. Among actual instances recently noted of comparatively small changes in design which resulted in material increases in efficiency and satisfactory operation were the following: Increasing the width of the armature teeth and decreasing the number of turns per coil; changing the shape of the pole-shoes and reducing the length of the air-gaps; increasing the area of the magnetic path in the armature core; extending the pole-shoes and decreasing the number of turns per armature coil; increasing the cross-section of the field magnet yokes, and decreasing that of the magnet core, at the same time increasing the depth of the field winding and decreasing its length along the core, so that even less expense for field wire was incurred than before. In no case was the speed increased and in one it was reduced.

Young designers are very frequently hampered by the concentration of effort upon one or two hobbies, to the exclusion or neglect of other equally important features. In all the cases above cited this class of error was prominent. One designer subordinated his ideas to the fact that the saturation of armature teeth produces a "stiff" field, and introduced so much reluctance there that the flux was throttled, the leakage was abnormal and too many armature wires had to be used to keep the speed down; another allowed the fear of sparking to exaggerate the length of the air-gap, not knowing that the simple expedient of saturating one pole-tip was a preferable substitute. Still another endeavored to economize by unduly reducing the cross-section of the magnet yoke in order to compensate for an unnecessarily large core; reversing his reasoning reduced the reluctance and the leakage coefficient, thereby reducing the ampere-turns required on the magnet—as well as the quantity of copper per ampere-turn.

There is no reason that the public will accept for the limitation of motor efficiencies to the figures mentioned above, and the most ignorant (technically) of motor users are rapidly becoming critical regarding the efficiency of small machines. Owners of industrial establishments in which motors are used on meter service, although devoid of the remotest conception of kilowatts, half-load efficiencies and other technicalities, evince lively appreciation of a motor that runs up a bill of $20 a month as against $25 paid for the service demanded by another machine of the same rating. Even among the least educated of power users in New York and other large cities the basis of judgment that is rapidly becoming general is not the cost of the motor, but the amount of energy it is going to waste. The prospective buyer does not thus express his anxiety concerning the meter bills, but that is the technical translation. As the losses in a motor are nearly the same at all loads, and as motors are almost invariably used in a class of industries to the success of which rigid economy of operation is indispensable, the efficiency is a more important matter, particularly in meter districts, than manufacturers appear to realize.

DESIGNS FOR SMALL MOTORS.

ONE HORSE-POWER BIPOLAR MOTOR, WITH DRUM ARMATURE.

BY CECIL P. POOLE.

The accompanying drawings and description will enable anyone with moderate machine-shop facilities to build a 1 h.p. motor to work on a 110-volt or a 220-volt continuous-current circuit. Two types of field magnet are given, the armature and shaft being the same in both cases.

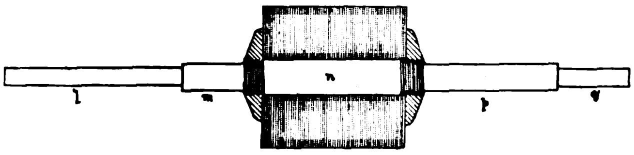

FIG. 1.—ARMATURE CORE AND SHAFT.

The armature is 4 ins. in diameter, outside, with twenty-four slots, each 7/32 in. wide and ⅝ in. deep. Fig. 1 shows the shaft and a cross-sectional view of the armature core. The discs are compressed by two cast-iron end plates, which are screwed on the shaft; these plates are ½ in. thick at the shaft, and taper to 3/16 in. thick at the outer edge, which is rounded as shown, to avoid abrading the insulation between the core and the windings. The full list of armature dimensions is as follows:

	Core, Body.	Heads.	Shaft. at l.	m.	n.	p.	q.
Diameter	4	2¾	½	¾	1"	¾	½
Axial length..	4	½	5	1¾	5"	3¾	2

The discs should have a shallow key-seat in the edge of the central hole, and the shaft should be correspondingly key-seated, and a spline, or perfectly straight key, ¼-in. square, should be used to transmit the movement of the discs to the shaft. If this is done, the slots in the periphery of the discs may be milled out; the armature core must be dismantled after the slots are cut, and the burr which is left by the milling cutter smoothed off. If the key and key-seats are properly fitted the discs will go back on the shaft in precisely the position in which the slots were cut, and the sides of the latter will be smooth. If the key is a loose fit, however, it will be advisable to use a straight edge in one of the slots to insure perfect accuracy in re-assembling the discs. It is scarcely necessary to urge a very careful and close fit of the key and its seats. In assembling the core, one of the cast iron heads should, of course, be screwed to place first; then put on a disc of vulcanized fibre, 1/16 in. thick, 4 ins. in diameter, and next thread on the iron discs. After the last iron disc put on another fibre disc and follow with the end plate or head of cast iron, which will have to be set up with a pin wrench. If the discs are purchased with the slots already stamped out notches will have to be cut in the fibre end discs to correspond with the armature slots; if the slots are to be milled the fibre discs will, of course, be cut along with the iron ones. The latter must be not over 1/32 in. thick and preferably thinner; care should be taken not to get steel discs, but the very best possible grade of charcoal iron.

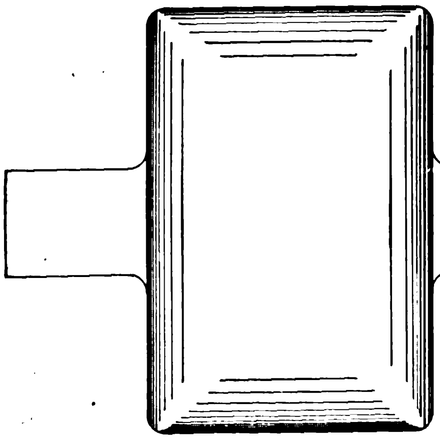

FIG. 2.—PLAN VIEW, IRON-CLAD MAGNET.

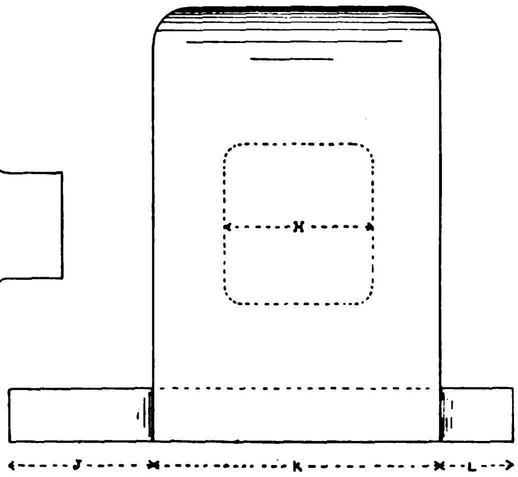

FIG. 3.—END ELEVATION, IRON-CLAD MAGNET.

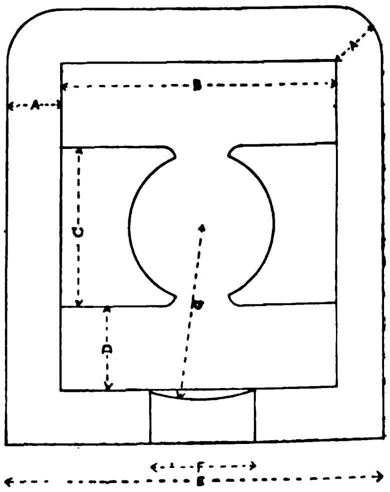

FIG. 4.—SIDE ELEVATION, IRON-CLAD MAGNET.

Of the two types of field magnets shown, the iron-clad is preferable from a constructional standpoint, as the only operations are boring out the armature chamber and the seats for the journal pedestals, and drilling the bolt holes for the latter. Fig. 4 gives a side elevation of the iron-clad magnet, Fig. 3 an end view and Fig. 2 a plan view. The thickness of the magnet core (the portion on which the coils are placed) parallel with the shaft is 4¼ ins. except right at the pole face, where it is rounded down to 4 ins.; this is necessary in order to reduce the flow of magnetism from the pole to the cast-iron end plates of the armature, which produces waste of energy by heating. The complete measurements of the field magnet are as follows:

	Inches
A—Thickness of yoke portion of magnet...	1½
B—Inside length of horizontal part of yoke	8
C—Vertical thickness of magnet core......	4½
D—Distance from core to yoke..............	2⅜
E—Total outside width of magnet frame..	11
F—Width of journal foot..................	8
G—Radius to which journal seat is bored.	4⅞
H—Horizontal thickness of magnet core (see above)	4¼
J—Length of journal foot, commutator side	4⅜
K—Width of magnet yoke or frame, axially	8¼
L—Length of journal foot, pulley side.....	2⅜

The bore of the pole pieces is 4 3/16 in. in diameter, and this figure must be rigidly observed for best results, as all the calculations are based upon this length of air-gaps. The above dimensions are intended to apply to a magnet made of the best grade of cast iron; Scotch pig should be used if it is obtainable, and if not, then the very best grade of soft iron. The casting should be allowed to remain in the mold until it is absolutely cold, care being taken not to remove any of the sand from about the magnet proper. The sand can be scraped away from the extreme end of the longer of the two pedestal feet, so as to enable the molder to ascertain when the casting is cold. It is frequently the case that a casting requires as much as two days to thoroughly cool, but it should not be disturbed before it is cold.

Figs. 5, 6, 7 and 8 give outside and cross-sectional views of the journal pedestal for this magnet; the two pedestals are alike in every particular, and when in position on the projecting feet of the field magnet frame their outer edges should be exactly flush with the ends of the feet. The pedestals are of iron; the base is curved to conform to the arc of the circle to which the upper surface of the foot is machined, and is ⅜ inch thick. The standard consists of two ribs at right angles with each other, each ⅜ in. thick, with their edges curved as shown. The box is of the ring-oiling type, with a single ring hung midway of the journal; the bushing is easily made from thin brass tubing, ¾ in. outside diameter, and with a very thin wall (not over 1/32 in.), babbitted to fit the shaft and having a slot ⅜ in. wide cut half way through it, midway between its ends. This bushing is shown in Fig. 12, which represents the bearing for the other type of magnet, to be presently described. The bushing is 1¾ ins. long; the oil ring is made of brass, one inch in diameter, inside, 1⅛ ins. diameter outside, and ¼ in. wide along the shaft. Reference to the side views of the journal pedestal will show a slot in the upper wall of the box portion, through which the oil ring is inserted before putting in the bushing. A cover should be provided for this slot to keep out dust, etc. The dimensions of the journal pedestals are as follows:

	In.
g—Length of base and journal box	2¼
h—Width of base	3
j—Outer diameter of oil reservoir	2
k—Axial length of reservoir, outside	1¼
Internal diameter of reservoir	2¾
Internal length of reservoir	1

The bore of the box portion of the pedestal must, of course, be made to fit snugly the outer diameter of the tubing used for a bushing, as the wall of the latter is too thin to admit of turning it down to fit a predetermined bore in the pedestal. After boring the pedestal to fit the bushing it should be mounted on a mandrel and its base turned to fit the circle of the foot on the magnet frame, namely, 9¾ ins. in diameter. Each pedestal should be fastened to the foot with two ¼-in. cap screws.

Fig. 9 gives a side elevation of a much lighter magnet, which may be used in connection with the armature above described, if the builder has sufficient skill and facilities to do the machine work accurately. The magnet core is a round piece of wrought iron, 3¼ ins. in diameter, with its ends turned down to 3⅛ ins. diameter for a distance of 4 ins. from each end; the total length of the core is 12¼ ins., so that the length of the untouched portion will be 4¼ ins. The pole pieces are of cast iron, only the very best possible grade being suitable. Where the core enters the cast iron the latter is 4 ins. square, with the corners rounded, and having two ribs or flanges, f, f, running along one edge; these continue clear up to the top of the pole piece, and are 1 in. thick by 2 ins. wide. Fig. 10 shows an end view of the magnet frame, and Fig. 11 a plan view. The hole occupied by the wrought iron core should be cored out to 2⅞ ins. diameter when the casting is made, and afterward bored to a driving fit of the end of the core.

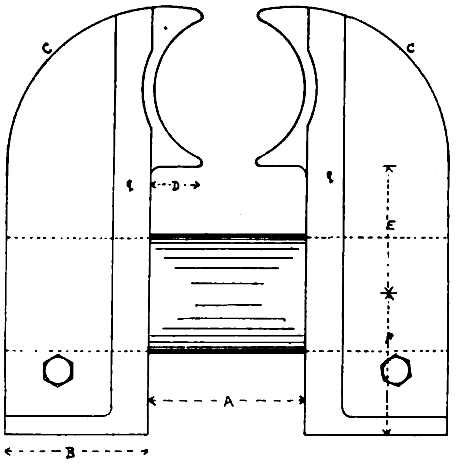

FIG. 9.—SIDE ELEVATION, SINGLE-COIL MAGNET.

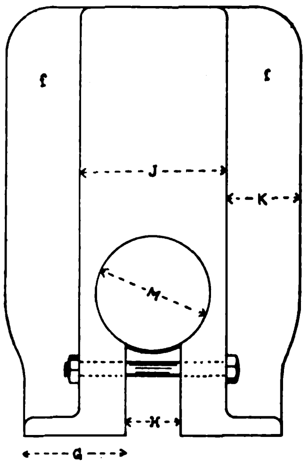

FIG. 10.—END ELEVATION, SINGLE-COIL MAGNET.

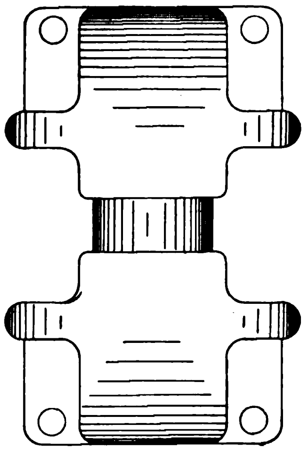

FIG. 11.—PLAN VIEW, SINGLE-COIL MAGNET.

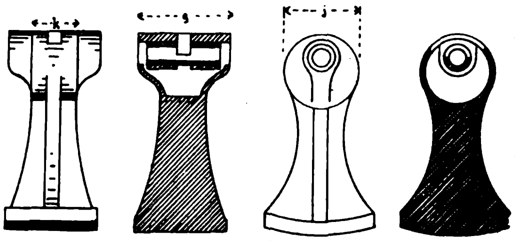
The first operation should be turning off the ends of the core; next, bore the holes in the pole pieces (or, more strictly speaking, the yokes). Then drill a ⅛-in. hole through the yoke just below the lower edge of the big hole and at right angles with it, to accommodate the clamping bolt shown in Fig. 10. Next drive one end of the core into one yoke and set up the nut on the end of the clamping bolt; then put on the other yoke and twist it on the core until the four horns of the pole pieces are exactly opposite each other, tighten up the second clamping bolt, and plane off the bottom surfaces of both yokes. To bring the pole horns into alignment, the simplest method is to cut out two heavy blocks of hard wood, say 3 ins. thick and 3½ ins. square; bore a ½-in. hole through the center of each block, run a ½-in. bolt, 12 ins. long, through the two blocks, and apply them to each side of the pole pieces, the bolt passing through the armature chamber in about the position to be occupied by the shaft. Set up the nut on the bolt until the blocks are hard against all four pole horns, and then tighten up the clamping bolt in the foot of the loose yoke.



FIGS. 5, 6, 7 AND 8.—SIDE AND END ELEVATIONS AND CROSS SECTIONS OF JOURNAL PEDESTAL.

After planing off the feet of the frame, bore out the armature chamber 4 3/16 ins. in diameter, and the seats for the journal yokes (in opposite faces of the side flanges, f, f), 5 ins. in diameter, and then remove one magnet yoke and put on the magnet coil. If the coil is separately wound in a form (which is preferable) only one yoke need come off; if it is wound directly upon the core, both yokes must come off, of course. The base of the machine must be of wood or brass. Wood is better, as, aside from its cheapness, it affords convenient space for the terminal posts and fuse-block of the machine. The base should be 15 ins. x 18 ins., made of two pieces of hard wood each 1½ ins. thick, glued and screwed together with the grains at right angles. The longer dimension of the base is to go parallel with the shaft, and the machine should be so set as to allow the pulley to overhang the edge of the base-board.

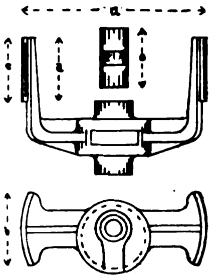


FIG. 12.—JOURNAL YOKE FOR SINGLE-COIL MAGNET.

The pulley should be 4 ins. in diameter and 2 ins. wide on the face; the latter should be crowned. The pulley should preferably be keyed to the shaft, with a set-screw in the pulley hub on top of the key. If only a set-screw be used to hold the pulley on the shaft, a "flat" must be filed on one side of the shaft under the point of the set-screw.

The journal box and yoke for this magnet is shown by Fig. 12. It must be made of brass or some other non-magnetic composition. The design and dimensions of the oil reservoir, journal box and bushing are exactly the same as those given for the journal box of the iron-clad magnet above. All the dimensions are given below, along with those of the magnet last described:

	In.
A—Distance between yokes	4¼
B—Thickness of yoke	4
C—Radius of outer curve of pole-piece	4¼
D—Length of pole horn	1⅝
E—Distance from pole horn to centre of magnet core	3¼
F—Distance from floor line to centre of magnet core	3⅞
G—Width of foot	2¾
H—Width of slot under core hole in yoke	1½
J—Width of yoke	4
K—Width of flange	2
a—Diameter of curve of journal yoke ends and seats	5
b—Vertical width of journal yoke arms	2¼
c—Length of machined portion of yoke arms	1¾
d—Distance from end of yoke arm to inner end of journal box, pulley end of shaft	2
—Distance from end of yoke arm to inner end of journal box; commutator end of shaft	4
e—Length of bushing	1¾
g—Length of journal box	2¼
h—Slot to let in the oil ring	⅜x1¼
j—Outer diameter of oil reservoir	2
Outer length of reservoir, axially	1¼

The windings for the armature and both of the magnets above described will be specified in the next article.

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

PROTECTIVE DEVICES.

In the early days of telephony, the fact discovered by Steinheil, that the earth could be used instead of the return wire of an electric circuit, was made use of, and telephone lines were generally constructed accordingly—that is, with but a single wire, using the earth as the return.

Lines so constructed were, however, soon found to be subject to serious difficulties, chief among which were the strange and unaccountable noises heard in the receiving instruments. There are many causes for such noises, some of which are not entirely understood. The swinging of the wire, in such manner as to cut through the lines of force of the earth's magnetic field, or the sudden shifting of the field itself, causes currents to flow in the line wire which may produce sounds in the receiver. On long grounded lines the variation in the potential of the earth at the ground plates, due to any cause whatever, will cause currents to flow in the line. The passing of clouds or bodies of air charged with electricity will induce charges in the line, and cause currents to flow to or from the earth through the receiving instruments. Electric storms, and auroral displays, apparently greatly heighten these effects. These noises are of varying character, and Mr. J. J. Carty well describes them in saying:

"Sometimes it sounded as though myriads of birds flew twittering by; again, sounds like the rustling of leaves and the croaking of frogs could plainly be heard; at other times the noises resembled the hissing of steam and the boiling of water."

The noises due to these natural phenomena, whatever their true cause may be, are chiefly annoying on long lines, short lines being disturbed only during heavy electrical storms. This is not the case, however, with the noises arising from the proximity of other wires carrying varying currents. Telegraphic signals can be plainly heard in a telephone instrument on a line running parallel with a telegraph line for a very short distance. The establishment of an electric railway, or electric lighting plant in a town using grounded telephone lines, will always cause serious noises in the telephones, and if the lighting current is alternating, the use of the telephones is usually out of the question at night time, while the plant is running.

Disturbances on telephone lines from neighboring wires may be attributed to one or all of the following three causes: Leakage, electro-magnetic induction and electrostatic induction.

Leakage may occur through defective insulation between the two circuits, or even when the insulation of the wires themselves is practically perfect; a heavy return current from a grounded circuit, such as of an electric railway, may, upon its arrival at the grounded end of the telephone line, have the choice of two paths, one through the telephone line, and the other a continuation of its path through the ground. This is the greatest source of trouble due to railway work, or grounded telephone lines. A strange fact in connection with this, is that the noises in the telephones do not correspond with the fluctuations due to the movements of the generator armature, as would be supposed, but to the movements of the armatures on the car motors. The tone in the receiver is an indication of the movements of the car, and variations in speed may be clearly noticed.

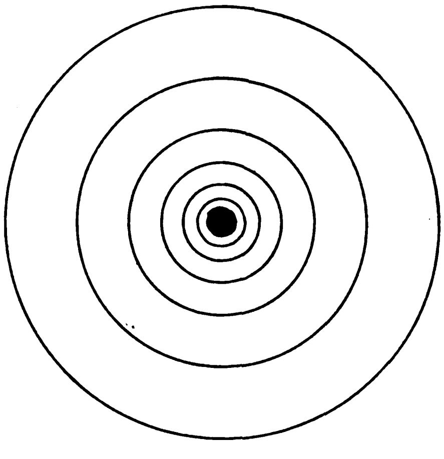

FIG. 1.—MAGNETIC LINES AROUND A CONDUCTOR.

Electro-magnetic induction is due to the fact that the telephone line lies in the field of force set up by the disturbing wire. About every wire carrying a current there is a field of force, or "magnetic whirl," consisting of closed lines of force surrounding the conductors. Such a condition is represented in Fig. 1. If the current is a continuous one, the lines of force will not vary after being once set up, and the telephone wire lying in this field will not be affected. If the current in the disturbing wire is fluctuating, the number of lines of force in this field will vary, or by a clearer way of expressing it, the field of force will expand and contract accordingly. This expansion and contraction of the field will cause its lines of force to cut the telephone wire, and will by the laws of electro-magnetic induction cause currents to flow in the latter. If the current in the disturbing wire is an alternating one, the field of force around it will be established in one direction, destroyed and established in the reverse direction and again destroyed, with every complete cycle of the current. It is easy to see that this will produce a maximum disturbance in the telephone wire.

Electrostatic induction may be explained by reference to Fig. 2, where a grounded telephone line is shown running parallel with a disturbing wire, which we will say is carrying an alternating electric current. The disturbing wire will receive from its source of current alternate positive and negative charges of electricity, and its potential will pass from a maximum in one direction through zero to a maximum in the other, twice during each cycle. Consider the condition where the potential of the disturbing wire is zero. No charge will then be induced on the telephone wire, so that its potential will also be zero. The charge on the disturbing wire then becomes, we will say, positive, and this induces a bound negative charge on the side of the telephone wire nearest the disturbing wire, and an equal positive charge on the opposite side. This latter charge is not bound, and flows to earth through the receivers at each end. This flow will be toward the ground through each receiver and the current is therefore from the center of the wire in each direction to the ground. The next instant the potential of the disturbing wire becomes zero, thus relieving the bound negative charge on the telephone wire, which flows to earth, or, more properly, is neutralized by a flow of positive electricity from the earth. Thus each change in potential of the disturbing wire causes a flow of current through the receivers at each end, this flow always being toward or from the middle point in the length of the wire. These currents produce noises in the receivers at each end in the ordinary way.

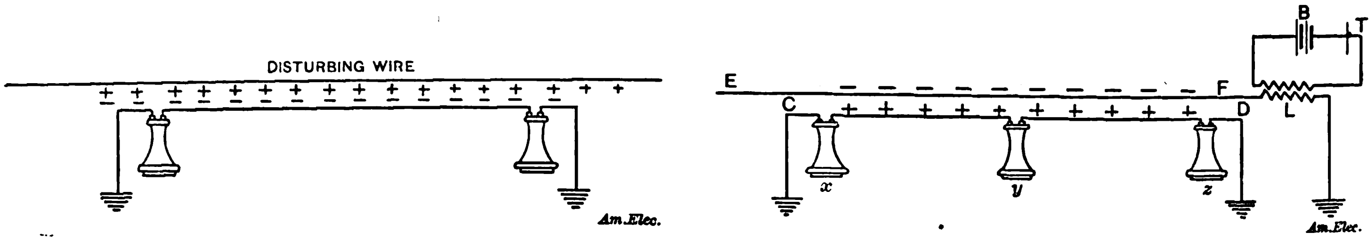

FIG. 2 AND 3.—ILLUSTRATING ELECTROSTATIC INDUCTION.

When two grounded telephone circuits run side by side, each acts inductively on the other, so that a conversation carried on over one circuit may be heard in the telephones on the other. This phenomenon is aptly termed cross-talk, and is usually explained in text books and articles on the subject by the supposition that it is chiefly if not entirely due to electro-magnetic induction.

In 1889, however, Mr. J. J. Carty, in a paper before the New York Electric Club, and again in 1891, in another paper before the American Institute of Electrical Engineers*, described a series of experiments which show conclusively that cross-talk between lines is due almost entirely to electrostatic induction, electro-magnetic induction playing so small a part as not to be noticeable.

The arrangement of circuits in one of his experiments is shown in Fig. 3, in which E F and C D are two well insulated lines, each 200 ft. long, and placed parallel with each other throughout their entire length, at a distance of ⅛ in. apart. E F is the disturbing line and is left open at E. At F it is connected through the secondary of an induction coil, L, with the ground. In the primary circuit of this coil is a battery, B, and a Blake transmitter, T. A tuning fork vibrating before the transmitter acted on the diaphragm in the usual way, and caused impulses on the line E F of practically the same strength as voice currents. These impulses are, of course, alternately positive and negative, and may be considered in the same light as the impulses on the disturbing line in Fig. 2. Three receivers, x, y and z, were placed in the line C D, the receiver y being at the middle point in the line. Upon operating the tuning fork its musical note could be distinctly heard in receivers x and z, while y remained silent.

In explaining the action of static induction in connection with Fig. 2, it was pointed out that the flow of induced currents would be either toward or from the middle point in the length of the wire. The silence of the receiver y in this case bears out that statement, showing the central point to be neutral. If this were electro-magnetic induction the induced current would pass from one end of the line, C D, to the other, returning through the ground, in which case all the receivers would be affected. As it is, however, the induced charges flow in each direction from the receiver y, to the ground at each end, or from the ground at each end to the receiver y, thus in no case causing its diaphragm to vibrate. The same results were obtained by grounding the point E through an ordinary telephone. The receiver wire still remained silent, while x and z were both affected to an equal degree.

It was also found that opening the central point of the line, C D, produced no effect whatever on the existing conditions; the noises in the receivers x and z were plainly heard and of equal loudness.

Many other experiments were tried, the results in each case pointing conclusively to the induction from voice currents being of an electrostatic instead of an electro-magnetic nature.

There is no doubt, however, but that induction from wires carrying heavy currents, such as are used in lighting and power work, is largely due to electro-magnetic effects, and this can be easily proven by experiments similar in nature to those described.

---

* These papers are almost classics and should be read by all interested in this subject.

INTERIOR WIRING.

FEEDERS AND MAINS.

BY CHARLES E. KNOX.

In discussing the feeders and mains in the last article, and also in previous articles, no special mention was made of mains. Inasmuch, however, as a main may be considered as a prolongation of a feeder in the nomenclature we have adopted, what applied to a feeder would, with certain modifications, also apply to a main.

Having discussed the various points to be considered in adopting a system of feeders and mains, let us suppose we have reached a point in laying out the wiring where the branch circuit work is mapped out, the location of the various distributing centers and rising shafts has been decided upon, and there only remains the planning of the arrangement of the feeders and mains.

If the building has more than one story, the first thing to be done is to make an elevation of the building, showing the height and number of stories. On this elevation the various distributing centers should be indicated diagrammatically, but with a view to keeping their relative arrangement as near as possible to their actual arrangement on the different floors.

Having done this, it is necessary to decide two questions (mentioned in last article) before proceeding further. These are, first, whether the hall or public lights will be controlled separately or together with the private lights from the main switchboard, because the settlement of this question will affect the arrangement and the number of the feeders and possibly of the mains. Let us first consider those cases where no distinction is made (so far as the feeders and mains are concerned) between the private and the public lights. The second question to be decided is whether there will be several floors supplied by one feeder, or whether there will be a separate feeder for each floor. We will first assume that there will be a separate feeder for each floor. As these questions were discussed generally in the last article we will not consider them here, except as to the method of procedure in arranging the feeders and mains in the various cases.

It seldom happens that more than one feeder is required for any one floor, but sometimes this may be necessary, as in the case of a hotel where a portion of one floor may be occupied by a ball-room or restaurant, or in a public building in which part of one floor may be devoted to the purpose of a lecture hall or auditorium. In such instances it is generally desired to control these rooms separately. They may then be treated as if they were separate floors.

With our elevation and the floor plans before us, we proceed to mark at each distributing center the number of lights supplied by the branch circuits starting from that center. This being done, a tentative lay-out of the mains running from the feeder center to the various sub-centers should be made.

Having done this, the next step is to find the number of lights supplied by the feeders and the mains. In the case of the feeders this is equal to the sum of all the lights supplied through the distributing centers on the floor, since we are now considering that they are all supplied by one feeder. In the case of a main, the load is, of course, equal to the number of lights supplied through the distributing centers, which are fed either by the main directly or by a prolongation of the main.

Having obtained the load of the feeders and mains, the next step is to get their estimated length. To do this, the horizontal length is first obtained by reference to the floor plans; the vertical length is estimated from the elevation of the building. These give us the apparent length of the feeder, and are accurate enough for the purpose of calculating the "loss" or "drop" and the size of wire. For the purpose of estimating the cost of the feeder, however, it is not sufficient. To get the actual length of the feeder we must try to conceive the exact course or route of the feeder, taking into consideration all deviating bends, off-sets, etc., making allowances or going around or under any obstructions, and also for connecting at each end of the wire. Even after having done this, experience shows that it is necessary to add about 5 per cent for slack, etc., to the estimated length thus obtained, in order to get the real length. If the building is already built, it is much the better plan to get these lengths directly from the building.

Next comes the question of the distribution of the "loss" or "drop" in voltage among the various conductors from the switchboard to the lamp. As this also was discussed in the last article, we will not again consider it.

Having determined on the loss to be allowed in the feeder, we have the three necessary factors for determining the size of wire required for the feeders and mains. These factors are the current in amperes (or the number of lamps), the length in feet (one way), and the loss (in volts) to be allowed. In the third article of this series we deduced the formula for determining the size of wire when these factors were given. The formula is

$$CM = \frac{L \times O \times 10.14}{E}$$

where CM = area in c.m. (size of wire), D = length of circuit (one way), L = number of lamps and E = the loss in volts.

Before calculating the size of the feeders, however, it is well to get the data necessary for calculating the size of mains. This is done in a similar manner to that referred to above in getting the data for the feeders. A preliminary arrangement of the mains has presumably already been made, and the calculation of the feeder and the mains should be made conjunctively, so that if it be found desirable, the loss that was allowed for the feeder may be increased and the loss allowed for the mains correspondingly decreased, or vice versa. It will frequently be found that a new arrangement of the mains will give better results as to size or loss than the original arrangement.

Figs. 1 to 5, inclusive, show arrangements of mains where there is a feeder for each floor and where there are several distributing centers on the floor, all of which are supplied from the feeder center by means of mains. Each of these figures, of course, shows but one floor.

Fig. 1 is an example where the feeder center is located in about the center of the building and supplies two distributing centers on each side of it. This arrangement of mains is ideal. The fuses at the origin of the mains are all located at one point (the feeder center), which simplifies matters when one of the main fuses blows, it being easier to discover the location of that particular fuse if it be known that all the main fuses on the floor are located in one cabinet. This arrangement also gives a uniform potential at each of the four distributing centers. Furthermore, where there is a considerable number of lamps supplied at the various centers, it keeps the mains, and consequently the conduits, down to those sizes which can be readily installed in the available space between the beams and the finished floor. Where, however, there are only a few lamps supplied at each center, it has the disadvantage of being slightly more expensive than the arrangement shown in Fig. 2. This is a very fair arrangement, and is the one generally adopted where the loads on the mains are light. What disadvantages it has are obvious when compared with the arrangement shown in Fig. 1.

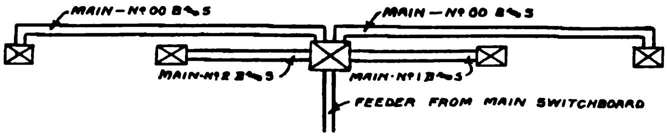

FIG. 1.—LAY-OUT ON ONE FLOOR.

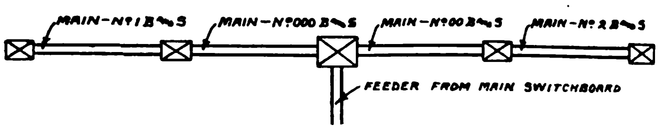

FIG. 2.—LAY-OUT ON ONE FLOOR.

Figs. 3, 4 and 5 show arrangements of mains where the feeder distributing center is located at one end of the building, the other centers being all located on one side of it. Fig. 3 shows a very poor arrangement of mains. Its disadvantage is that, owing to the rule of the Fire Underwriters, it is necessary to place a "fuse at every point where a change is made in the size of the wire (unless the cut-out in the larger wire will protect the smaller)," and consequently to place a number of fuses in "series," located at different points. This always causes delay and confusion in time of "trouble." It is well to keep the number of fuses in "series" down to the lowest possible point, and also to centralize them as far as possible. This arrangement also has the disadvantage of making it difficult to get a uniform distribution of potential at all the distributing centers. Its sole apparent advantage is that of economy.

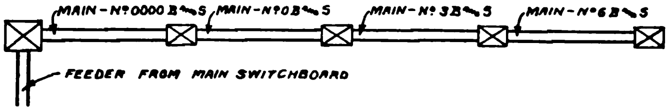

FIG. 3.—LAY-OUT ON ONE FLOOR.

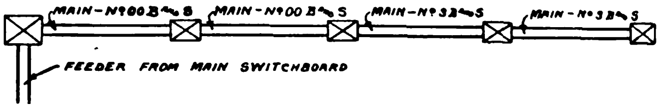

FIG. 4.=LAY-OUT ON ONE FLOOR.

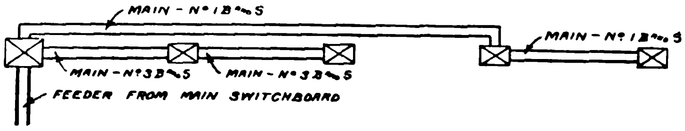

FIG. 5.—LAY-OUT ON ONE FLOOR.

Fig. 4 shows a similar arrangement to that of Fig. 3, but slightly better in that we have only two different sizes of main wires and have, therefore, diminished the number of fuses on the mains just one-half. This method is slightly more expensive, but for the reason given is undoubtedly preferable to the former.

The writer heard recently of a case where a multiplicity of fuses caused considerable annoyance. It happened in an office building, where one floor of the building was rented for a purpose not originally contemplated; some additional wiring and fixtures were installed, making the load considerably beyond that originally carried by the feeder and the mains, but not, however, beyond their safe carrying capacity. The fuses happened to be considerably below the carrying capacity of the wire; when the lights were turned on (at the time, of course, when they were most needed), one of the branch circuit fuses supplying two arc lamps immediately blew. This fuse was replaced and the lamps again turned on. This time a number of lights went out, including the two arc lamps. The branch circuit fuses were found to be all right, but a main fuse had blown. This was replaced, the lamps turned on, and the lights went out again. This time it took a longer time to find what fuse had blown, as the attendant happened to be unfamiliar with the arrangement of the mains and cut-outs, but finally it was found that the fuse on a main of which the main above mentioned was a prolongation, this fuse being located at another distributing center, had blown. This was replaced, and then the feeder fuse blew. It happened that the two arc lamps, in starting, took about 20 amperes, and this was sufficient to blow each fuse successively. The arrangement of the mains and the fuses in this case was unavoidable, but it shows the necessity of reducing the number of fuses in series to the lowest point possible.

Fig. 5 shows an arrangement of mains which is preferable to the arrangement shown in either Fig. 3 or in Fig. 4.

The next case to consider is that where a feeder is not limited to supplying one floor only, but may supply two or more floors. This gives more scope for the arrangement of the feeders and the mains. In such instances there may be several rising places for the feeders; in fact, if suitable rising shafts could be found, a good arrangement would be to have the distributing centers placed near these rising shafts at each floor, with a set of feeders rising at each one of the shafts and feeding several floors at each point by means of vertical mains. Where it is not necessary to control each floor separately, this generally makes the cheapest and best arrangement.

Figs. 6 to 9, inclusive, show different arrangements of feeders and mains of this type (i. e., where a feeder may supply more than one floor). Their relative advantages and disadvantages are evident from what has been already said in regard to the arrangements shown of the first type (see Figs. 1 to 5). Figs. 6 and 7 are examples of cases where there are no horizontal mains at all. This is a good fea-

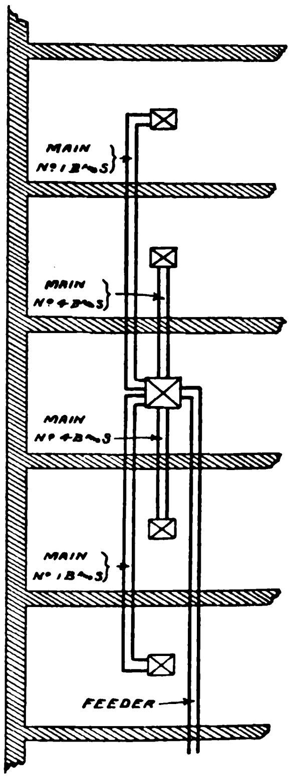

FIG. 6.—VERTICAL MAINS.

ture, particularly where the mains are large, as it keeps large sizes of conduits off the floor. It is nearly always easier to find room vertically for large sizes of conduits than it is to find room for them between the beams and the finished floor. The data for feeders and mains of this type is, of course, procured in a manner exactly similar to that adopted in the previous case.

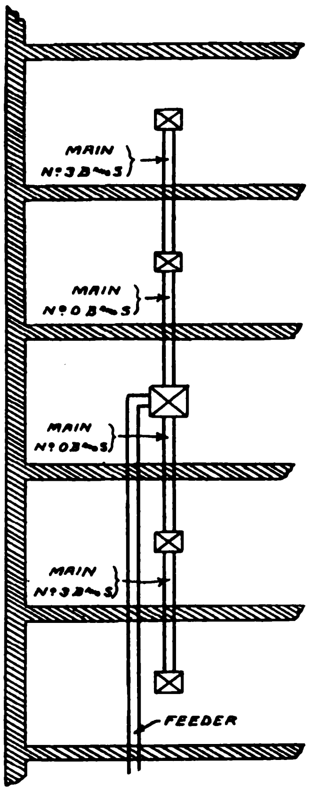

FIG. 7.—VERTICAL MAINS.

The only remaining case to be considered is that in which separate feeders are required for the hall or public lights. What has been said above in regard to the feeding systems in general will also apply, with slight modification, to the hall feeders. The hall feeders, however, usually have much lighter loads, and consequently are smaller in size. It is very rarely necessary or desirable to have a separate feeder for the hall lights on each floor, but one feeder can easily supply the hall lights on several floors. In fact, usually the only limit to the number of floors that may be supplied by one feeder is the refinement of control desired from the main switchboard.

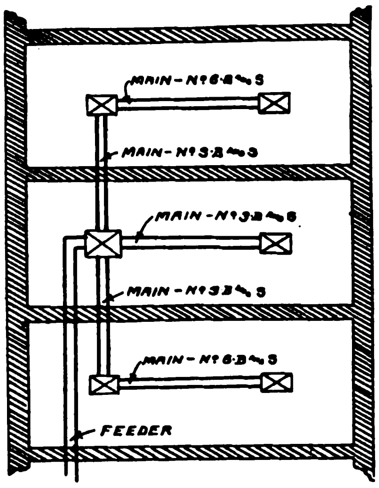

FIG. 8.—COMBINATION MAINS.

We have already mentioned that it is sometimes wise to have two sets of feeders for the hall lights, one set controlling a portion of the hall lights on each floor, the other set controlling the remainder. The character and use of the building and the number of public lights required usually serve as guides for determining or not if this provision is necessary. Of couse, in procuring the data for the feeder and mains of this type the number of hall lights is kept separate from the room lights. Several of the diagrams in the previous article show arrangements of hall feeders.

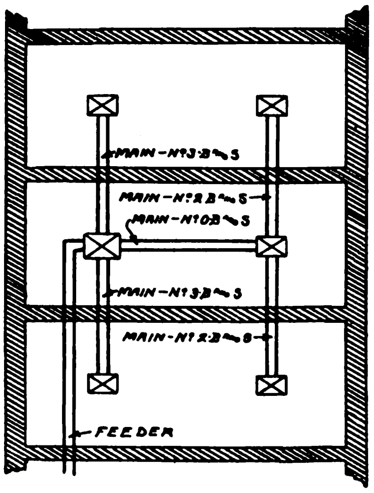

FIG. 9.—COMBINATION MAINS.

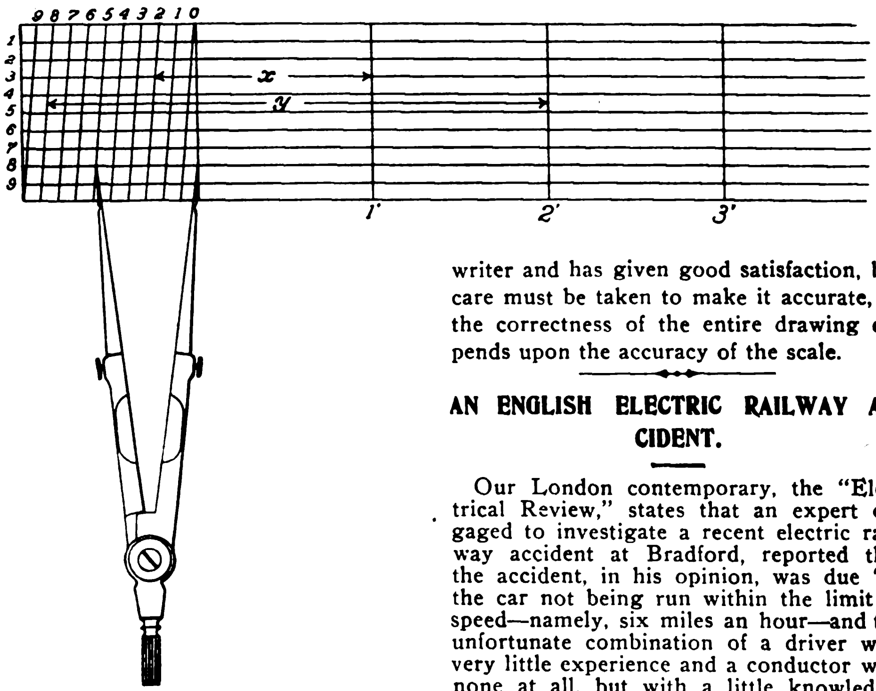
THE DECIMAL DIAGONAL SCALE.

BY ROBERT W. BOARDMAN.

The draughtsman or student is often called upon to make drawings involving the use of measurements to a hundredth or thousandth part of an inch, and as such a scale may not always be at hand, it is the purpose to show here how to construct one in a very short time that will answer the purpose satisfactorily. Construct the scale as shown in the figure by drawing eleven horizontal lines 1-10 of an inch apart; then divide the scale into inches by the vertical lines 0, 1', 2', 3', etc. The division upon the left has the upper and lower lines sub-divided into tenths of an inch. which are then joined by diagonal lines running from each upper tenth to the next consecutive lower tenth.

As each diagonal traverses the ten equal spaces it advances 1-10 of an inch; hence, for one space it advances 1-100 of an inch, and by glancing at the numbers at the side of any particular horizontal line, we have the hundredths in addition to the tenths marked on the top. For example, the dividers are set to read 58-100 of an inch, which is found by glancing along the top and finding that the point of the dividers rests on the fifth line, which gives us $\frac{5}{10}$ in.; then looking at the side we find that it also rests on the eighth horizontal line, which gives us $\frac{8}{100}$ in.; hence, $\frac{5}{10} + \frac{8}{100} = \frac{58}{100}$ of an inch. Distance x in a similar way equals 1 23-100 of an inch, and the distance, y, equals 2.845 in. From the latter it may be seen that by taking measurements between the horizontal lines, distances can be laid off which are correct to a thousandth part of an inch.

The scale has been frequently used by the writer and has given good satisfaction, but care must be taken to make it accurate, as the correctness of the entire drawing depends upon the accuracy of the scale.



DECIMAL DIAGONAL SCALE.

◆

AN ENGLISH ELECTRIC RAILWAY ACCIDENT.

Our London contemporary, the "Electrical Review," states that an expert engaged to investigate a recent electric railway accident at Bradford, reported that the accident, in his opinion, was due "to the car not being run within the limit of speed—namely, six miles an hour—and the unfortunate combination of a driver with very little experience and a conductor with none at all, but with a little knowledge, which is proverbially a dangerous thing, a slippery road, and extra pressure on traffic due to Barnum's Show. The driver used the brake-power in an injudicious manner, but the conductor put on the hand brake, and thus deprived the driver of full control of the brake power. He also caused the trolley to be disconnected, thus depriving the driver of the power of reversing, which might have prevented the accident!" The expert considers that the brake-power was ample, and that by means of the graduation of the electric brake the speed can be regulated with ease and certainty provided that six miles an hour is not exceeded. He approves the addition of a slipper brake.

STEAM ENGINE PISTONS.—II.

BY JAMES F. HOBART, M. E.

It was found by early engine builders, that unless the piston swept over the end of the cylinder bore there would be a bad ridge left when the piston terminated its stroke. To permit the piston to sweep into the counter bore, and still reduce clearance to a minimum, and at the same time secure sufficient strength of piston, the latter was made thicker at the middle and chamfered off at the edge, so as not to cover the steam part when the piston is at the end of the stroke. Some engine builders cut a short chamfer in the edge of the piston, and, as described in the November issue, the piston sometimes revolved in the cylinder until the part was covered.

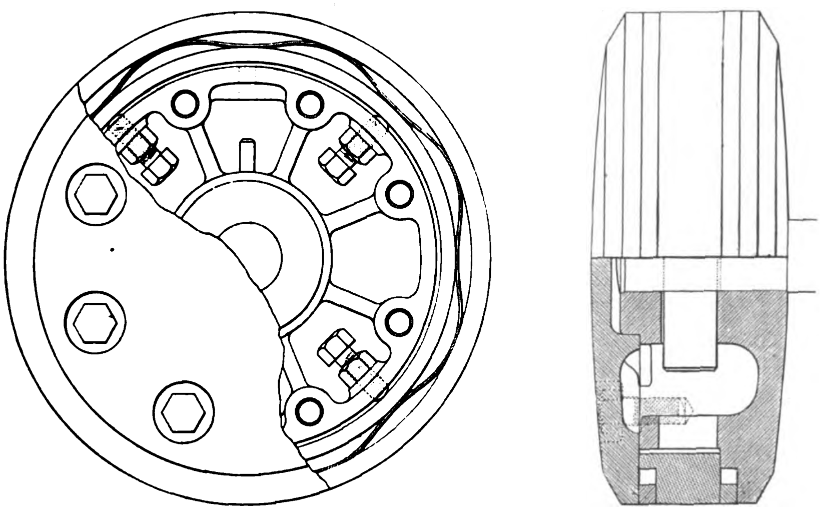


FIG. 1.—CHAMFERED PISTON SPRING PACKING, KEYED ROD.

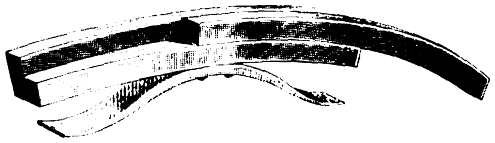

FIG. 3.—SECTION OF PACKING RINGS.

The piston shown by Fig. 1 is free from this defect, as it is chamfered all around, and it makes no difference in what position it is placed in the cylinder. The weight is carried on a central ring, which is adjustable in the usual manner, two packing rings are used, and they are both steam and spring adjusted.

The center ring is given a peculiar shape, the usual custom being to turn this ring somewhat smaller than the bore of the cylinder. In this, however, that portion of the ring which rests on the cylinder is turned to fit. The upper portion of the ring is then turned off, giving the desired clearance. The ring is, therefore, turned "out of round" or on two separate and distinct centers. Full bearing surface below and clearance above are thus secured from the start.

The two packing rings are turned a little smaller than the bore of the cylinder, cut apart and halved together at the joints. Thus they keep in easy contact with the cylinder when in place, but are supplemented by light springs which keep them in contact with the cylinder until worn out. It is claimed that this piston needs no attention whatever, except to center it about every six months.

Some pistons are made of very complex form, especially the packing thereof. The one shown by Figs. 2 and 3 an example.

In this piston double rings are used. Each complete ring is formed of several segments overlapping, as shown in cut, in order to insure steam tight joints. This may be known as sectional packing. This type of packing ring is very satisfactory in pistons of large engines. The section of piston shown at the lower portion of cut shows method of cutting up the double rings, also attaching small springs thereto. The springs are of the very best steel with spring temper, and it is claimed that the sectional packing sets so closely against the cylinder that there is no leakage of steam and no excessive pressure.

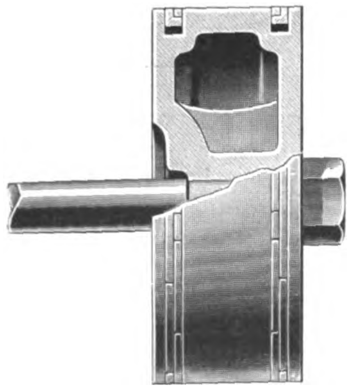

FIG. 2.—SECTIONAL PACKING.

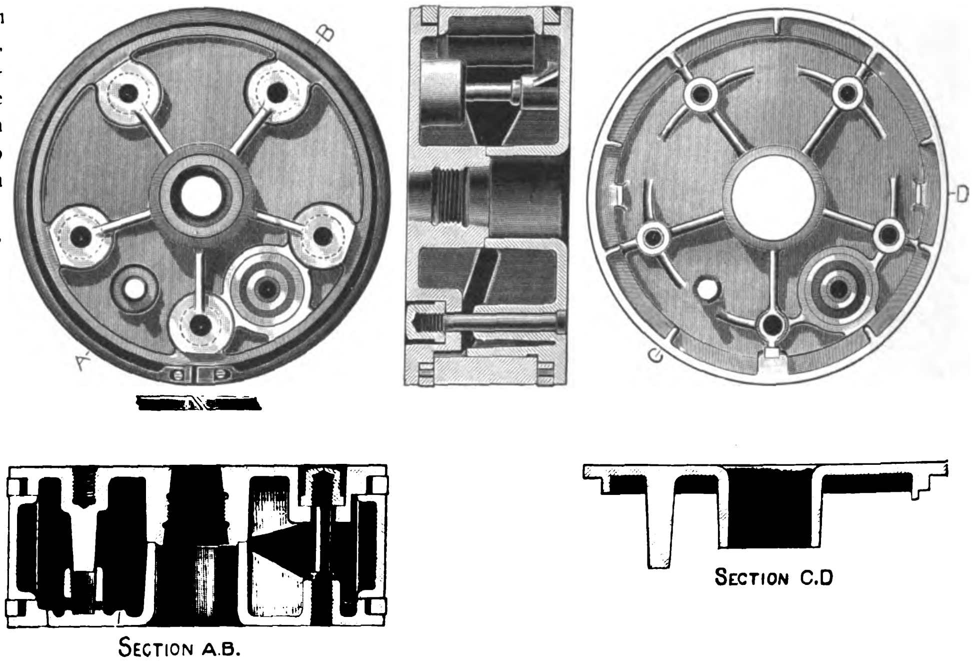

FIG. 4.—"POP PISTON."

Probably no more novel piston exists than the one illustrated by Fig. 4. Here there is a central ring which is independent of the packing rings, and is free to move separately from them. The rings, however, are made fast to the piston itself in a very novel manner. The rings are made much too large for the cylinder, sprung in with considerable force and pinned by dowels passing lengthwise with the piston rod, into the follower and the body of the piston.

Then the rings are turned off to fit the cylinder and the holes in the rings are filed a little so as to allow the rings "limited expansion," from which they take that name.

It is claimed that these rings do not leak, or cut the cylinder, and they run easier than pistons having their rings forced against the surface of the cylinder.

The "pop" feature of this piston is to take care of more water in the cylinder than can be contained in the clearance. To this end a plug of considerable diameter is fitted into each end or side of the piston, under a pressure of 200 lbs. to the square inch. On this pressure will start the plugs and drive them into the space inside the piston.

In case of more water than the clearance can take care of, and this may happen at any time, or never, one of the plugs is driven in by the pressure, which might break the engine if not relieved, the cavity inside the piston is then, by the driving in of the plug, added to the clearance space of the engine and takes care of the water until it can be driven off through the exhaust.

The action above described does not call for an immediate stopping of the engine to replace the plug, for the machine can run indefinitely with only the loss due to the increased clearance. The plugs can be replaced by the engineer, and a device gives notice when they are driven out.

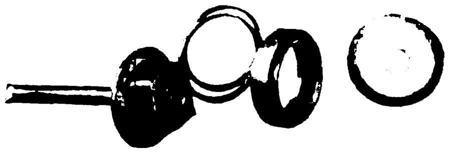

FIG. 5.—PISTON FOR SMALL ENGINES.

An excellent form of piston, having separate adjustable bull ring and follower bolted on, is shown in Fig. 5 for small engines, and Fig. 6, for large engines. The half-tones show the construction well—for which there is claimed great strength and rigidity with light weight, and consequently very little friction and wear, and no leakage.

The piston rods are pressed in by hydraulic pressure and the rods riveted in the smallest sizes; in the larger sizes the pistons are pressed on the rods and then secured by a steel nut. The pistons and rods are finished together after assembling in every case, insuring good and true work.

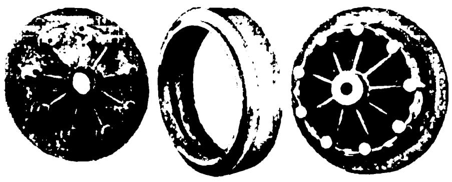

FIG 6.—PISTON FOR LARGE ENGINES.

The pistons used in gas engines are entitled to a word in this connection. They are nearly all of the trunk form, or a modification thereof, and the one shown by Fig. 7, although used also in a steam engine, is a fair sample. This piston carries two snap rings, and in some cases they are made of German silver. That metal is a favorite for steam packing adjustment rings, for the reason that it does not corrode under the trying conditions in which it is used. This piston carries the crosshead pin of the engine, but there is no adjustment there. In fact, there is no need of it in any single acting piston, for the pressure is always in one direction, hence there is no pounding in the crosshead connection.

In some gas engines the crosshead pins are of steel, one-fourth the diameter of the piston, but are made hollow for lightness and are held in place by easily reached adjustable bearings. In one variety of gas engine four cast-iron snap rings are used. In another form are sectional rings set out by German silver springs, which enable the rings to be used until entirely worn out.

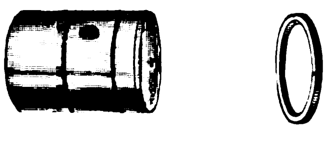

FIG. 7.—SINGLE ACTING PISTON.

ECONOMIC STEAM PRODUCTION.

Economy in the application of steam has been a subject of thorough and intelligent discussion and effort since the days of Watt, the result of which has given us the present excellence in engine design and construction. Doubtless many minor improvements will yet be made, especially in electrical and other secondary apparatus for the application of steam energy to the various commercial uses; but this field in general has been and is being thoroughly exploited.

Steam production, however, as a separate subject, has not received the attention its importance demands. What special attention it has received has come principally from manufacturers and others interested in the introduction of "improved" forms of boilers, heating systems, feed water heaters, economizers and kindred apparatus.

Since the production of steam is so apparently inseparably linked with the production of electricity, it is fitting that this subject be thoroughly and intelligently discussed, and thereby secured such attention to its details as will secure improved methods and appliances.

It is not the purpose of the writer to cover the field in one article, but rather to introduce the subject and follow it up in later issues with definite details, with the hope that other and more competent minds will be interested, thereby securing to the public much needed information relating to new developments and improvements, and including contrasts of different methods and the benefit of personal experiences.

To my mind there appears to be little probability of material improvement, except as to minor details, in boiler construction, but there is room for decided improvement in boiler room practice. There are comparatively few engineers, or even "steam experts," who give any special attention to steam production, except incidentally and as connected with the application or use of steam energy.

As an illustration in this line, about a year since, while visiting a lighting station in one of the cities of the central section of the country, I was shown through the plant by the courteous engineer in charge. While in the boiler room, noting a special form of boiler, with an "improved" furnace attached, I asked about the capacity that could be realized. (The boilers were of 300 h.p. capacity, as rated by the manufacturer.) The engineer replied: "We have taken 625 h.p. from that one on one occasion when in a pinch." I remarked, "You pushed it pretty hard." He replied: "Yes; but we had to do it. She stood it, though, all right, and carried our load for full three hours." A little later, while looking over the engines, he told me they had been tested only two or three days previously, and on my inquiring as to the quantity of water the engines took he said they found they were using 15.2 lbs. of water per i.h.p.

I said nothing to the engineer, but mentally calculated that the load that boiler carried required but little over one-half the h.p. indicated or delivered by the engine, and was therefore, at the time the engineer referred to, when boasting of its wonderful achievement, evaporating not to exceed 320 boiler h.p., or less than 7 per cent above the rated capacity. The engineer was, when talking about the boiler, referring to engine h.p. delivered instead of to the h.p. delivered by the boiler.

That engineer did what a large majority of his profession, and not a few consulting engineers, are constantly doing—made no distinction between boiler h.p. and engine h.p. He had no intelligent conception of steam production as distinguished from steam consumption, and was therefore badly mixed in his account of the performance of his boilers.

The reader will readily see how such confused ideas of conditions and results hinder, when they do not altogether prevent, intelligent practice and improvement. How is a man with such confused ideas to judge intelligently of the utility or value of an "improved" form or make of boiler or furnace or other appliance connected with the steam producing part of a plant?

This incident, while it relates alone to the boiler and furnace, will serve to indicate the necessity for distinct and exact information as to the details of the production of steam, as distinguished from its application. In the next issue I hope to be able to call attention to some of the many details in relation to which increased knowledge and improved practice will result in increased economy.

Lessons in Practical Electricity

HOW TO DESIGN A DYNAMO.

Continuing the calculations of the last section it is to be noted that the armature must be divided into two parts, the teeth and the core proper, for the teeth are fluxed at a different density from that which occurs in the core. The teeth are wedge shape and their average width will be found to be .209 inches. This quantity we multiply by the length of the armature and by the number of teeth a pole subtends, which gives us 32.19, the area of the magnetic path in the teeth. The length is equal to twice the length of the teeth because there are two paths, one on either side of the armature. To find the permeability we must refer to a curve of the magnetization of wrought iron. This curve is shown in Fig. 2, and it may be added that wrought iron is very uniform in its magnetic qualities and almost any permeability curve for wrought iron will do. We have a total flux of 3,095,240 lines passing through 32.19 square inches, a density of 96,000 lines per square inch. From the curve we find the permeability at this density to be 580, and from the formula as shown below we obtain ampere turns necessary to force 2619046 lines through the teeth.

$$\text{amp. turns} = \frac{2 \times .6958 \times 2619046 \times .3132}{32.19 \times 580} = 61$$

The armature itself is an easy calculation. The length of the path must be taken from the drawing of the disc by measuring the length of a line through the path of least reluctance, as shown in Fig. 4. Its area is equal to the armature length multiplied by the thickness of the ring, less the depth of one of the slots. As there are two paths from pole piece to pole piece through the armature of equal length, this area must be doubled. Its permeability from the curve is 1350, and the necessary ampere turns calculated from this data is 103.

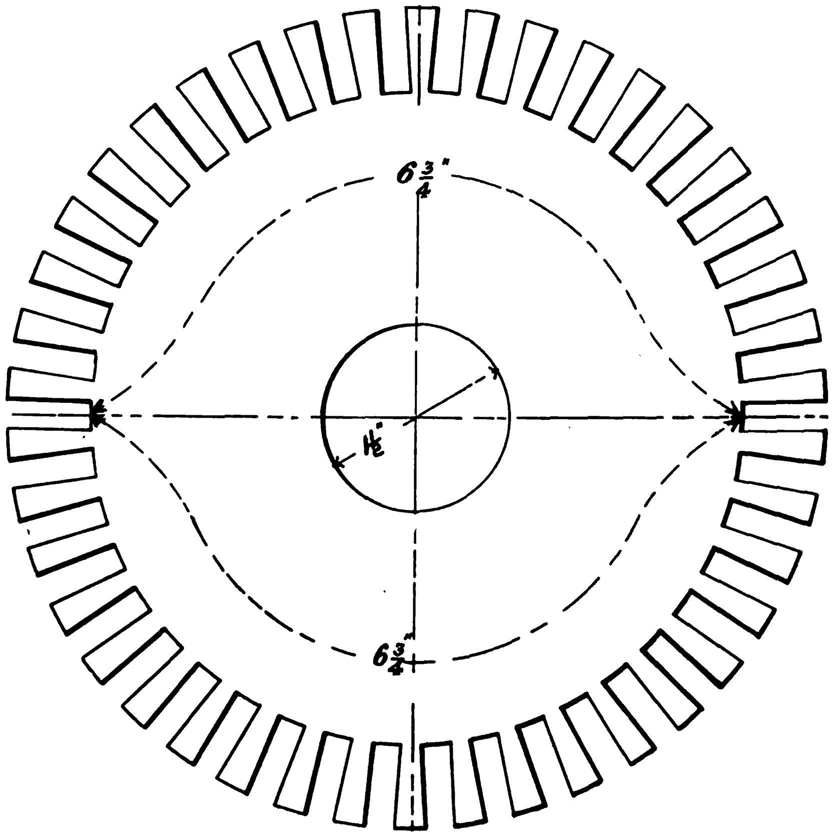

FIG 4.—MAGNETIC PATH THROUGH ARMATURE FROM POLE TO POLE.

We may now summarize the following data:

Ampere turns necessary to force 4,190,474 lines through the field magnets. . . . . =	726
Ampere turns necessary to force 2,619,076 lines throught the gap space. . . . . =	1410
Ampere turns necessary to force 2,619,076 lines through the teeth =	61
Ampere turns necessary to force 2,619,046 lines through the armature core. . . . . =	103
Total ampere turns for shunt coil. . . . . =	2300

Comparing this value with 3792, the ampere turns we estimated, we find that when we have calculated the series coil we shall approach this value and shall have ample room on the field frame as it is.

The shunt bobbin must therefore furnish 2300 ampere turns. We will find the length of a single turn to be 37 ins., and, as previously explained, its resistance must be 125 divided by 2300, 125 being the voltage of the dynamo at the full load. Its resistance per foot is .01765, and the most suitable wire is No. 22 Birmingham gage. It will be noted that the wire chosen is somewhat larger than the actual wire that the formula dictates, for the reason that it is always well to have a margin, for it may be necessary to drive the dynamo a few revolutions slower than the rated speed, or it may be that the permeability of the field magnet is not what curves or experiments have predicted it to be, and furthermore, the conductivity of the wire may be somewhat less than that of pure copper. If the machine should have a slight excess of voltage, that can be taken care of by the rheostat. The object of the calculation is that this excess shall not be so great that it shall cause a large amount of power to be consumed in the rheostat.

On the field magnet we have designed we can allow a space 1¼ ins. deep and 3½ ins. long on which to wind the coil, and on such bobbin we can wind 2726 turns, and as we have two such bobbins we shall have 5452 turns in all. The ampere turns are 2300, from which we may calculate the amperes at .44, and the watts consumed to be 55. The square inches of surface which these bobbins afford for radiation is equal on their sides to 302 square inches. On the ends the actual radiation surface is, of course, 206 ins., but it may be assumed to also include the hole in the center of the bobbin because that is filled by a mass of metal which is capable of conducting away much heat. The total radiating surface may therefore consist of sides 302, ends 430, total 732 ins. The square inches per watt are 13, which is a very large allowance. The bobbin will not even become warm. The temperature that it will attain over and above the surrounding air may be calculated by multiplying the watts by 100 and dividing by the square inches, giving in this case 7.5 degs. F., a figure so low that it is extremely probable that the manufacturer would prefer to shorten his field magnet and wind on less wire, thereby economizing both copper and steel and not greatly affecting the efficiency of the machine. It is probable that the shunt wire could be reduced one-half without involving a serious rise in temperature. This would divide the copper by two and reduce the length of the magnetic circuit nearly 3 ins., and though the field excitation would be increased to about 100 watts, it would still be within 2 per cent of the total output of the machine, and such a change would be advisable. It would be difficult to build such a machine within efficiency much exceeding 85 per cent, and therefore a slight saving of 1 per cent is not worth this extra expenditure of iron and copper. The methods of recalculating are the same as those which have already been shown and need not be discussed further. We shall therefore continue the calculation of the series coil with the field magnet as it is, for to follow the recalculation through its various phases would simply involve arithmetical repetition without imparting any new principles.

Letters on Practical Subjects

Transforming Direct and Alternating Current Motors.

To the Editor of American Electrician:

In a recent number, F. B. D. asks if he can modify a ¼-h.p. direct current motor to furnish an alternating current, presumably single-phase, of 7200 alternations per minute. Having performed a similar experiment some time ago, I would suggest that "F. B. D." will find this a very easy matter, as there is no rewinding necessary.

Simply slip a pair of collecting rings over the commutator, "tapping" these in on diametrically opposite segments, but keeping them insulated from each other and the remaining commutator bars.

Assuming that he has a bipolar machine, it will now be necessary to raise its speed to 3600 r.p.m.—a speed quite safe in so small a machine, provided it is well balanced.

This increase in speed is most easily accomplished, in a shunt motor, by inserting in series with the field an adjustable resistance.

Having adjusted the speed to the desired value by this means, an alternating current of about 2 amperes, at a pressure of about 77 volts, and a periodicity of 7200 alternations, can be drawn from the rings. This would be the maximum output of the machine.

In the same number "T. L. D." asks if he can run a 125-cycle fan on a 60-cycle circuit.

If the motor is of the induction type and has multipolar field of eight poles, its normal speed on the 125 circuit will be about 1800 r.p.m.; while if placed on the 60-cycle circuit, its speed will be only about 900 r.p.m., and it will take more than its normal current, due to decreased reactance on the lower frequency.

Now, by simply reversing the terminals of four of the field coils the poles are reduced to four and the motor will now run at 1800 r.p.m. on the 60 circuit. This makes the speed right, and can be done by starting anywhere on the field ring, reversing two coils in succession, then skipping two and reversing the next two.

If the current is still too much, it can be reduced by inserting a reactance coil. Of course, if the motor has but six poles the above plan of reducing the poles is not applicable.

New York, N. Y.

◆

Connecting Transformers.

To the Editor of American Electrician:

Sir—I have two transformers for 1100 volts each, and I desired to connect them to a 2200-volt circuit. They were not provided with double coils whereby the voltage might be raised by reconnecting them. I decided to connect the primaries in series across the mains. I found that as soon as I loaded one of the secondaries the results were satisfactory, if only a few lamps were put on, but as more lamps were put on the voltage fell, and this occurred before the transformer was loaded to anywhere near its capacity. It then occurred to me to load the other transformer, which I did, and found that as I increased the load the brilliancy of the lamps on the first transformer rose, and that the best results were obtained when the current in both transformer secondaries was equal. I then connected the secondaries in multiple with each other, and found that I could load the circuit thus provided with the combined capacity of both transformers with just as good results as if the primaries were fed from a 1100-volt circuit.

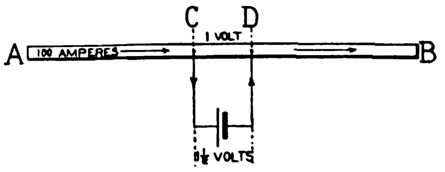
An Electrical Paradox.

A letter by Mr. C. D. Blake, entitled "An Electrical Paradox," which appeared last month in this department, has brought a large number of communications, a selection from which, and of various degrees of merit, are printed below. In order to render the references of the writers clear, the letter which led to the discusion is reprinted immediately following:

To the Editor of American Electrician:

Sir: From the accompanying diagram some very ludicrous conclusions may be drawn on apparently logical grounds. AB represents a feeder of, say, an electric railway system, carrying 1000 amperes. The little distance DC represents a length of this feeder in which the drop of potential is 1 volt. If we apply an e.m.f. of 1½ volts to these terminals, opposed in direction to the direction of the current, we shall reverse the latter, stopping the main current altogether, because it is presumably impossible to have two currents flowing in opposite directions in the same wire. If this is true for the position shown, we can reduce the distance CD to a smaller amount and apply a lesser voltage and the same result will still hold. If all this is true, we can take any battery, however small, and similarly connect in a short section of a feeder carrying a powerful current and stop the latter altogether.



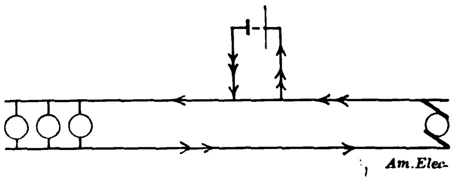
The much mooted question of current in the Brooklyn Bridge cables could thus be very easily solved by the proper application of a few cells of dry battery. The conclusion savors so much of the impossible that, in spite of the apparently logical premises, it cannot be credited; and it has been my experience that the would-be solvers of this problem are either compelled to make astonishing assumptions or quickly argue themselves into difficulties in endeavoring to evade the issue. I submit it on its merits to your readers.

C. D. BLAKE.

New York, N. Y.

To the Editor of American Electrician:

The "Electrical Paradox," as referred to by Mr. Blake in the November number of the "American Electrician," is explained by a glance at the accompanying diagram.



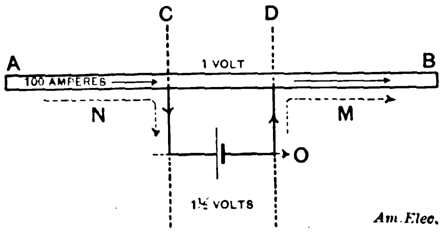
The battery current, instead of flowing in the opposite direction to the current in the feeder, completes its circuit by flowing with the current in feeder through the load, generator and back to battery.

O. H. HUTCHINGS.

Dayton, Ohio.

To the Editor of American Electrician:

Gentlemen: In reference to the letter of C. D. Blake in issue of November, 1898,



I would say that if an e.m.f. of 1½ volts is applied to the terminals CD, opposed to the direction of flow of current in conductor AB, the flow of current in AB is neither stopped nor reversed, but the action of the battery of 1½ volts is to form a better path for the current in the main conductor, and the battery current will assist the flow of main current in the direction of NOM.

T. W. VARLEY.

New York.

To the Editor of American Electrician:

Referring to Mr. Blake's electrical paradox in the current number of the "Electrician," it appears to me that the only thing that would happen would be to increase the fall of potential between the points indicated. In the case that he mentions, instead of there being a fall of 1 volt in a given length of wire by the connecting up of a battery having a voltage of 1½ volts to that length, it would simply increase the fall to 2½ volts. If at a certain point there should be 500 volts and 499 a foot further on, the 1½-volt battery would be struggling against that force and not against the 1-volt drop. Yours truly,

CHARLES HARDING.

Cincinnati, O.

To the Editor American Electrician:

As to the "Electrical Paradox" of Mr. Blake, it seems to me that the confusion arises from a misunderstanding of the method of determining the total e.m.f. As I understand his statement, the drop in potential between C and D is 1 volt; now, by opposing 1½ volts he would merely reduce the applied e.m.f. 1½ volts, as this voltage would act in opposition to the applied e.m.f. and with the drop in potential. That is, the voltage at D would be the voltage at C, minus the drop in potential and minus the 1½ volts. Putting the 1½ volts in opposition to the e.m.f. at C would have the same effect as introducing a resistance which would cause a drop in potential of 1½ volts.

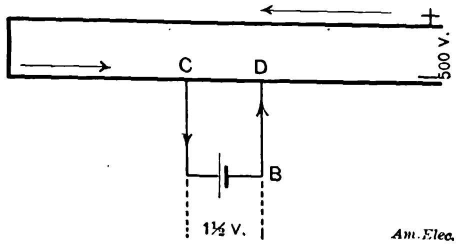
If a dynamo, having the same resistance as CD, were placed between C and D and made to generate electricity at a pressure of 1½ volts and in an opposite direction to that of the applied e.m.f., then our conditions would be similar to those given by Mr. Blake. The dynamo would cause a pressure of 1½ volts between C and D, but this would not stop the current, but would merely make a decrease of 1½ volts in the applied e.m.f.

HORACE SHRADER.

New Orleans, La.

To the Editor of American Electrician:

Referring to the letter of Mr. Blake in your November issue, suppose in the accompanying diagram the total resistance of



the circuit is 5 ohms, and the total current 100 amperes. If CD has 1-100 ohm resistance, it would have a drop in it of 1 volt, that is a counter e.m.f. of 1 volt. That part of circuit shown with heavy lines, and which carries, say, 100 amperes, we will call circuit A. Now, at CD insert a battery of

1½ volts (and call it circuit B), so that its e.m.f. will be in opposition to that of the larger circuit A. Then this 1½ volts will act as counter e.m.f., in CD to current in A, and must be added to the counter e.m.f. produced by the 1-100 ohm resistance of CD, making 2½ volts counter e.m.f. This produces the same result in circuit A as if CD had a resistance of 2½-100 ohms.

Consequently there is no reason for the flow of current from the battery in B through CD stopping or changing the direction of the current in circuit A. All that will be done will be to change the amount of current. Taking the special case above:

$$\frac{\text{500 volts.}}{\text{50 ohms.}} = \text{100 amperes; then adding in the}$$

$$\text{drop caused by battery B, } \frac{\text{500 volts.}}{\text{5.015 ohms.}} =$$

99.709 amperes current.

One might as well try to stop a river's flow by throwing up a 1-ft. dam, on the ground that its fall is ½ ft. in the distance equal to the width of the dam, and that the water would not flow up stream 1 ft. to get over the dam.

S. T. Foster, Jr.

Laredo, Texas.

To the Editor of American Electrician:

The apparent paradox described in the November "American Electrician" is really very easily explained. It can mystify only those of your readers who have failed to thoroughly grasp the distinction in meaning between electromotive force and "difference of potential."

If we take a short section of the feeder referred to by Mr. Blake—a section of, say 15-1000 ohm resistance—it is perfectly true that the current produced by an impressed e.m.f. of 1½ volts will be 100 amperes. It is also true that if this current were to be opposed to the main current the latter would be neutralized. The error lies in supposing that a battery of 1½ volts e.m.f. is necessarily going to maintain a difference of potential of 1½ volts at the terminals of any external resistance to which it may be applied. A large induction coil may generate an e.m.f. of a million volts, but this does not mean that it will send a million-ampere current through a wire of 1 ohm resistance.

But to return to the paradox. Let us assume that we have a dry cell of 1½ volts e.m.f. and ½ ohm internal resistance —which is a low estimate. When we connect this cell to the section of feeder (resistance 15-1000 ohm), we will find that its terminal potential difference has dropped to about 44-1000 volt. If we decrease the length of section and, consequently, its resistance, our potential difference will decrease in a like ratio; until finally, when the resistance of the section becomes zero, the difference of potential at the battery terminals will also be zero, and the current flowing in the battery will be at its maximum. This current is found by dividing the e.m.f. by the internal resistance of the cell; and in the above case it would be exactly 3 amperes.

In short, to maintain a potential difference of 1½ volts under the conditions set forth in the paradox, we would require a battery capable of continuously delivering a current of 100 amperes at that pressure. It is evident that "any battery, however small" might experience some difficulty in meeting this requirement.

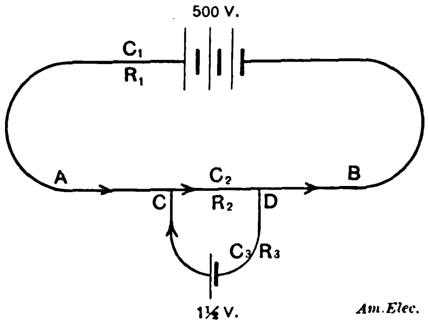
W. B. Hale.

Chicago, Ill.

To the Editor of American Electrician:

Sir: When one comes to look closely into Mr. C. D. Blake's "Electrical Paradox," appearing in the November number of your paper, the apparent absurdities vanish. It is simply a case of derived circuits containing two e.m.fs., and it may be solved by the methods usually applied to similar problems.

Since the e.m.f. of the cell is greater than the p.d. between the points C and D, in Mr. Blake's diagram, the current in the cell will flow in the direction of its e.m.f., and will utilize as part of its circuit the section of the feeder CD, increasing the current in the latter. The increased current produces an increased p.d. between C and D which virtually increases the resistance of CD, as regards the rest of the feeder circuit, and therefore decreases the current in this latter part of the feeder; but the decrease is so small that if Brooklyn Bridge depended for its safety upon the method of protection suggested by Mr. Blake it would be doomed to destruction.



In support of the above, I offer the following proof: In the enclosed diagram, which is the same as Mr. Blake's, except that the feeder circuit is drawn complete, let C_1 be the current in any section of the feeder other than CD; let C_2 be the current in CD, and let C_3 be the current flowing through the cell; further, let R_1, R_2 and R_3 be the resistances of these different parts of the circuit. Then, assuming that the feeder e.m.f. is 500 volts, and applying Kirchhoff's laws:

$$C_2 = C_1 + C_3,$$
$$C_1 R_1 + C_2 R_2 = 500$$
$$\text{and } C_1 R_1 - C_3 R_3 = 500 - 1.5.$$

Now, according to the conditions of the problem, before the cell is connected to the feeder,

$$R_2 = \frac{1}{1000} = .001 \text{ ohm.}$$

$$R_1 = \frac{500}{1000} - \frac{1}{1000} = .499 \text{ ohm.}$$

and let $R_3 = .3$ ohm.

Substituting these known values in the above equations, and solving, the following is obtained:

$$C_1 = 999.99667 \text{ amp.}$$
$$C_2 = 1001.66167 \text{ amp.}$$
$$\text{and } C_3 = 1.665 \text{ amp.}$$

The analogy between the electric current and the flow of water in pipes, so often used, may be very happily applied in this instance.

André J. Picolet.

Philadelphia, Pa.

To the Editor of American Electrician:

The communication under this heading in the November issue is of sufficient interest to warrant careful consideration, although it is difficult to conceive how any one other than the talented scientific reporter to some great Sunday New York newspaper can be misled by the argument offered.

Mr. Blake considers the case of a power feeder carrying 1000 amperes and takes a short section of it, between the ends of which is a drop of 1 volt. He says if we apply an e.m.f. of 1½ volts to the terminals of this section, this applied e.m.f. being opposed in direction to that of the 1000 amperes current, we thereby reverse it and "stop the main current altogether."

Mr. Blake points out that if we take a still shorter section the drop, or voltage, between terminals will be correspondingly reduced, and he offers the conclusion that "we can take any battery, however small, and connect in this way with a sufficiently short section of a feeder carrying a powerful current and stop the latter altogether." Mr. Blake evidently does not believe this to be true; but he thinks it requires "astonishing assumptions" to clear up this seeming paradox. In reality, the "astonishing assumptions" have been made by Mr. Blake himself in jumping to his remarkable conclusion.

We are not warranted in assuming any conclusion of an argument directly on the strength of the truth of our premises, but every intermediate step must be in perfect logical sequence and therefore unquestionably true also.

Now, it is, of course, perfectly true that if we take any section of a wire carrying current and apply and maintain at the terminals of this section an e.m.f. equal to the drop due to the original current, but opposed to it in direction, we shall entirely stop the current in this section. (We assume here—and this in no way affects the general question, but merely saves unnecessary complication—that the drop in this section is so little, in comparison with the total voltage of the circuit, as not to appreciably affect the current.) It is not true, however, that a small battery will do for this purpose. In the case of a 1000-ampere current a very large storage battery would be required, and the connections would have to be very much larger than the original feeder, so as to have a much lower resistance.

In such a case, when the battery and connections were so adjusted that no current was passing in the section of feeder, the whole of the 1000-ampere current would pass through the battery instead. (In reality, the total live current would be slightly increased, but, as before stated, we need not now consider this.) If the battery voltage were slightly higher there would be a corresponding reversed current in the feeder section, and this additional current would be added to the 1000 amperes passing through the battery, but would not appear on the main line. When the current was just killed in the section, the latter might be cut without affecting the main line circuit.

Now, in practice these conditions could not be maintained. Imagine the feeder section so bent as to be directly connected to battery terminals. Then, to just kill the current in the section, our battery would have to be just able to give through itself 1000 amperes on dead short circuit. If the battery were any smaller than this, the current in the section would not all be killed, and if it were any larger a reverse current would flow. It is not worth while to consider how large a battery would be necessary, nor how long, or how short, rather, a time it would last.

In the case of Mr. Blake's small battery the voltage (say, 1½ volts) refers only to open circuit, for the external voltage of such a cell falls rapidly as we lower the external resistance and allow current to pass; and so, if we connected such a cell to the section of a large feeder (the resistance of which section in the present case is .001 ohm), the voltage would be infinitesimal, even at first, and would almost immediately disappear.

This paradox is readily solved, then, if we confine ourselves strictly to facts. It serves to illustrate the manner in which the "yellow journal" scientists palm off their imaginations for fact and "educate" a long-suffering public.

Trying to stop a 1000-ampere current in a circuit by means of a dry cell is like trying to take the strain off a 6-inch steel cable by tying a piece of string alongside of it. Well, it may help a little; but, as Josh Billings used to say, "It ain't worth bragging on."

V. C. WYNNE.

Utica, N. Y.

To the Editor of American Electrician:

The solution of the apparent paradox suggested by Mr. C. D. Blake in your November issue is quite simple, and need not involve any "astonishing assumptions" or the evading of the issue. At first sight it may seem puzzling, as it deals with what might be termed a "negative resistance," meaning a resistance which is less than zero; that is, one which not only does not tend to hinder the current, but assists it. A so-called "booster," for instance, might in some respects be considered such a negative resistance. But this term need not be used, as he might call it an "astonishing assumption."

The original line current in Mr. Blake's problem will simply tend to flow through the battery branch of the circuit in preference to flowing through that portion of the line wire which is between the battery connections, and which for convenience we will call A. The line current not only meets with less resistance in the battery branch, but it is even assisted in flowing that way by the battery which is in series with the generator. In other words, the line current will be "boosted" to the extent of 1.5 volts in the battery branch, while it will be checked to the extent of 1 volt in the other branch A. Or it might be said that the battery branch is a negative resistance, while the resistance of A is positive.

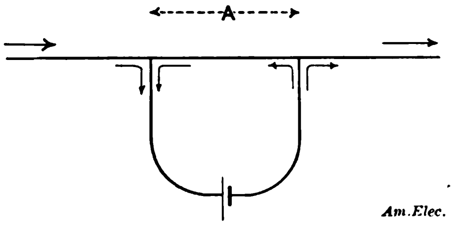


FIG. 1.

The actual results obtained will depend on the nature of the battery. If it does not polarize and has practically no internal resistance, like a very large accumulator for instance, the result will be that all the line current will be deflected from the portion A, will flow through the battery, will be "boosted" by the voltage of the battery and will then flow on through the rest of the line; but none of the original line current will then flow through the branch A; it will be stopped, as Mr. Blake supposes. Not only that, but a reversed current will flow in A, as the battery will discharge itself through it. The accompanying diagram, Fig. 1, shows how the currents will flow in this case. It will be seen that this is nothing more than an accumulator which is being short circuited by A, while it is discharging through the rest of the circuit.

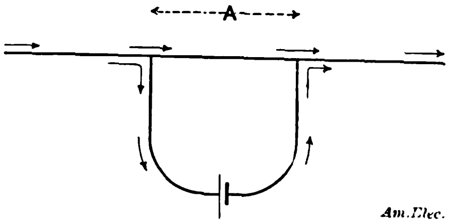

FIG. 2.

But if the battery is small, as compared with the line current, it will merely tend to act like the large battery, as it will soon be polarized by the large current, after which it will simply act like an electrolytic bath which is shunted by the resistance A, the line current flowing through it and through A in parallel and in the same direction. If it is a small accumulator it may tend to be reversed, but if a primary battery, it will take as much current as can be forced through it in the normal direction by the sum of its own voltage, and that at the terminals of the part A. The balance of the original line current will flow through A. This is shown in Fig. 2.

It naturally follows that if with a large battery the current in A is reversed, while with a small battery it is direct, there must be some condition under which there will be no current at all in A. This can readily be shown to be the case when the current in the battery circuit is that which it would give on short circuit, that is, when its effective voltage is zero.

The confusing feature in the problem is that the part A acts like a negative resistance toward the battery, tending not only to short circuit it, but to discharge it through even a less resistance than that of a short circuit. Moreover, the battery current, if the battery is small, will flow through the rest of the circuit and generator, and not through the part A.

If the two battery connections be moved very close together, a point will evidently be reached when there will be two currents flowing in opposite directions in different parts of the same wire. It will then be the equivalent of two independent circuits connected together at practically one point.

The original problem is nothing more than a potentiometer in which the battery is connected in the wrong direction. Or it is like the case of a single cell discharging in series with a large number of others, or in series with a dynamo; if a wire be connected across the terminals of this single cell a current will flow in that wire, either in one direction or the other, depending on the main current and the internal resistance of the cell. Or the curious case may exist of such a wire connecting the terminals of a cell and no current at all flowing through the wire. This will evidently be the case when the volts lost in the internal resistance of the cell are exactly equal to the e.m.f. of the cell (less the polarization, if any).

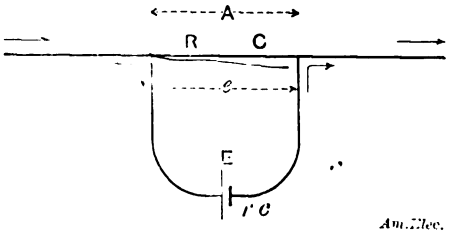

FIG 3.

The algebraic relations are very simple if proper care is taken with the signs. Referring to Fig. 3, let R, C, r and c, represent the resistances and currents in the two branches as shown; let E be the e.m.f. of the battery, and e the difference of potential between the ends of the portion of the feeder A. Then

$$e = C R$$

and

$$e = c r - E$$

The E in this is preceded by the negative sign because, being an e.m.f. or a rise of potential, its algebraic sign must be the opposite to that of a difference of potential like e, which is a fall of potential; it is in the omission of the proper sign that an error is likely to be made. Or, to put this last equation in a different form

$$e + E = c r$$

which means that the loss of voltage in the battery branch, namely c r, is equal to the sum of the true loss of voltage e and the voltage E, which has been added in that circuit; these two equations are evidently the same. Equating these two values of e gives

$$C R = c r - E;$$

from this and the fact that the sum of the two branch currents is equal to the original line current, all the various values can be found.

To illustrate this with an example, the values given by Mr. Blake may be substituted; that is let e = 1, E = 1.5 and assume the internal resistance of the battery with its leads to be 2.5 ohms; then the current in the battery circuit will be found to be 1 ampere; therefore the current in the portion A will be 99 if the original was 100. Dividing the value of E by r gives 0.6 ampere, which is the current which that battery would give on short circuit; this current will be seen to be less than the 1 ampere found above, showing, as was stated above, that the battery would be discharged faster than on short circuit. Substituting 0.6 ampere, 2.5 ohms, and 1.5 volts in the second equation gives e = zero, which shows that there would be no difference of potential at the terminals of the portion A in that case, and therefore no current. The current would therefore be stopped in that portion A if the original line current were only 0.6 ampere.

Carl Hering.

Philadelphia, Pa.

To the Editor of American Electrician:

There is an ancient mathematical riddle by which one is proved equal to two, which seems to me closely analogous to the problem propounded in my letter of November. My experience with such problems has been that the propoundee is first astounded with the absurdity of the result, and then prefacing his reply with a few remarks as to the ignorance of the propounder, proceeds to expose not his own ignorance (for the propounder does him more justice than to assume that he thinks one really equal to two), but his own precipitation. The sober second thought is seldom wrong, and as written communications are usually so composed, most of the foregoing replies are wholly or partly correct, but some of them are wholly or partly wrong.

Referring to the paradox, it is sufficient to say that the battery and the main e. m. f. are in series and the short length of cable constitutes a shunt between them. Current will flow in this shunt in the direction that the difference of potential between its ends dictates, and this depends on the current capacity of the battery and the resistance of its internal and external circuits. If these resistances are sufficiently low and the current capacity correspondingly great, the current in the short section of cable may be stopped or even reversed, the main current flowing through the battery. If, on the other hand, the resistance of the internal and external circuits is high, as would be the case with a small cell, the battery would fail to hold up its voltage and current would flow through it in precisely the same direction as if it were a simple piece of wire connecting the two points. If the points were placed near enough together, it might be possible to have an eddy, or an actual case of currents flowing in opposite directions in the same cable.

C. D. Blake.

New York, N. Y.

Electrical Catechism

253. What is meant by hysteresis?

Hysteresis is a sort of friction between the molecules of iron, or of any other magnetic substance, which causes the magnetization to lag behind the magnetizing current. The result is that when the magnetizing current increases the magnetization of the iron also increases, but when the current decreases the magnetization does not drop off exactly with the current; but for each value of the decreasing current the corresponding magnetization is greater than it was for the same value of the increasing current. This is illustrated in Fig. 1. When the current (or ampere-turns in the coil) increases from zero to a value represented by the length of the base line from O to A, the magnetization of the iron core increases by an amount represented by the ordinate or vertical distance from O to D. In the same way, a current OB causes a magnetization OG, and a current OC causes a magnetization OH. Now as the current becomes less, the magnetization corresponding to a given current is the same as before until the current becomes less than OB, and the resulting magnetism is less than enough to "saturate" the iron. As the current falls below this amount, the magnetism no longer falls off so rapidly as it increased, so that when the current has decreased to OA, the magnetism has only dropped to OF, instead of to OD. When the current drops to zero, some of the magnetism still remains for a time and may have the value of OE or less. The effect of hysteresis in instruments is that such instruments as depend upon the attraction or repulsion of a soft iron core by a coil, do not give the same reading for an increasing current as for a decreasing current except when the core is magnetically saturated.

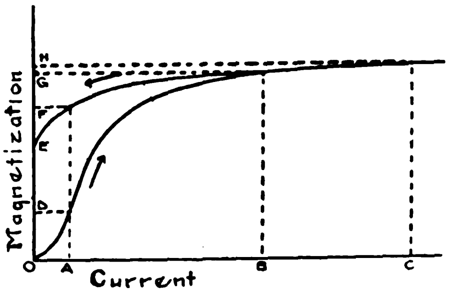

FIG. 1.

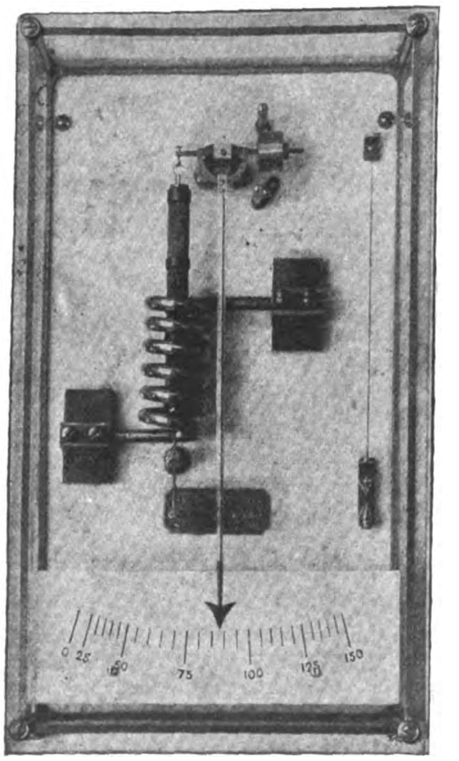

FIG. 2.

254. What instruments are based upon the attraction of a core into a coil?

Familiar examples are the ammeters used with Brush arc dynamos and those formerly sold with Edison dynamos and with Westinghouse alternators. One of the latter is illustrated in Fig. 2, in which the bundle of fine iron wires is seen hung from one end of a sort of balance having a counterweight at the further end and a long pointer hung below.

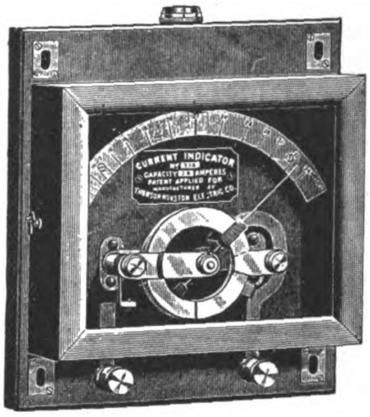

FIG. 3.

255. What is the principle of the eccentric instruments of Thomson-Houston and Fort Wayne companies?

These instruments, illustrated in Fig. 3, have a stirrup of soft iron hung eccentrically in a coil in such a way that the iron stirrup is furthest from the coil when no current is passing; when current passes through the coil, the soft iron strip becomes magnetized; the magnetic lines of force about the coil always tend to take the easiest path; in this case, the easiest path is through the iron strip and the path becomes shorter and easier when the strip is closer to the coil. The attraction between the coil and iron causes the iron to move so as to approach the coil, but it can only approach the coil by turning around on the pivots. The weight is so adjusted as to tend to keep the strip furthest from the coil and thus gravity opposes the attraction of the strip.

Queries and Answers

What are the best glasses to use for arc lamp testing? R. T. K.

A combination of green and yellow glasses.

How may an electric bell be safely installed on an electric light circuit? F. A.

In series with a lamp of the same voltage as that of the circuit. If a large bell, two lamps in parallel series may be required.

Can the winding of an ordinary telephone generator be so connected as to give a continuous current? J. E. R.

No; for a continuous current an armature with a commutator having many segments, would have to be substituted.

1. What is the inside diameter of the ring in the ammeter described on p. 469 of October issue? 2. What is the size of the iron screws, S and S? 3. Will ordinary No. 10 magnet wire be suitable for winding the coils? D. H.

1. 4½ ins. 2. About 1½ ins. long under the head and about a quarter inch diameter. 3. Yes.

I use current from a 107-volt circuit for a dental lamp, and would like to have means for lighting an alcohol lamp from the same circuit. How may this be done? A. R.

Put a 32 c.p. lamp in series with a spark coil, and make and break the circuit between the metal terminals at the wick. The coil can be made by winding a few pounds of No. 14 wire on a core of soft iron wire.

What do the initials S. K. C. on machinery of the Stanley Company signify? R. J. F.

The initials are those of Mr. William Stanley, Jr., founder of the Stanley Electric Manufacturing Company; Mr. John F. Kelley, electrical engineer of the company, and Mr. C. C. Chesney, superintendent of works.

How does a step-up transformer differ from an ordinary transformer? A. D.

Not at all, except in constructional features, due to the very high voltage and large capacity. An ordinary 1000—100 volt transformer would be a 100—1000 volt step-up transformer if its secondary were connected to a 100-volt circuit, the primary then developing 1000 volts.

Can a multipolar permanent magnet be made? If so, what would be the best way to magnetize it? A. C.

The most practicable way to make a mulipolar permanent magnet would be to build it up from a number of ordinary horseshoe magnets, magnetizing the latter by bridging with the legs the field gap of a dynamo.

In what manner does the self-induction of a telephone line counteract the capacity of that line? C. H.

The variable field of force that sets up the capacity effect also sets up an inductive effect, but the e.m.f. of one is opposed to that of the other. Consequently, if the capacity effect, or e.m.f., is the larger, it will be decreased by the amount of the inductive effect, or e.m.f., or vice versa.

How can I restore dry cells to their original power? W. A. M.

Send a current of one or more amperes through the cell, being careful to connect the positive pole of the cell to the positive side of the circuit from which current is derived. If two amperes are used, the cell should be in circuit about thirty hours, and proportionately with other currents. It will scarcely pay to restore dry cells.

Why does moving out the iron coil or shoving in the brass case of a medical coil reduce the strength of the shock? L. N. S.

In the first mentioned case withdrawal of the core reduces the number of lines of force acting on the secondary. In the second case the eddy currents set up in the brass cylinder about the primary set up lines of force that neutralize part of the lines of the primary.

How much current can be carried in a piece of copper ½ in. x 1-32 in. in cross section? L. L.

According to the navy rule of 1000 amperes per square inch the bar would carry 15.6 amperes. Practically, it will carry very much more with safety from overheating, all rules as to carrying capacity referring to inclosed and insulated conductors, and to a rise of but from 15 to 20 degs. in temperature.

I have a 1000-volt alternator which I would like to change to 2000 volts. Could this be done by doubling the speed or changing the connections at the collector rings? E. W. B.

The speed could not be doubled with safety, and unless the armature winding is in multiple it would have to be replaced by wire of double the length and half the cross section. Practically this could not be done, owing to the space that would be required for the extra insulation for 2000 volts.

What is the formula for calculating a tinfoil condenser, paraffined paper being used? F. F. K.

In the following formula A is the area in square feet of one side of the foil; t the thickness of the dielectric in inches; M the capacity in microfarads; K the specific inductive capacity:

$$A = \frac{15.458 \times t \times M}{K}$$

The specific inductive capacity of paraffine is about 2.4, and that of paraffined paper may be assumed to be the same.

I am in charge of three direct-connected compound-wound dynamos running an incandescent circuit and connected in parallel. At full load they give 750 amperes each at 120 volts, or the equivalent of 120 h.p. each. An indicator card shows that two of the engines are developing 156 h.p. each, and a friction shows that each engine develops 15 h. p. running light. This gives 21 h.p. unaccounted for, and I shall be obliged if you will tell me where it goes. J. S.

The loss is in the generator windings and in additional mechanical friction, the latter, however, forming but a small proportion. Such a loss is not excessive, as from the data given the machines work at an efficiency of about 85 per cent at full load.

The capacity of a 7-plate pasted storage cell had dropped from 120 to 30 ampere-hours. The sides of the negative plate facing the positives are rough and covered an eighth of an inch deep with a grayish deposit, though twice cleaned lately. In the bottom of the cell there is a grayish deposit instead of the usual chocolate-colored one. What is the trouble? A. M.

The cell is evidently sulphating, and the process will continue, if not checked, until the cell is dead. The most common cause of sulphating is internal short-circuiting; to remedy, carefully examine if there are flakes of active material or other conducting substance connecting the plates. If this has already been done and the cell does not revive under continuous but moderate overcharging, alternated with light discharging, there is something else the matter. A little common salt, accidentally spilled into the cell, would make it act in the way described, and as battery solution is very cheap and since other deleterious substances may have got into the cell, it would be better to throw out the solution, wash out the jar, rinse off the plates with pure water or battery solution, and refill with solution made from pure acid and water. In the type of cell referred to, the negatives often give out before the positives.

What must be the length of a piece of German silver wire .15 in. in diameter, for a resistance of 200 ohms? J. N.

The resistance of a wire is expressed by the following formula:

$$R = \frac{LK}{D^2}$$

where R is the total resistance of the wire, L is its length in feet, D^2 is the square of the diameter in mils—that is to say, in thousandths of an inch—and K a certain constant which is equal to the resistance of a piece of wire 1 ft. long and 1 mil in diameter, and is known as the specific resistance of the metal. German silver has a specific resistance constant, taking the foot mil as a basis, of 125.9. Applying the formula to the case in hand we have

$$200 = \frac{L \times 125.9}{(150)^2}$$

whence $L = 35{,}742$ ft.

How is the mean spherical c.p. of an electric arc or incandescent lamp taken? J. L.

The spherical c.p. of a lamp is taken by rotating the lamp through equal angles in a number of different vertical planes passing through its center, taking the c.p. at every step. The average of the c.p. at all these angles is the mean spherical c.p.

How is the starting resistance connected to the rotating part of an induction motor? P. T. C.

The starting resistance is connected in series with the winding in which the currents are induced. This may or may not be the rotating part. The induced winding is a closed circuit, but on starting is opened and a resistance inserted in order to prevent the induced currents from attaining too great a value. The resistance is usually cut out by means of a sliding collar on the shaft, which short circuits it.

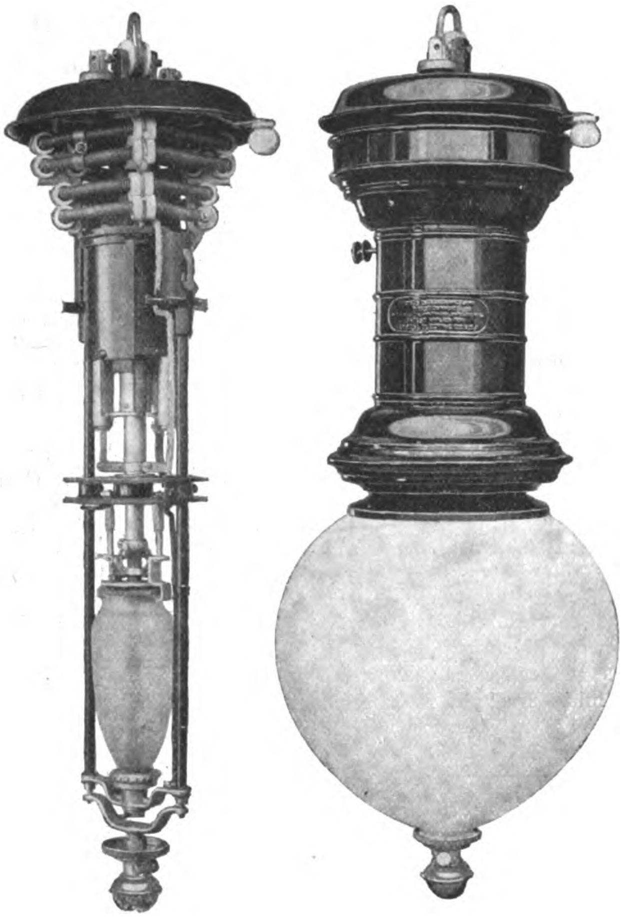
Is the heat radiated from an electric lamp proportional to the watts or to the c.p.? H. K.

Of the energy from an incandescent lamp about 3 per cent. is radiated as light and the remainder as heat. In an arc lamp the efficiency is somewhat better, bearing the ratio of 15 and 85. If the lamp is placed in an enclosed space, the light is ultimately transformed into heat by radiation.

New Apparatus and Appliances

220-VOLT INCLOSED ARC LAMP.

A perfected form of carbon feed arc lamp for direct connection across 220-volt mains is being placed on the market by the General Electric Company. It operates with 150 volts at the arc, takes a normal current of 2.5 amperes, and with one trimming has a life of from 130 to 150 hours, requiring no attention during that time. The carbons are so proportioned that the upper carbon at the end of any run of 130 or 150 hours may be placed in the lower carbon holder for the next run. The light is of less volume and more violet in color than standard 110-volt lamps, but the advantages of a 220-volt lamp capable of independent operation sometimes compensate for the diminution of light, as compared with the 5-ampere lamp for use two in series across 220-volt mains. A variable resistance at the top of the mechanism allows the use of the lamp on circuits of from 210 to 250 volts, and disconnection from the circuit is effected by a quick-break switch applied to each lamp.



INTERIOR AND EXTERIOR OF 220-VOLT ARC LAMP.

The 220-volt lamp is weatherproof, and may be used without a hood. It is especially suitable for lighting vestibules, doorways, window fronts, etc. It may be used with the closed outside globe, as shown in the illustration, or with the single globe and flared reflector. The casings are of several designs, the standard weatherproof casing being finished in black enamel.

ACETYLENE SEARCHLIGHT.

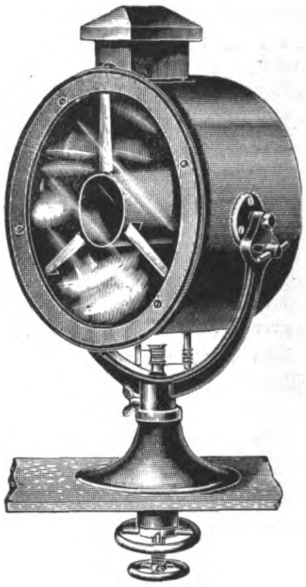
One of the first applications of the wonderful acetylene light to commercial use was in the form of a searchlight. One ½ ft. burner only, with a candle power of about 25, can be manipulated by reflection so as to give an effective beam of over 2000 c. p., the cost of running this being from ½ to 1 cent per hour, according to the quantity of carbide purchased at one time.

The value of this light is thus evident, and for any form of work at night the simplicity of the apparatus, its light weight and small cost render it a great boon to contractors.

While its general uses are too numerous to mention, one of its greatest advantages is when used on small boats for making landings, picking up buoys and running up channels at night.

The cut herewith shows an acetylene searchlight mounted upon a pilot house stand, as intended for the roof of a pilot house. The motion around the vertical axis is given by the large wheel, and the motion around the horizontal axis by the small wheel, the shaft of which passes through the vertical axis.

The gas connection is made through a pipe inside of the shaft of the small wheel and extending below it, with a swinging joint, so that the piping to the generator supplying the gas can be permanent, it thus not being necessary to use rubber tubing inside the pilot house. Some idea of the power of this light can be gained from the fact that objects within a radius of 600 to 1000 ft. away can be distinguished under most favorable conditions.



ACETYLENE GAS SEARCHLIGHT.

Of course, the light can be mounted on other stands than the one shown. There is an adjusting screw at the back for adjusting the light to concentrate the rays of the light or disperse them.

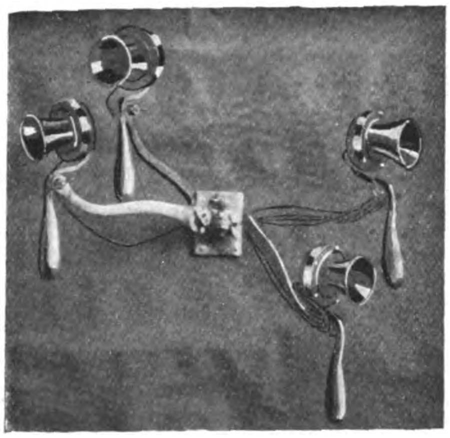
The horizontal cylinder shown inside the searchlight is intended to cut off the direct rays from the burner, which would otherwise spread out too much; when necessary, the cylinder can easily be removed. Two sizes of this light are made—one 14 ins., outside diameter; the other 12 ins., with a deeper reflector. The power of these two sizes is about equal. The small one is best adapted to small boats. Many of these lights are being used on boats in the rivers of the South, as well as on some of the smaller ocean-going vessels.

In the form of a signal light it is used by the United States Government, the flash being obtained by the use of a key which shuts off the gas as required. The key resembles the Morse telegraph key. Experiments at Sandy Hook showed that flashes could be seen for over thirteen miles, and it is reported they have been seen for over thirty miles.

These lights are manufactured by J. B. Colt & Company, 3 West Twenty-ninth Street, New York.

TELEPHONE TRANSMITTER ARM.

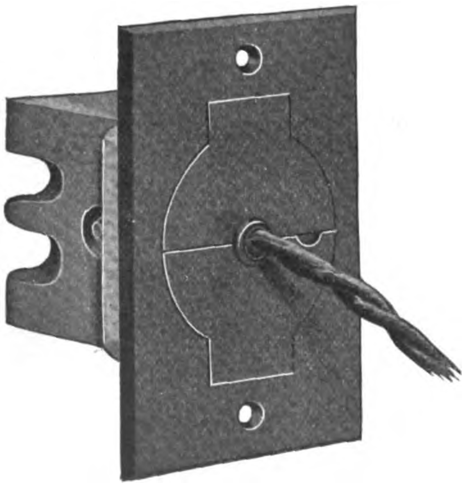
The cut shown herewith illustrates a new telephone arm to which considerable importance is attached, on account of its construction allowing the transmitter to be held constantly in a horizontal position, thereby keeping the carbon in the transmitter always in the same relation to the diaphragm. The old style of telephone arms whenever raised throws the granules back from the diaphragm, and, when lowered, throws them against the diaphragm, thus causing constant disarrangement of the granules and interfering with good transmission. With the arm illustrated above it is claimed that this trouble is obviated. A transmitter used in connection with this arm will never pack, as the constant motion tends to keep the carbon loose and free in the transmitter. This appliance is manufactured by A. Y. Gordon, Massillon, Ohio.



TELEPHONE TRANSMITTER ARM.

FLUSH PLUG RECEPTACLE.

A flush plug receptacle, containing some interesting features, recently placed on the market, is shown in the accompanying illustration. In this type of receptacle the plug, when in place, does not project beyond the face of the receptacle plate, thus avoiding not only unsightliness in appearance, but the constant danger from the plug being struck and damaged. When the plug is in place it is entirely covered by the doors of the receptacle, an extension acting as a bushing and preventing the cords from being cut by the metal doors. Among other advantages claimed for the plug is that it is easily and quickly wired, a large binding post being provided, while the slots and holes in the porcelain are amply large to admit of the wire being slipped in. It has large, well-fitting contacts, which are always under tension, and in the box is a porcelain barrier between points of opposite polarity, thus entirely eliminating possibility of accidental short circuits. This plug is made to fit standard iron boxes, and is manufactured by Zimdars & Hunt, 127 Fifth Avenue, New York.

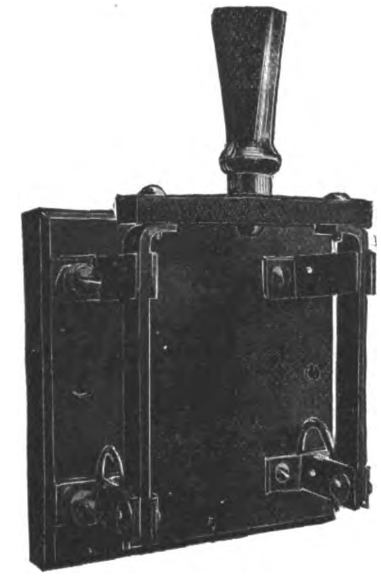


FLUSH RECEPTACLE.

BULL DOG SWITCH.

The switch illustrated herewith, known as the Shawmut Bull Dog switch, was devised to meet the demand for a strong, substantial entrance switch at a low price. It is made to meet the underwriters' requirements, and gives in addition a spring to suit a certain class of customers who prefer this feature. The makers state that to insure a surplus of strength the switch, whose capacity is 25 amperes, is made of 50-ampere stock.

The appearance, as will be seen from the cut, is unusually neat, since the rolled copper shows off to advantage against the handsome Monson slate. The switch described is made by the Shawmut Fuse Wire Company, 93 Federal Street, Boston.



BULL DOG SWITCH.

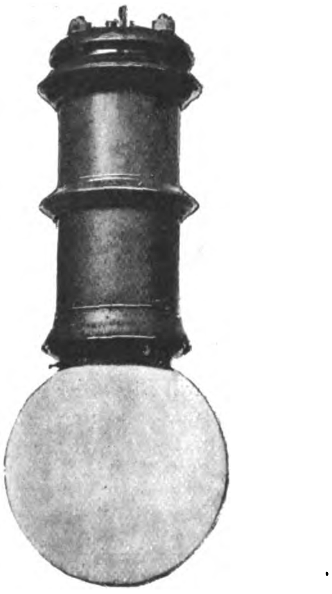
C & C—FORBES GENERATING SETS.

The following illustration shows a C & C generator connected to a Forbes vertical engine of the marine type, which combination is being placed in a number of sizes on the market by the C & C Electric Company of New York, and known as C & C—Forbes sets. The Forbes engine is well built of the best material, and, while of unusual lightness, is yet strong and serviceable. The governor employed is of Rites type, by means of which close regulation is assured. One of the special features of the set is the combined coupling and balance disc or flywheel. Among other features of this engine is its remarkable balance, the engine running so noiselessly as to give no sound audible beyond a short distance. The economy of the engine is unusually high, doubtless due to its very small clearances. The dynamos used in these sets are the well-known C & C open or closed ironclad type, which are particularly adapted for the service for which these sets are intended. The sets are produced in various capacities ranging from 2½ to 17 k.w.

MARINE GENERATING SET.

THE AMERICAN ENCLOSED ARC LAMP.

The accompanying cut illustrates a new type of inclosed arc lamp, known as the "American." The construction throughout has been made substantial, and the mechanism simplified so as to reduce to a minimum the liability to get out of order. The contact is permanent without the use of brushes, and the question of trimming, always an important one in inclosed arc lamps, has in this lamp received special attention. The outer globe can be easily and safely lowered and the inner globe removed when retrimming has to be done. The inner globe is made of heat-resisting and tough glass that will not fracture from any change of temperature.



A NEW ENCLOSED ARC LAMP.

The length of the lamp over all is 29 in., and it is made in japanned iron and brass for outside service. For inside use it is finished in many fancy designs in ornamental brass. The maker is Chas. J. Bogue, 213 Centre Street, New York.

NEW LAKON TRANSFORMERS.

A new type of Lakon transformer is shown in the accompanying illustrations, which show several interesting features. Though of the oil type, the transformers may be used without oil, but the company does not advise its omission.

The method of hanging is shown in Fig.

1, and is extremely simple. The light hanging hook can be held in position and lag screws and bolts put in place by one man, and when the transformer is hoisted to be hung upon the hook it can be swung into position and quickly and easily lowered into the hanging hook.

In order to secure a high all-day efficiency the transformers have been designed for a very low core loss, and good regulation is secured by a symmetrical arrangement of the windings, shown in Figs. 2 and 3, and a liberal use of copper. The primary and secondary cables are brought out on opposite sides of the case through heavy porcelain bushings, and are firmly cemented into the porcelains, thus obviating chafing or wearing away of the insulation where the cables come through the case.

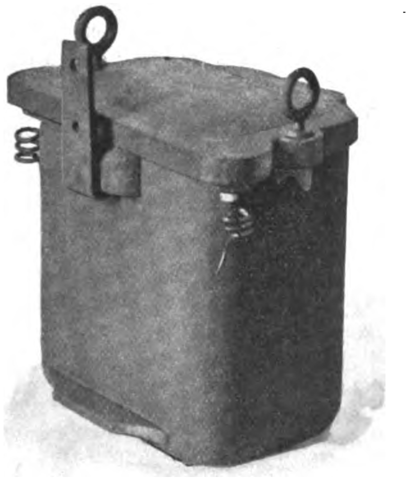


FIG. 1.—LAKON TRANSFORMER.

The aging of iron has been investigated by this company, and they state that they will replace within two years any transformers that will show any marked change in efficiency due to aging of iron. The coils are so arranged that a very large surface of copper is exposed to the oil, thus keeping the temperature down to a low figure.

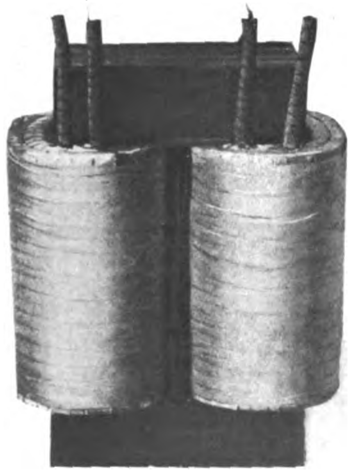

FIG. 2.—LAKON TRANSFORMER.

The transformers are designed to withstand a very high break-down test between primary and secondary and between primary and core, while a very high insulation between primary and secondary is a safeguard against burn-outs from lightning. A transformer cannot be made in which the insulation in itself is enough to withstand the extremely high potential of a lightning discharge, and the company advocates a more general use of lightning arresters. Metallic ground shields are placed in transformers when specified, but the company do not advise the use of them, on account of the increased danger of a puncture in the insulation due to a lightning discharge. The ground shield being connected to earth, affords a free path for lightning, and they believe that the transformer is more liable to be burned out by lightning when ground shields are attached. The ground shield will prevent the lightning discharge from appearing on the secondary circuit, but it is not a protection to the transformer.

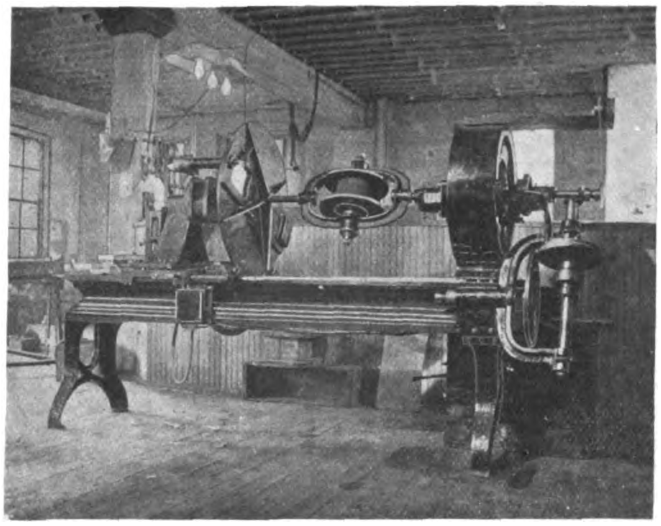
The manufacturers are the Lakon Company, Elkhart, Ind.

COIL WINDING MACHINE.

In these days of close competition every means of reducing cost is of the utmost importance, and this applies particularly to such labor consuming operations as coil winding, if not done by special machinery.

The accompanying illustration is made from a coil winding machine which has been in operation 18 months, doing the work of eight winding machines of another type, which it displaced. It will be seen from the cut the form on which the coil is to be wound is rigidly attached to a frame mounted on a carriage; the carriage is moved forward and backward corresponding to the size of wire and length of form to be wound. The reel from which the wire is taken is placed in a yoke forming part of main shaft, with which it rotates, turning simultaneously on its own axle, and unwinds the wire in proportion as it is placed on the coil. By the introduction of a novel tension device, through which the wire passes before it is laid on the form, the bulging of the wire on a square coil is entirely avoided.

The machine is motor driven, with a controlling device attached to the carriage so as to be within reach of the operator. The reversing mechanism is also operated electrically. The machine is perfectly automatic in all of its movements, registers the number of turns on the coil and reports any defective insulation which may pass through tension device. All adjustments are easily made, and the carriage feed can be adjusted to 0.001 in., so as to insure a solid coil. The makers of the machine are the Jantz & Leist Electric Company, 222 East Ninth Street, Cincinnati, Ohio.



MACHINE FOR WINDING MAGNET COILS.

A SMALL STURTEVANT GENERATING SET.

The "Midget" generating set, illustrated herewith, is probably one of the smallest and most perfectly designed direct-connected machines ever constructed. The photograph is from one of a number recently built by the B. F. Sturtevant Company, of Boston, Mass., for the United States Navy, to be used in torpedo-boat service. The salient features of the design are reliability, low temperature, good regulation, ability to stand continuous overloads, a minimum of attendance, high weight efficiency and great compactness.

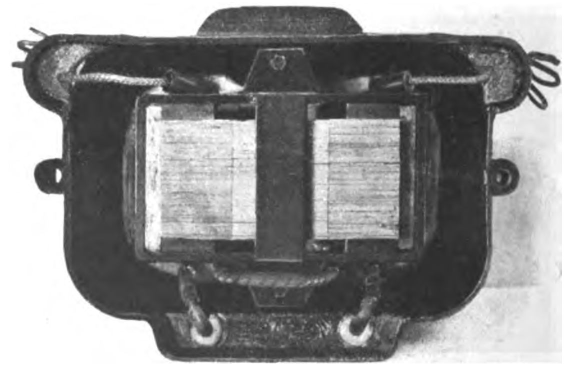


FIG. 3.—LAKON TRANSFORMER.

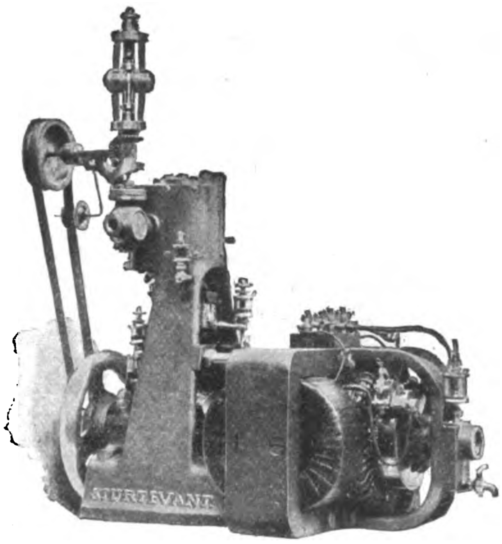
This generating set was designed to be

able to develop its rated output continuously with absolutely no sparking at the brushes and with a temperature rise not to exceed 60 degs. F., while the total weight of the engine and dynamo complete, ready for steam pipe, was limited to 500 lbs. for a rated capacity of 1.5 k.w. The speed adopted was 1000 r.p.m., and as the engine weighed 150 lbs. complete, the weight of the dynamo could not exceed 350 lbs. In the finished design of the generator this weight was reduced to 250 lbs., of which 75 lbs. was the weight of the armature complete, making the total weight of the entire set only 400 lbs.; that is, 100 lbs. within the limit. This brought the weight efficiency of the output complete to 0.266 lbs. per watt output at rated capacity.



SPECIAL MARINE GENERATING SET.

In order to insure a steadiness in running, as well as to economize in head room, the center of gravity was kept as low as possible by the adoption of the consequent-pole type of magnetic circuit, giving a four-pole field, with only two field coils, which coils, being placed on the horizontal pole-pieces, reduce the height of the frame and consequent height of the shaft center to a minimum, and at the same time render a sub-base necessary.

The field magnet consists of a wrought iron forging, to which are bolted the horizontal pole-pieces. The armature is of exceptionally large diameter, in order to facilitate ventilation and present as great a radiating surface as possible.

The core discs are mounted on a brass spider, having a flange support for the armature coils on the back end and an extended sleeve for support of commutator on the front.

The ventilation of the core is facilitated by means of air ducts placed in the center and at each of its ends, which air ducts consist of a series of radial vanes, which, when rotated, act as a centrifugal blower. As the back end of the spider is completely closed and oil proof all the air is drawn through the commutator, which is of skeleton construction and also of very large diameter.

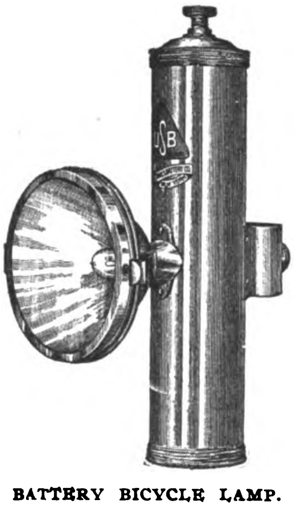
The brush holders are of the reaction type, two only being used, as the armature is of the two-circuit, four-pole, barrel-wound type, without cross connections. The brush yoke is supported by a projection from the out board bearing.

The generator is compound-wound for a constant e.m.f (at constant speed) at all changes of load, from no load to 50 per cent overload, and can stand this variation without sparking at the commutator or any movement of brushes. A continuous overload of 25 per cent. can be carried with safety. The weight efficiency at the rated output is remarkable, considering the amount of overload that can be carried and the low temperature rise.

The engine upon which the effectiveness of the combination depends is of special construction, designed to form a symmetrical part of the whole machine. Its single cylinder is 2 ins. diameter by 2 ins. stroke, all parts are provided with continuous oiling devices, the bearing surfaces are large and carefully finished, and every feature essential to sustained operation at 1000 r.p.m. has been introduced.

ELECTRIC BICYCLE LAMP.

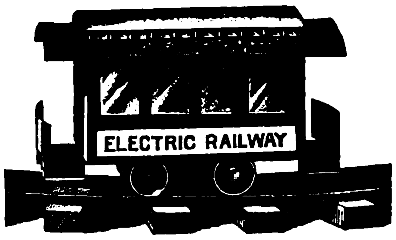
The bicycle lamp outfit shown herewith is actuated by a battery, which, when exhausted, is returned to the makers, or an agent, for restoration, a new battery being supplied in exchange for a small sum. The lamp contains two cells, having the appearance of sealed rubber cylinders, with contact-disc on each end. The mere placing the cells in position in the lamp case makes the necessary electrical connections. To light the lamp it is only necessary to turn the screw at the top. The makers are the United States Battery Company, 256 West Twenty-third Street, New York.



BATTERY BICYCLE LAMP.

TOY ELECTRIC RAILWAY.

With the approach of the holiday season, manufacturers of toys are announcing their 1898 novelties, and among the most interesting of these is an electric railway, shown in the cut. The car is 7 in. long, 4½ in. high, has iron wheels and is made of polished brass. The car runs on a circular track 3 ft. in diameter and of 2-in. gage, made of polished rolled steel, the speed being about 150 ft. per minute. The current is conducted through the rails and wheels of the car to the motor. The battery consists of three zinc-carbon elements, which may be set up by the purchaser in ordinary table glasses, the solution for charging being furnished with the battery elements.

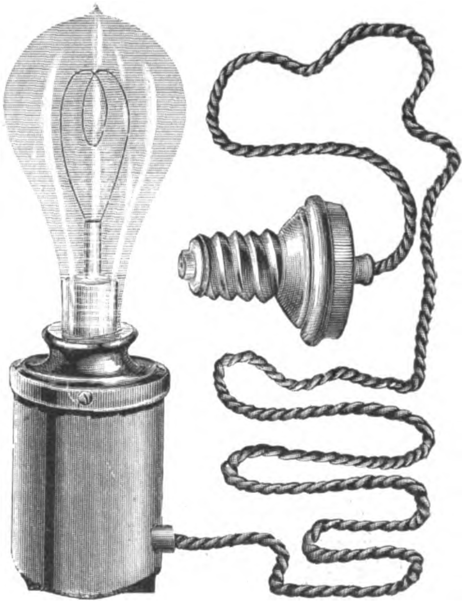


TOY RAILWAY CAR.

This toy is made by the Carlisle & Finch Company, 828 West Sixth Street, Cincinnati, Ohio.

MAGNETIC LAMP HOLDER.

An interesting form of lamp holder is shown in the accompanying illustration, which will be found particularly useful in machine shops, as it can be so placed as to have the light shine exactly where wanted when working with the different kind of tools. Another application is in boiler shops, as the holder can be fixed at any desired position within a boiler. In fact, it will find application wherever a portable light is needed and where iron is present.

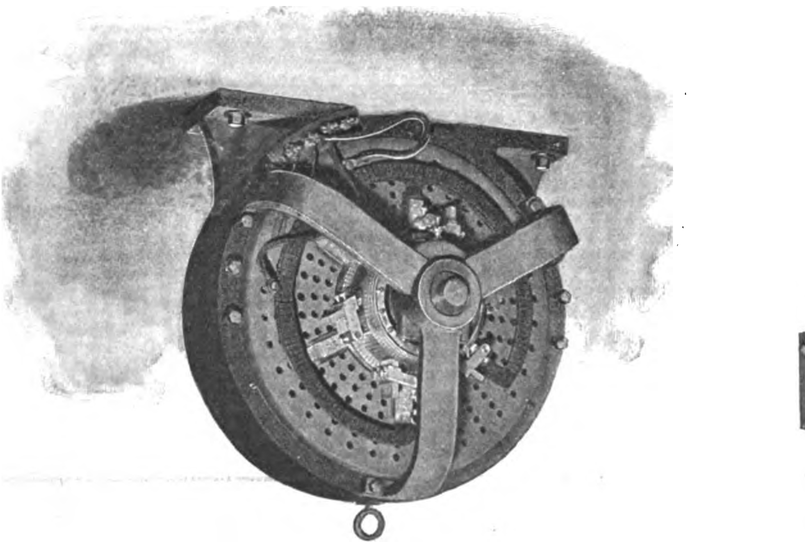


PORTABLE LAMP HOLDER.

The current for the lamp passes through a coil of low resistance, thereby magnetizing the lamp holder and causing it to adhere to any iron surface against which it may be placed. This very useful appliance is made by Jenkins Brothers, New York, the well-known manufacturers of valves and packing.

DIRECT-CONNECTED, CEILING-TYPE MOTOR.

We illustrate below a new motor made especially for direct connection to machine tools, printing presses, line or countershafts, etc., and which is of an exceptionally compact design and constructed for direct attachment at minimum expense. Both armature and pole pieces are of laminated steel. The armature and commutator are mounted on an independent spider, which is bored to fit the shaft of the tool to be driven. Ample room between spider and core is left for ventilation, and radial apertures are provided running from center to circumference for the same purpose. As a result of this construction and the careful design otherwise, the temperature rise of one of these machines tested under ten-hour continuous run, loaded, was less than 10 degs.



CEILING MOTOR FOR DRIVING COUNTER SHAFT DIRECT.

Cast-iron perforated plates are fitted on each side of frame, protecting both the fields and armature, and in special cases the commutator has been similarly protected, although this is not ordinarily necessary. The brushes are of carbon, and are clamped positively in the holder, the construction of which is such that the tension can readily be adjusted. This type of holder is far superior to that of any depending on a sliding contact between the carbon and holder.

The bearings are of bronze, of the ring oiling, self-aligning type, and are carried on three arm spiders attached to the frame, thus making a machine entirely self-contained and very compact. Oil wells of ample capacity are provided. The machine is built inverted as a ceiling motor, for which use a simple and efficient belt tightener is provided.

These machines are made in six sizes, all based on 100 r.p.m., by the Triumph Electric Company, Cincinnati, Ohio.

AN ELECTRICIAN'S DRILL.

The useful tool shown in the accompanying cut is the result of the thought aroused in an inventor after noticing the trouble often encountered by electricians in getting a small wire through a hole after it has been bored in a beam or partition. The tool consists of a twist drill, with several small eyes through the web or center. After the hole is drilled in the wood the end of the wire is inserted in one of the eyes in the drill, the latter is then inserted in the hole, and the wire pulled through from the other side. Several eyes are pierced in the drill, so that if one part should wear or break away another can be used. The manufacturers are the Cleveland Twist Drill Company, of Cleveland, Ohio.

COMBINED DRILL AND WIRE-FISHING TOOL.

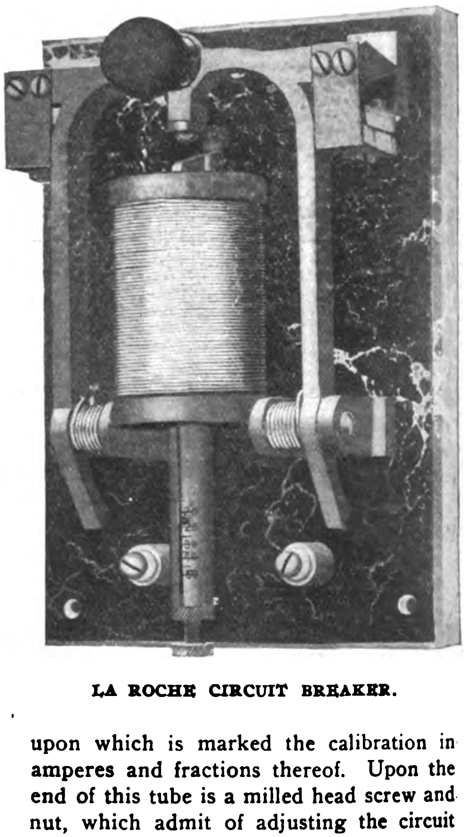
NEW LA ROCHE CIRCUIT BREAKER.

In the new type of circuit breaker, illustrated herewith, the carbons are attached to the breaker parallel to the clips. As the breaker opens, the carbons attached to the blades move with a cam motion, which keeps a rubbing contact on the stationary carbon until the blades are at a safe distance from the clips. The circuit is then finally broken through the carbons and below the clips, thus preventing burning ot the clips or blades.

The blades are of the wedge type and close into "V" shape clips. These are laminated and flexible to an extent that they adapt themselves to the shape of the blades, and absolute tight contact is thereby formed. The latch and trigger are made of case-hardened steel, and are of the compound lever type, so constructed as to permit of a very weak solenoid being used, as the force of the blow required to operate the breaker will be very small. This method of construction is new in this style of instrument.

The hinge posts and blade arms do not carry any current, and it will be noticed, by referring to the cut, that there are two phosphor bronze springs in each hinge. These springs are quite weak, and only sufficiently strong enough to give the switch a quick and sharp break. Owing to the peculiarly shaped blades and clips, it is an impossibility for the circuit breaker to stick, and the construction of the clips tends to throw the blades out by their own action. This breaker would really operate without these springs in the hinge, the springs being there only to assist in quickening the motion.

On the bottom of the lever arms are two projections which are parts of the blade frame, and come in contact with a buffer, so that when the breaker is opened and performing its function the blow on the hinge post is reduced to a minimum. Underneath the solenoid is a copper tube, upon which is marked the calibration in amperes and fractions thereof. Upon the end of this tube is a milled head screw and nut, which admit of adjusting the circuit breaker to open at any desired point within its guaranteed high or low ampere ratings.

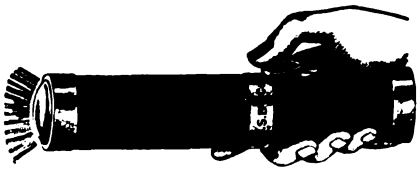


LA ROCHE CIRCUIT BREAKER.

This new type of circuit breaker, which is manufactured by F. A. La Roche & Company, 13th and Hudson Streets, New York, is made in sizes from 15 to 500 amperes.

SAFETY POCKET LIGHT.

The accompanying illustration shows a handy electric flash or emergency light for the use of watchmen, engineers, electricians, miners and others. The makers state that it will give from 6000 to 8000 illuminations before needing recharging. While not intended for prolonged burning, it gives excellent results for emergency uses, as in the examination of machinery, where a flame lamp would be unsatisfactory, or where there is danger of explo-



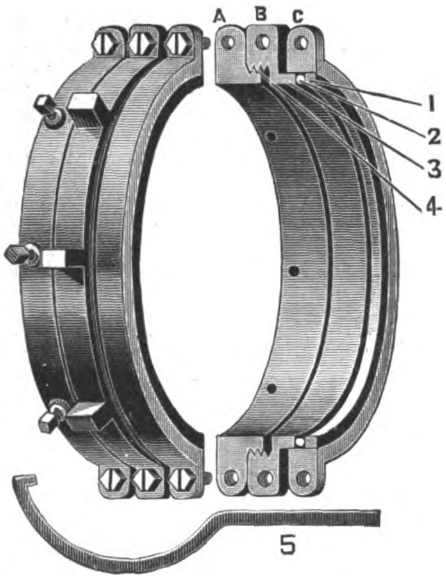
POCKET LAMP AND BATTERY.

sion, as in oil, alcohol or malt tanks, where there is escaping gas, etc.

When used a contact ring is thrown over in contact with the brass band shown, which closes the circuit. The lamp, which is made by James S. Barron & Co., 24 Hudson Street, New York, can be carried in the pocket without danger from chemicals leaking.

STEAM JOINT CLAMP.

The value of a device that will enable a serious leak to be stopped without shutting down a plant or taking down pipes, will be at once evident to the engineer. The clamp shown in the cut herewith has been designed for this purpose, and consists of three separate parts. A rigid clamp, A, with a male thread, is held firmly to the pipe by set screws; a loose clamp, C, which holds the packing and the follower ring; a loose clamp, B, with a female thread and lugs for spanner, which, when screwed away from A, forces with its blank face the packing into the clamp, C, thus making a joint. In the cut packing is designated by 1, the follower by 2, the blank face, B, by 3, and the male and female threads in A and B by 4. As the clamps are made in halves and held together by set screws they can easily be attached to a pipe, and the pipe covering can be replaced over the clamp. The manufacturers, James McCrea & Company, 16 South Canal Street, Chicago, state that a clamp can be attached to a pipe with steam on, in a few minutes.



SECTIONAL CLAMP FOR STEAM JOINTS.

NEW BOOKS.

The Metric System. Hartford: The Hartford Steam Boiler Inspection & Insurance Company. Price, $1.25.

This book was published with a view to facilitating comparisons between the units of the metric system of weights and measures and those of the English and American systems. The book contains an interesting prologue giving a brief history of the metric system, an explanation of the units of the metric and other systems, and a very comprehensive array of tables, giving the equivalent in each system of the units of the other, reductions of values from 1 to 100 in each system to equivalent values in the other system, etc., etc. The tables include linear, square and cubic measures; liquid, dry and energy measures and temperature scales. The volume is of convenient pocket size—3¼ ins. x 5¾ ins.—and substantially bound in red sheepskin.

PERSONALS.

MR. H. L. SHIPPEY, manager of the John A. Roebling's Sons Company, has just returned from a visit to Europe, much refreshed from a sojourn there of several months. Mr. Shippey is a firm believer in the physical benefit of travel, and in various trips has visited most of the places of interest throughout the world.

MR. H. E. RAYMOND, formerly in charge of the polyphase power and transmission plant at Taftville, Conn., has accepted a position from the General Electric Company as its representative at Kingston, Jamaica. Mr. Raymond is one of the few engineers who have had an extended practical experience in the operation of the polyphase system, and in addition is well versed in all of the branches of electrical engineering.

MR. HENRY FLOY and Prof. R. C. Carpenter, of Cornell University, have entered into a partnership as consulting engineers, with offices in the St. Paul Building, New York. Mr. Floy is well known as one of the leading electrical engineers of the country, having occupied a prominent position in that capacity with the Westinghouse Company for a number of years, while Prof. Carpenter has an international reputation as a mechanical engineer. The combination is thus one of unusual strength, and will undoubtedly occupy a very prominent position in the engineering field.

MR. W. HEATHCOTE, engineer of the Replogle Governor Works, at Akron, Ohio, called at the Chicago office of the "American Electrician" while en route to Los Angeles to install a new type of the Replogle governors which are to be used in the Southern California Power Company's plant. Mr. Heathcote reports that his company has been compelled to run overtime for some weeks past in order to keep up with their trade. This company has just shipped large orders of governors to Finland, Italy, Japan, Russia and other foreign countries, which shows the appreciation of engineers in every part of the globe for first-class American apparatus.

TRADE PUBLICATIONS.

DYNAMO BRUSHES. — Non-sparking brushes are fully described in a bulletin that is being distributed by the Western Electric Company, of Chicago and New York.

FEED WATER HEATER.—A handsome wall hanger in three colors is sent us by the Robertson Manufacturing Company, 204 Fulton Street, New York, which very clearly illustrates in three colors the "New World" return copper coil feed water heater.

STORAGE BATTERIES.—The storage battery auxiliary plant of the Commercial Cable Building is described in a circular issued by the Electric Storage Battery Company, Drexel Building, Philadelphia, Pa. Excellent views of the plant are given, and also a diagram showing curves of the regulating effect of storage batteries in isolated plants for office buildings.

THE PATTERSON, GOTTFRIED & HUNTER COMPANY, Limited, New York, has issued a little catalogue which will be of interest to everybody that has to do with machine tools, in which are described engine lathes, turret lathes, sharpers, power presses, milling and grinding machinery. These tools are thoroughly described and illustrated, and dimensional tables are given concerning them.

STEAM SEPARATORS AND OIL ELIMINATORS.—Numerous types of Hoppes separators are illustrated and described in a well-executed catalogue issued by the Hoppes Manufacturing Company, of Springfield, O. These separators are made in vertical and horizontal forms, and for all classes of service. The company calls attention, in a folder accompanying the book, to some exceptionally strong testimonials.

ELEVATING AND CONVEYING MACHINERY.—In a 136-page catalogue, the Aultman Company, of Canton, Ohio, describe their various manufactures, consisting of elevating and conveying machinery, labor-saving appliances, power transmission machinery, sprocket wheels, chains, gears, pulleys, etc. A considerable section of the book is devoted to elevating and conveying machinery, many types of which are well illustrated.

STEAM REGULATING DEVICES AND STEAM PUMPS.—With this title the Mason Regulator Company, 6 Oliver Street, Boston, Mass., have issued a pamphlet containing descriptions of the various Mason apparatus. The descriptions are thorough and clear, in both these respects being above the average of similar matter in trade publications. In fact, as a descriptive treatise on steam appliances, this little pamphlet might be employed with profit as a text-book for engineering students.

PUSH BUTTON SWITCHES.—In an artistically gotten up leaflet the Anchor Electric Company, 71 Federal Street, Boston, illustrates and describes its latest type of push button switch, and also the Anchor snap switch and the Anchor plugs and receptacles, the latter being designed to be placed at several points in a room without disfiguring the walls or floor, and are at all times available for attaching a cord for a lamp for the piano, dining or parlor table, or when a temporary lamp is needed.

POWER PUMPS. — "Efficient Power Pumps" is the title of a handsome new catalogue issued by the Goulds Manufacturing Company, Seneca Falls, N. Y. The catalogue contains, besides illustrations and descriptions of a most comprehensive line of power pumps, triplex and other types, a quantity of valuable information concerning the general operation of pumps, the capacity of pipes and cylinders, friction of water in pipes, etc., which is not usually found outside of the standard engineers' reference books.

A STEAM ENGINE INDICATOR can be built for $2.50, it is stated, by following the instructions and working drawings contained in a new book entitled "How to Build an Indicator," written by A. C. Lippincott and published by the New York Publishing and Model Company, No. 1 Cortlandt Street, New York. That is to say, the materials necessary to the construction of the indicator described in the book may be obtained for $2.50, the labor, of course, not being counted as an item of expense. The price of the book in paper covers is 50 cents; in cloth binding, 75 cents.

A MONTHLY TELEPHONE BULLETIN.—A telephone bulletin, issued on the 15th of each month, has just been inaugurated by the Farr Telephone & Construction Supply Company, of 357 Dearborn Street, Chicago. The first issue of the Bulletin, dated October 15, shows a number of telephones, parts, auxiliary appliances, batteries, etc., which the Farr Company is offering to the trade. The price of each instrument, battery and appurtenance is given also. Although a diversity of styles is shown by the illustrations, the company states positively that none of its products infringe the patent rights of any other manufacturer.

ELECTRICAL MEASURING INSTRUMENTS.—Under this title an attractive catalogue has just been issued by James G. Biddle, of Philadelphia, Pa. The catalogue, which is known as Catalogue B, contains descriptions and illustrations of an extensive line of high-grade laboratory and portable testing instruments of English and American manufacture. Among the makers represented by Mr. Biddle are James White, Glasgow; Elliott Brothers, London; Societé Genevoise, Geneva; the Weston Electrical Instrument Company, Newark, N. J., and Elmer G. Willyoung & Company, Philadelphia, all of whom are well known to the trade as producers of standard measuring instruments and accessories.

THE B. F. STURTEVANT COMPANY, of Boston, Mass., has contributed two catalogues to trade literature which are very interesting. The first, a book of 24 pages, describes its blowers, heaters and ventilating apparatus, and is well illustrated. The second booklet is devoted to the subject of mechanical draft, and its application to the B. F. Sturtevant Company's works. The company states in its catalogue that the addition of the blower has enabled the use of yard screenings costing $2.00 per ton, where heretofore it was necessary to burn Cumberland coal costing $3.65 per ton. The use of mechanical draft in its own plant has enabled the company to do away with a tall brick chimney, which is replaced by a small smokestack, extending only 31 ft. above the boiler room floor.

ELECTRICAL DECORATIONS.—The pioneer in the line of electrical decorative work, the Edison Decorative and Miniature Lamp Department (General Electric Company), Harrison, N. J., is still maintaining the enviable reputation that it long ago established on its extensive line of made-up electrically illuminated devices for show window displays, or for use outdoors for decorative illuminations. These devices are especially in demand for holiday decorations, and have been successfully exhibited in many parts of the country. Their system of renting these devices enables handsome displays to be made at a price vastly below what it would cost to build the same decorations specially for one occasion. This department publishes an illustrated catalogue of decorative devices, in which the fullest details are given as to the sizes and weights of the various pieces, as well as the current consumption, number of lamps, etc. The department also publishes a handsome catalogue of candelabra, series, decorative and other miniature lamps and receptacles, and carries so extensive a line of these goods as to be able to ship many thousands of its standard products at a few hours' notice.

BUSINESS NEWS.

M. DAVIS & SONS, Salem, Ohio, is the style of a new electrical manufacturing firm who have put on the market, among other things, a new switch cut-out and an improved arc lamp mast arm for street service.

THE OTTO GAS ENGINE WORKS, Philadelphia, state that they have been awarded the gold medal at the Omaha Exposition in competition with a number of different makes of gasoline engines.

THE YORKVILLE ELECTRIC CONSTRUCTING COMPANY is a new firm which has just established its offices at 23 Barclay Street, New York City, and is prepared to do a general electrical supply and construction business.

THE G. & E. ELECTRIC COMPANY, Binghamton, N. Y., successors of the Columbia Mfg. Company, of the same city, are manufacturers of dynamos, motors, direct connected elevators, for passenger and freight service; also of the Climax water motor and the G. & E. boring machine.

THE LAVARITE MANUFACTURING COMPANY, New York, is putting on the market a compound for coloring and frosting electric lamp globes, which is claimed to be unusually durable and effective and can be furnished at a very moderate cost. The company's offices are at 21 and 23 Ann Street.

A FOUR-STORY ADDITION, 50 ft. x 120 ft., to its factory is being erected by the Phillips Insulated Wire Company, of Pawtucket, R. I., as well as a one-story annex, 65 ft. x 120 ft., these extensions being rendered necessary to provide facilities adequate to the increase in business enjoyed by the company.

PATRIOTIC DESIGNS IN LAMP SHADES have been perfected by the Phoenix Glass Company, of Pittsburgh and New York City, which include likenesses of Admirals Dewey, Sampson and Schley, etched in the glass. These are made for incandescent lamps, gas fixtures, etc.

THE CHICAGO EDISON COMPANY, 139 Adams Street, Chicago, is offering some bargains in second-hand machinery. This apparatus has been taken from the company's own plants, being displaced by apparatus of greater capacity, and not, it is stated, because of any defect or lack of satisfactory service.

WILLIAM ROCHE, New York City, reports that his new 7 in. x. 3 in. battery cell for gas engine work is meeting with great success in the trade. The cell has been tested by prominent gas engine builders with very good results. Physicians find this an excellent cell for cautery work, where it gives satisfactory results.

THE HARRISBURG FOUNDRY AND MACHINE WORKS, Harrisburg, Pa., is about to let a contract for the erection of a two-story brick and stone building, with ground dimensions of 260 ft. x 140 ft. At present this firm has unfilled orders for more than forty engines, and an increase of facilities has become a necessity.

MR. SEATON M. SCOTT, consulting engineer, with offices at 11 Broadway, New York City, is prepared to make plans and specifications for electric lighting stations and street railway plants, and to supervise the construction of such plants. Mr. Scott also announces that he is prepared to furnish designs for special machinery, and, if desired, to supervise the construction of such machinery.

THE MUELLER ELECTRIC COMPANY has just been organized by Messrs. William Mueller and H. J. Schuette, with headquarters at 713-715 Burling Street, Chicago, Ill. Mr. Mueller, who is already well known in the electrical trades, assures his customers that their orders will receive prompt attention, as the new company has an experienced corps of employees. The Mueller Electric Company has issued a new catalogue of its specialties.

WIRT RHEOSTATS, manufactured by Charles Wirt, of 1028 Filbert Street, Philadelphia, Pa., are in such demand, it is reported, as to necessitate an extension of the manufacturer's floor space and facilities. A feature to which is attributed much of the success of these rheostats is the close graduation obtained by providing an unusually great number of divisions, which is rendered practical by the peculiar construction of the rheostat.

AN EASTERN OFFICE has been established at 205 Postal Telegraph Building, New York City, by the Simplex Telephone Company, of Cincinnati, manufacturer of interior telephones. This office will be in charge of E. L. Harper & Son, who will spare no effort to duplicate in their territory the success attained by the Simplex instruments in the installations already made in the West and elsewhere.

A NEW BATTERY MOTOR has been brought out by the Porter Standard Motor Company, of Lebanon, N. H. It is known as Porter Motor No. 7, and possesses the unusual feature of a six-coil armature and a field magnet similar in type to larger motors designed for use on power circuits. The machine is symmetrical and substantial in appearance and is said to be highly efficient. It requires two cells of the new compound Fuller battery, or any other good type, to operate it.

THAT SOFT COAL can now be burned by the use of suitable stokers without smoking or soot is likely to bring considerable business to the American Stoker Company, of New York City, which has been remarkably successful in its new stoker, as it performs the office of promoting smokeless combustion to perfection. As soon as the public finds that the smoke nuisance can be abated, the ordinances against it will undoubtedly be still more stringently enforced.

THE STEWART ELECTRICAL COMPANY, Cincinnati, Ohio, has been reorganized and is now under the management and proprietorship of Mr. E. W. Mullikin, lately President of the American Laundry Machine Company, and now Treasurer of Campbell Manufacturing Company, of Cincinnati. Mr. Mullikin brings into the company ample capital and a large business experience. Mr. John A. Stewart remains with the company, which bears his name. He is too well known to the electrical trade to need introduction.

ENCLOSED ARC LAMPS appear to be steadily gaining ground, judging from the installations reported by the General Electric Company, among which are 700 lamps placed on alternating current circuits by the Edison Lighting Company, St. Louis; 130 lamps put in store of the May Shoe and Clothing Company, Denver, and 200 lamps installed in the store of Boggs & Buhl, Allegheny, Pa. The lamps put in by the St. Louis Edison Company were of the single globe type and those used by the Allegheny establishment are of the double globe type.

I-T-E CIRCUIT-BREAKERS, manufactured by the Cutter Electrical & Manufacturing Company, of 1112 Sansom Street, Philadelphia, are in successful operation in all parts of the world. This company makes a large variety of circuit breakers, a type being made to apply to every case requiring such a piece of apparatus. It is stated that the greatest possible care is exercised in the manufacture of the I-T-E circuit-breakers, both as to materials and workmanship, no expense or labor being spared to make them everything that they should be.

THE ELECTRIC APPLIANCE COMPANY, Chicago, states that arrangements have been consummated whereby it will carry a large stock of magnet wire of Eastern manufacture, in addition to its stock of line and other wires so that users of magnet wires may rely upon having their orders promptly filled. The company also states that its combination fuse-block and lightning arrester for telephone circuits is meeting with conspicuous success. For heavy duty circuits the company furnishes Wurts arresters, of the merits of which everyone knows.

AMERICAN INCLOSED ARC LAMP.—Chas. J. Bogue, 213 Centre Street, New York, who is placing the Hero American inclosed arc lamp on the market, is one of the oldest electricians in the city, and has had over eighteen years' practical experience in lamp construction work. As is well known, Mr. Bogue also manufactures all kinds of electrical goods, comprising armatures, commutators, dynamos, motors, etc. His name is well known to all dealers and users of electrical goods, and he and his manufactures have earned a high reputation from the quality of the work and materials put in them.

STANDARD PAINT COMPANY IN EUROPE.—A European factory was recently established at Hamburg, Germany, by the Standard Paint Company, 81 John Street, New York, manufacturers of the widely known and as widely used "P. & B." compounds, tapes, etc. This step, it is stated, was rendered necessary by reason of the greatly increased volume of foreign business which has come to the company. The German factory will produce exactly the same line and quality of goods that have made the reputation of the "P. & B." products turned out by the American establishment.

GOOD TELEPHONES AT LOW COST are what the Eastern Telephone Mfg. Company, of Meriden, Conn., states it is making. It is explained that this company's instruments are made in very large quantities and all parts are thoroughly standardized, so that special fitting, winding, or other features are unnecessary; furthermore, the company has no travelling representatives and sells for cash only. These details combine to greatly reduce the cost at which reliable instruments can be produced, it is stated, and enable this company to offer inducements to prospective telephone buyers.

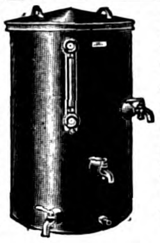
THE MOGADORE INSULATOR COMPANY, Mogadore, Ohio, which succeeded the J. S. Monroe Pottery Company, announces that it is in position to furnish promptly all forms of porcelain and clay work used by electrical engineers, such as wiring tubes, knobs, cleats, etc., and is also well equipped for turning out special work to order. In taking over the business of the J. S. Monroe Pottery Company, Messrs. J. A. Dixon and I. M. Martin succeeded Messrs. J. S. and E. D. Monroe. Mr. G. A. Monroe retains the same interest in the new concern that he held in the old one.

THE CLEVELAND ELECTRIC TRADING COMPANY, 806 Cuyahoga Building, Cleveland, Ohio, reports a very prosperous fall trade, in both new and second-hand apparatus. The shipments of machinery have extended from Connecticut to California, and from Northern Minnesota to Texas. This company handles second-hand goods of high grade, either on consignment or by direct purchase, as desired, and is selling agent for some very good lines of supplies and machinery. The company is now arranging to increase its facilities for handling work, both in repairs and second-hand goods, and hopes to enter upon the new year with a factory of its own which will be well equipped for handling all classes of electrical work.

THE LARGEST SALE OF BOILERS ever made is a feat claimed by the Stirling Company, of New York and Chicago. The sale referred to is one recently made to the Cramp ship-building establishment, at Philadelphia, the contract calling for 40,000 h.p. of water-tube boilers of the Niclausse type. The Stirling Company has acquired the exclusive right to manufacture this type of boiler in America, as well as similar rights for the Yarrow and Mosher types, all of which were recently tested under conditions of actual naval service in the Hispano-American war. The shops of the Stirling Company, which were extended last spring to provide for increasing business, have become inadequate to the company's needs, and it is stated that ground will be broken soon for another large addition to the works.

THE THERMOSTATIC FIRE ALARM CABLE, manufactured by the Montauk Multiphase Cable Company, of 100 Broadway, New York, is attracting attention at the Twentieth Triennial Exhibition of the Massachusetts Charitable Mechanic Association, now being held in Boston. The cable is thermostatic at every point of its length, and reports of tests made at St. Louis, Mo., and at Melbourne, Australia, recently, state that it is entirely effective. The St. Louis report states that "the flame of a match will set it off anywhere," and the Melbourne rereport states that "when a flame was applied to the covered cable for a few seconds it was at once set in motion and registered a prearranged signal at Bouverie Street." The report continues: "The experiments were an unqualified success."

THE EMERSON ELECTRIC MFG. COMPANY, of St. Louis, Mo., has recently completed and is ready to furnish a device by



THE—
CROSS OIL FILTER
actually reduces oil bills 50 per cent. or more. Sent on approval. Capacities ranging from 3 to 120 gals. per day. Used in 18 countries. It is specially adapted to Electric Light and Power Plants. Established 8 successful years.

CLING=SURFACE
Is a Belt Dressing, but so much more that
We will send you a Sample Can and guarantee that the belts will stop slipping; the power shall be **permanently** increased; the belt can be run slack, and the leather shall become as soft as calfskin; also absolutely waterproof.
We will further agree that the increased power (in a fair-sized plant) shall earn the cost of the Sample Can **EVERY MONTH.**
This applies to Leather, Rubber, Cotton or Rope—and also to OILY DYNAMO Belts.
CLING-SURFACE MFG. CO., 188-194 VIRGINIA STREET, BUFFALO, N. Y.

means of which large church organs can be operated satisfactorily with the use of alternating current motors. This special adaptation of alternating current motors has been worked up in response to numerous inquiries extending over a number of years, and they believe that it is the only device on the market by which churches, placed beyond the reach of direct current, can operate their orban bellows with an electric motor. Printed matter describing this device is now in course of preparation, and will be ready for distribution to interested parties within a short time. In the meantime the Emerson Company would be glad to receive inquiries from interested parties to whom they will send blue print and give all information.

THE WARREN ELEC. MFG. COMPANY of Sandusky, Ohio, have just closed a contract with Armour & Company, Chicago, for one 7000-light, 350-k.w. Warren alternator of 7200 alternations and 360 r.p.m, and two 3600-light alternations and 360 r.p.m., and two 3600-light 600 r.p.m. These machines are to be installed in the new central station which is being erected by Armour & Company at the Stock Yards, Chicago. The Warren Electric Manufacturing Company are to be congratulated over this large order, as the competition was very fierce. The record, however, that the Warren apparatus has made in the past proved a sufficient guarantee to Armour & Company, and they feel assured that they have secured the best on the market. This contract was closed by Mr. J. Holt Gates, the Chicago representative of the Warren Company.

A NEW TYPE OF SHADE HOLDER, known as the "Ideal," has been brought out by the Central Electric Company, of Chicago. The holder is made of a single piece of metal and said to be so constructed as to prevent its getting out of shape under ordinary usage. The company recently moved into a suite of handsome offices located at 264-270 Fifth Avenue, where more room is afforded for the extensive stock of goods carried by this company than at the old headquarters. The company is preparing to carry a most complete line of portable table and desk lamps and has put in a large stock of miniature incandescent lamps in anticipation of the Christmas holiday trade. These lamps are furnished in clear and natural colors, and of all candle-powers and voltages. A new type of miniature lamp has been brought out which is adapted for use in a standard socket, and is obtainable in voltages from 90 to 125 inclusive. The small dimensions of this lamp and its standard base make it particularly convenient for use in electric sign and decorative work.

CAN WATER WHEELS BE GOVERNED ?

If you will give us a description of your water wheels and how they are set we can refer you to a plant similarly arranged, where our governors are in use. Our governors are now being used to regulate over SEVENTY-FIVE THOUSAND HORSE POWER of water wheels in this country alone. We sell our governors with a POSITIVE GUARANTEE that they will give a better speed regulation than any other make of governor.

LOMBARD WATER WHEEL GOVERNOR CO., No. 61 Hampshire St. (Roxbury District), BOSTON, MASS.

POSITIONS WANTED.

AS ENGINEER AND ELECTRICIAN of small city lighting plant; am thoroughly familiar with central station work, and can build new arc lamps for installation. Address ELECTRICAL, care AMERICAN ELECTRICIAN, Havemeyer Building, New York.

AS ENGINEER and electrician of small lighting plant. Will work on salary or commission. Both have several years' experience. First class reference. Address C. & F., care AMERICAN ELECTRICIAN, Havemeyer Building, New York.

AS FOREMAN OR SUPERINTENDENT of electric works or plant by a married man, holding same position now Good designer of electrical machinery and apparatus; has a thorough mechanical knowledge; can get work out very cheap. Good reasons for wanting to change; good references. Address "ELECTRICAL," care of AMERICAN ELECTRICIAN, Havemeyer Building, New York.

BY YOUNG MAN, with electric railway, light or manufacturing company. Has a good technical education; is a first-class draughtsman, and has had over five years' experience in the manufacture and repair of electrical machinery. Can furnish the best of reference as to character and ability. Will go anywhere. Address "R. W. B.," care of AMERICAN ELECTRICIAN, Havemeyer Building, New York.

AS DYNAMO TENDER, or in any capacity in an electric light or power plant, where a thorough knowledge of the installation and operation of electrical apparatus is required. Have been engaged in station work in British Columbia for seven years, part of the time as station superintendent. Thoroughly experienced. First-class references. Address "DYNAMO," care of AMERICAN ELECTRICIAN, Havemeyer Building, New York.

PROPOSALS INVITED.

PUBLIC AND PRIVATE LIGHTING

VINCENNES, INDIANA.

Sealed proposals will be received for lighting the streets, alleys and public places of the City of Vincennes, Indiana, with arc lights of not less than 2000 candle power each, for a period not to exceed 20 years, from the 25th day of December, 1900, for all night and every night in each year. Also to furnish commercial and private lighting to the citizens of said city for the same period of time. In submitting proposals separate bids must be made viz: Street, commercial and private lighting, specifically stating the kind and number of lights and the maximum price for each public light; for private and commercial lighting. No proposition will be considered unless accompanied by full and complete plans and specifications, by which it is proposed to furnish the light, which must be attached to each proposition submitted. And all bids must be deemed to cover and include all incidental matters and things necessary to the full and complete working of a first class modern lighting plant. Said proposals must be filed on or before the 2nd day of January, 1899, with the City Clerk of said city, and final acceptance will be made only after full and complete investigation by the Common Council, as to the merits of each and every bid submitted, and an Ordinance covering the proposition accepted has been passed by said Common Council. The Council reserves the right to reject any and all bids submitted. All information desired by bidders will be furnished on application to the Clerk. None of said bids to be opened unless by order of and at a regular session of the Common Council.

AN UNPARALLELED TIME RECORD

Was made every day during the period of the Omaha Exposition by the trains of the Chicago, Milwaukee & St. Paul Railway on its Chicago & Omaha Short Line.

Altho its trains hauled from ten to thirteen well filled sleeping cars and coaches each night, yet schedule time of arrival at Omaha and at Chicago was an accomplished fact—a record to be proud of, and which has resulted in establishing the Chicago, Milwaukee & St. Paul Railway in the minds of the traveling community as the shortest, best and most reliable route from Chicago to Omaha, as well as to California.

All coupon ticket agents sell tickets via the Chicago, Milwaukee & St. Paul R'y. For information regarding the line address Geo. H. Heafford, General Passenger Agent, Chicago.

New York Patent Bureau.

TO THE INVENTOR:—The object of the Bureau is to aid him in disposing of his invention or patent, and to bring it before the proper authorities and companies in whose line of business the patent or invention would be of value. A small fee is charged for the registration of the invention in this Bureau to secure the above advantages, and on the sale of the invention a minimum percentage of the sale price is charged.

TO THE MANUFACTURER:—The services of the Bureau will be of great value; copies and particulars of each new invention bearing particularly on their own line of manufacture will be sent them immediately as they are brought out, thus keeping them fully informed upon the latest developments in their own line of work. Should the manufacturer desire to purchase the invention, the Bureau will consummate the sale without any additional fee further than that for its yearly services. Any inquiries will be cheerfully answered.

THE JENKIN'S SWITCH.

It is thoroughly built, of the best materials only. The lower contacts are ground and therefore make the contact between the current-carrying parts as nearly perfect as possible. The double-pole switch is built up from the single pole style, the upper contacts being formed by strong phosphor-bronze brushes, bearing upon the brass contact-piece on the insulated armature. It has a neat metal cap. The movement is quick and positive. The switch is guaranteed to stand constant hard use. Made in three styles—single pole, double pole and three-way—also flush plate. FREE samples to the trade only.

Experimental Science.

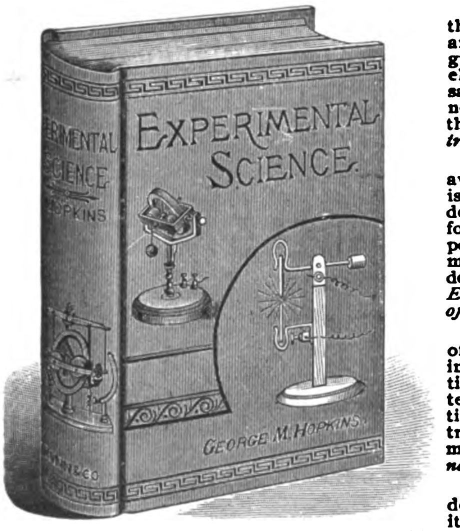
By GEO. M. HOPKINS.

Seventeenth Edition, Revised and Enlarged. 740 Pages. 800 Illustrations. Elegantly Bound in Cloth.

Price, by mail, postpaid, $4.00; Half Morocco, $5.00.

This is a book full of interest and value for all who desire to obtain a practical knowledge of physics.

What is said of "Experimental Science."



"The electrical chapters of the book are notably good, and the practical instruction given for building simple electrical machinery may be safely carried out by those—not a few—who like to make their own apparatus."—*Electrical World.*

"All teachers of science are aware that real knowledge is acquired best by the student making experiments for himself, and any one who points out how those experiments may be easily made is doing excellent work."—*English Mechanic and World of Science.*

"The work bears the stamp of a writer who writes nothing but with certainty of action and result, and of a teacher who imparts scientific information in an attractive and fascinating manner."—*American Engineer.*

"The portion of the book devoted to dynamic electricity covers over one hundred pages, and is extremely interesting and valuable."—*Brooklyn Standard-Union.*

MR. THOMAS A. EDISON says: "The practical character of the physical apparatus, the clearness of the descriptive matter, and its entire freedom from mathematics, give the work a value in my mind superior to any other work on elementary physics of which I am aware."

PROF. D. W. HERING, University of the City of New York, says: "I know of no work that is at the same time so popular in style and so scientific in character."

PROF. W. J. ROLFE, of Cambridgeport, Mass., writes: "The book is by far the best thing of the kind I have seen, and I can commend it most cordially and emphatically."

Hundreds of cordial recommendations from eminent Professors and Scientific men.

A new and very high grade of Insulation

FOR ELECTRIC ROADS.

This material has been thoroughly tested by Messrs Stone & Webster of Boston, who give it the highest testimonial.

It has already met with great popularity, one or two of the heaviest consumers in the country using it to the exclusion of all others. After enlarging the plant in this department we are fully equipped to supply the material in any quantities.

The usual standard of excellence of the Sterling Supply & Mfg. Co. will be maintained in the manufacture of this material.

$1.00 per Year. 10 Cents per Copy.

INDEX TO ADVERTISERS, PAGE 7.

THE only reasons that higher prices are being constantly paid by the most prominent steam users in the United States for Cahall Boilers are—that they are better made, last longer, cost less for maintenance, show a higher efficiency and make drier steam than any other kind. Send for illustrated catalogue.

NEW YORK, July 18, 1898.

THE ELECTRIC STORAGE BATTERY CO.,
NEW YORK,

Gentlemen.—In answer to your inquiry of how we were satisfied with the storage battery of 58 cells installed by your company at the White Plains residence of Mr. Whitelaw Reid, will say that battery has been in constant use every day for 3 years and 10 months, and it has done all you said it would. Battery has not cost us one cent for any purpose since it was put in, and has required but very little attention.

Very respectfully,
JAS. A STILLMAN, Ch. Engr. Tribune Bldg.

RHINECLIFF, DUTCHESS Co., N. Y., August 2, 1898.

THE ELECTRIC STORAGE BATTERY CO.,
NEW YORK,

Gentlemen.—The Battery which you installed for us in October, 1896, has been in constant operation ever since, giving splendid satisfaction. It is of 720 Amp. hour capacity, and we have frequently taken over 800 Amp. hours from it for electric lighting. It is very remarkable, but true, that after the hard service sometimes required of it there is no visible deterioration. The battery has given absolutely no trouble whatever, the only care required being to charge and discharge, and occasionally replace evaporation.

Yours very truly,
C. H. VAN WERT, JR., Chief Engineer.

The Best Socket, and why.

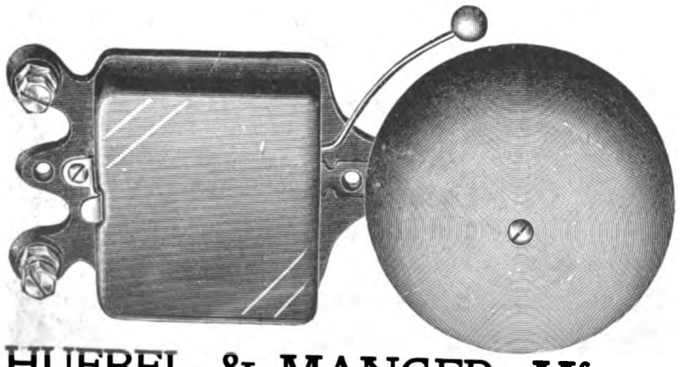
THE first thing required of a socket is to hold together. The frame of a **PAISTE SOCKET** is like the trunk of an oak tree—all in one piece, firm and deep rooted. Notice the heavy base, double the usual thickness, and how the frame is sunk into it. You will then appreciate the solidity that keeps **PAISTE SOCKETS** firm in spite of shaking floors and jarring machinery.

And it has other points of advantage just as strong.

Send for a sample (free to the trade) and you will see why the **PAISTE SOCKET** is coming to be everywhere recognized as the best socket made.

H. T. PAISTE CO., {PHILADELPHIA. CHICAGO.

No. 189 IRON BOX BELL.



THIS Bell has our Patented Non-Turning Binding and Contact Posts; has a Double Adjustment, and rings well on one cell of battery.

IT IS A RELIABLE BELL.

We also make a full line of **Cast Bronze Push Buttons, Floor Pushes, Door and Window Springs, Gas Keys, Letter Boxes,** and all styles **Wood and Rubber Switches.**

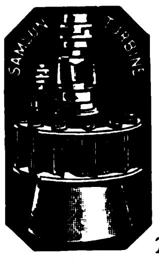
WATER WHEELS



ADAPTED TO ALL HEADS FROM

3 Feet to 2000 Feet.

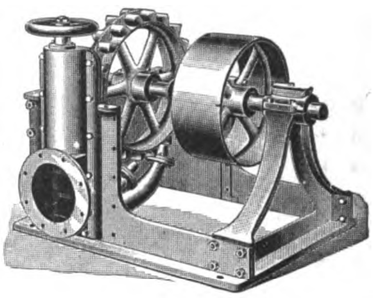
ESPECIALLY ADAPTED TO ALL KINDS OF

ELECTRIC POWER and LIGHTING PLANTS

Recent tests at Holyoke enable us to guarantee:

The largest power ever obtained from a Turbine of the same diameter. The highest speed ever obtained from a Water Wheel of the same power. The highest mean efficiency ever obtained when running at half to full gate. We guarantee also: *A runner of the greatest possible strength. A gate unequaled in quickness and ease of opening and closing.*

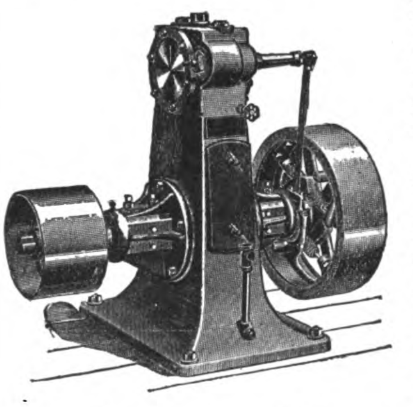
Our experience of **36 Years** building Water Wheels enables us to suit every requirement of water power plants. Complete satisfaction is guaranteed. Send for pamphlet, and state your **head** and full particulars.



AUTOMATIC STEAM ENGINES With Suitable BOILERS

Built in latest style, of latest design, and **highest excellence.** Sizes from **3** horse power upwards. Send for Engine Pamphlet D.

JAMES LEFFEL & CO.
SPRINGFIELD, OHIO, U. S. A.



Thousands of Horse Power of the Case Steam Engines are now in daily use. They are being supplied on the order of the Government and many leading firms. The advantages of these machines are many, and are set forth in a catalogue just issued for free distribution. All sizes from 2 1-2 to 25 Horse Power are shown with many interesting applications.

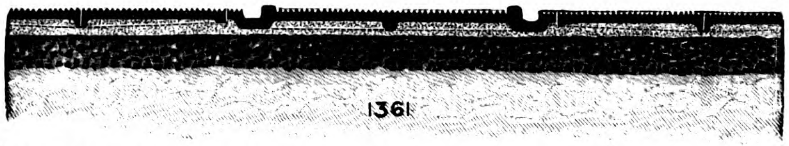
THE STANDARD PAINT COMPANY,
81 & 83 John St., NEW YORK.



BOILER ROOM FLOOR Cast Iron Plates and Cast Plate Track

for use in connection with our "Industrial" Railways. Track plates come five feet long and twenty-seven inches wide, and with the rails cast in, rising only one-quarter inch above floor level.

The size of the floor plate is 13 inches square, and is cast with retaining hooks which hold it securely in position.

They make the best boiler room floor without any exception whatever. They are so small they don't get loose, and so heavy that slice bars dropped on them do not break them.

The small diamond point projections prevent the slipping of the workman's foot and permit a broom to easily sweep out the ashes or dirt.

A new "Industrial" Railway Catalogue, covering several new features, is just from the press. Valuable data not published elsewhere is therein contained. To those interested it is sent free.

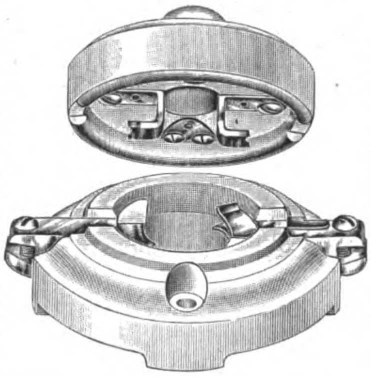
THE GARTON-DANIELS ELECTRIC CO.,

KEOKUK, IOWA.



Paiste Lock-Cap Rosette.

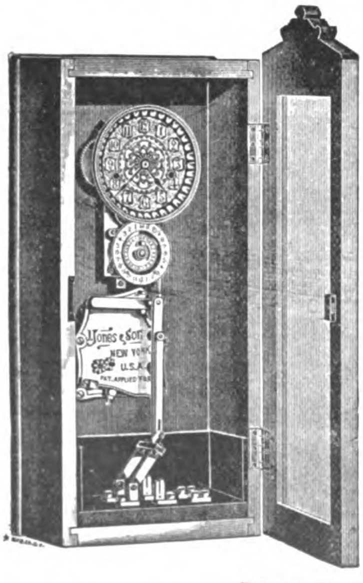
THIS is the neatest and simplest of all rosettes. The brass lugs inside of the cap engage in the knife switch contacts in the base, thus holding the cap on securely. A small spring at the side also catches in a slot on rim of cap, absolutely preventing cap from turning. A slight pressure on the spring releases the lock and permits the cap to be taken off. FREE samples to trade only.

H. T. PAISTE CO., PHILADELPHIA. CHICAGO.

Superior Quality At Low Prices

J. Jones & Son

Anything In the Electrical Line



... OUR ...

Automatic Time Clock

does its work to an infinite degree of accuracy, turning on and shutting off the current at times set for its operation. We furnish it with 2, 3 and 4-pole switch, and, within reason, of any capacity.

The Automatic Time Cutout

is a simple and most reliable device. The Clock is a fine Nickel Plated Parker, with time set on the face, the winding key being inserted from the front, so that after once being put in position it is not necessary to remove it, as would be the case if the ordinary alarm clock with winding key and alarm set on the back was used.

EASTERN HOSPITAL FOR INSANE.

KNOXVILLE, Tenn., Oct. 13, 1898.

Warren Electric & Specialty Co.,
Warren, Ohio.

DEAR SIRS:—Your circulars and so forth received. We purchase our lamps from your company, but the fact is they burn so long I cannot send you an order very often.

One of your lamps burned for us on a post out doors, where we used it for lighting the yard, over two years. Our engineer claims it burned two years and six months.

I send you a name and will follow with an order when we need them.

Yours truly,
EDWARD S. SHEPPARD, Steward.

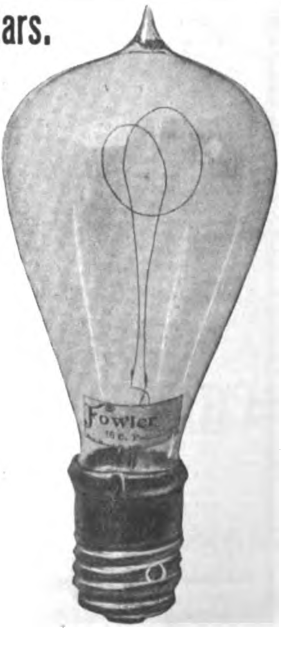
NEW LIST AND DISCOUNTS.

A. A. McCREARY, 136 Liberty St., NEW YORK.

They Wear Turned Over Collars.



OURS is the only lamp made that is not "plastered together." We use no plaster whatever, but our specially shaped globe is securely held by a collar which fits over the bead on our globe, and inside of the base, and which is soldered fast, so that we have

A LAMP THAT
- Will never work loose in the base, and so short circuit inleading wires.
- Will not soak up moisture to chew off the inleading wires.
- Is worth more after it is burned out, as base is not clogged up with plaster, but may be detached and used again.

QUALITY.—It is not possible, in a written description, to show the good qualities of our lamp for light giving, life and efficiency but we claim that our lamps will give longer average life, and maintain their candle power better than any other lamp using the same current, if used under the same conditions.

GIVE THEM A TRIAL.

An alarm clock...

with a progressive attachment (one that will ring a little longer to-morrow morning than it did this morning) is necessary to get some people up in time for business; all of which goes to show that they never profit by experience. Some people buy wire because it's cheap, others buy Okonite wire because it's good; the Inspector never throws out Okonite, but you can't say as much for some others; hence experience would indicate that Okonite is the wire to use to be sure of satisfactory results.

TELEPHONE MEN

will be glad to know that a COMPREHENSIVE TREATISE ON TELEPHONY has at last been produced.

American Telephone Practice,

By KEMPSTER B. MILLER, M. E.,

is now in press and will be ready for distribution in a short time.

This work will include all of the matter published during the last two years in the AMERICAN ELECTRICIAN under the same title, revised and brought strictly UP TO DATE, together with a large amount of matter never before published.

Mr. Miller's experience as telephone expert in the United States Patent Office, and his subsequent experience as chief electrician and superintendent of one of the largest telephone manufacturing companies in this country, has enabled him to write on the subject from its practical as well as its theoretical side.

It will cover the PRACTICAL FEATURES OF TELEPHONE WORK with an attention to detail not found in any other book.

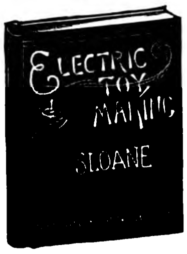
We sell magnetos at very low prices.

Electric Toy-Making.

Very Fully Illustrated. $1.00.

Dynamo Building and Electric-Motor Construction.



This work treats of the making at home of Electrical Toys, Electrical Apparatus, Motors, Dynamos and instruments in general, and is designed to bring within the reach of young and old the manufacture of genuine and useful electrical appliances. The work is especially designed for amateurs and young folks.

"This is a work in which the American boy will find explanations of the details of a great number of pieces of electrical apparatus which he may construct with his own hands and for his own amusement and pleasure. The nine chapters of the book treat respectively of batteries, permanent magnets, electro-magnets, electric motors, electric bells, miscellaneous toys, spark and induction coils, and power dynamo, and miscellaneous receipts and allied subjects, the hand formulæ. The chapter on primary batteries will be found especially valuable."—*Electrical World.*

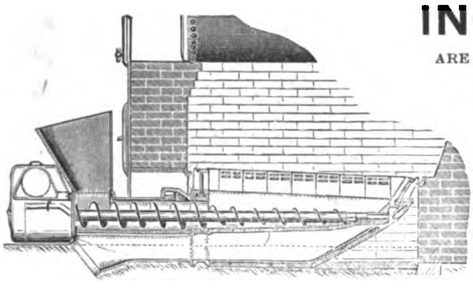
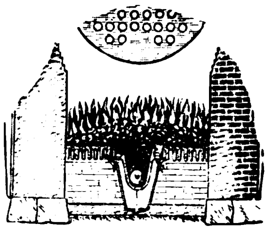
AMERICAN STOKER



SIDE VIEW OF STOKER.



END VIEW.

COMPACT, POSITIVE, PRACTICAL.

The fact that our Stoker has no mechanical parts in contact with the fire distinguishes it from all other forms of Stokers and insures a low cost of maintenance. As our system is not dependent upon natural draft, it is especially adapted to meet the requirements of a variable power demand.

ESTIMATES FURNISHED.

Our new Catalogue is a Work of Art, and will be mailed free upon application.

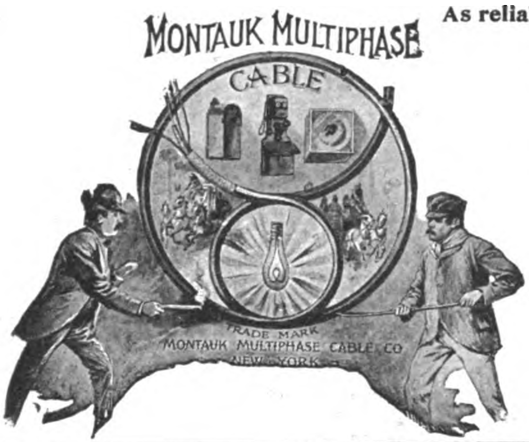
We offer to the Public New and Marvellous ELECTRIC CABLE



As reliable as a Galvanometer, as Infallible in Action, and Continuously Thermostatic

Standardized in sizes for all interior electric adaptations. It is the only cable in the world combining Fire and Burglar alarm protection with all other interior electric wiring work, in same installation.

We confine ourselves to the manufacture and sale of this Cable exclusively, it being auxiliary to all other electric interests.

By the use of this Cable every infinitesimal part of every wire hereafter installed for whatever purpose in all buildings is made a detective point for the discovery and automatic notification of fire. We have opened up a new and rich field for the Electrical Contractor. If you are not acquainted with us and the Cable, you should be. Write or call and become so.

Write for Illustrated and Descriptive Printed Matter.

We own the sole and exclusive right to manufacture and sell the Montauk Multiphase Cable and Central Station Controller, by virtue of the following patents: No. 546,261, Sept. 10, 1895; No. 546,262, Sept. 10, 1895; No. 565,053, Aug. 4, 1896; No. 565,178, Aug. 4, 1896; No. 565,188, Aug. 4, 1896; No. 565,217, Aug. 4, 1896; No, 565,410, Aug. 4, 1896; No. 594 034, Nov. 23, 1897; No, 594,247, Nov. 23, 1897; No. 594,281, Nov. 23, 1897, which broadly cover not only the method of manufacturing, but the basic principle upon which these cables are constructed.
